DEPT. OF APPLIED CHEMISTRY
Acc. No.
Date 7/9/76
CALCUTTA UNIVERSITY.

The AMINCO-BOWMAN™ Spectrophotofluorometer
now features the
NOZONE™
Sealed Lamp Housing

That's a no-ozone, sealed lamp housing which meets EPA, OSHA and FDA regulations for ozone emission.* This new lamp housing controls ozone emission, freeing the SPF from the need for exhaust fans, hoods, windows or deozonators (a patent is pending on this unique design). You will be able to take your SPF to any location in the lab without installing a new exhaust vent. In addition, the new design includes a magnetic arc stabilizer to reduce drift to less than 10^{-3} per cent of the signal per hour. The stabilizer also controls inherent arc wander to maintain lamp performance in old or otherwise marginal lamps. The new NOZONE housing is also standard equipment on the Corrected Spectra SPF, Ratio SPF and Photon Counting SPF and is available as an accessory for existing SPF's.

Rp387

n an actual test, ozone
ission was less than, and
 not accumulate above
5 ppm in a 9 x 12 x 8
aled room dur-
 an 8-hour
riod.

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^{a} if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth; 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Characterisation of Aleutian disease antigens — *G. W. Notani, E. C. Hahn, N. H. Sarkar and A. J. Kenyon* 56

Release of diacylglycerol-enriched vesicles from erythrocytes with increased intracellular [Ca^{2+}] — *D. Allan, M. M. Billah, J. B. Finean and R. H. Michell* 58

Calcium ions regulate cyclic AMP and beating in cultured heart cells — *I. Harary, J.-F. Renaud, E. Sato and G. A. Wallace* 60

Alteration of electrical activity in molluscan neurones by cyclic nucleotides and peptide factors — *S. N. Treistman and I. B. Levitan* 62

N-demethylation of morphine in rat brain is localised in sites with high opiate receptor content — *J. Fishman, E. F. Hahn and B. I. Norton* 64

Immunocytochemical evidence for the presence of arginine vasotocin in the rat pineal gland — *E. P. Bowie and D. C. Herbert* 66

Functional roles of luminal sodium and potassium in water transport across desert scorpion ileum — *G. A. Ahearn and N. F. Hadley* 66

Fast block to polyspermy in sea urchin eggs is electrically mediated — *L. A. Jaffe* 68

Translation of RNA from unfertilised sea urchin eggs does not require methylation and is inhibited by 7-methylguanosine-5′-monophosphate — *E. D. Hickey, L. A. Weber and C. Baglioni* 71

RNA synthesis in fully-grown mouse oocytes — *P. M. Wassarman and G. E. Letourneau* 73

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance. Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references. Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space. Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material. Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text. We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Complementation of *ts* mutants by a herpes simplex virus *ts*-transformed cell line — *J. C. M. Macnab and M. C. Timbury* 233

Lectin-mediated attachment of glycoprotein-bearing liposomes to cells — *R. L. Juliano and D. Stamp* 235

Mycoplasma pneumoniae is a polyclonal B-cell activator — *G. Biberfeld and E Gronowicz* 238

Purported difference between human T- and B-cell surface morphology is an artefact — *E. Alexander, S. Sanders and R. Braylan* 239

Microbial cells living immobilised on metal hydroxides — *J. F. Kennedy, S. A. Barker J. D. Humphreys* 242

Phenotypic difference between *uvr A* and *uvr B* mutants of *E. coli* — *N. Suzuki and A. Nakazawa* 244

An intracistronic region of gene A of bacteriophage φX174 not involved in progeny RF DNA synthesis — *W. E. Borrias P. J. Weisbeek and G. A. Van Arkel* 245

Expression of flagellar genes carried by bacteriophage lambda — *M. Silverman, P. Matsumura, R. Draper, S. Edwards and M. I. Simon* 248

"Non-rigid" nucleotides in tRNA: a new correlation in the conformation of a ribose — *A Jack, A. Klug and J. E. Ladner* 250

Production of nerve growth factor by the mouse adrenal medulla — *G. P. Harper, F. L. Pearce and C. A. Vernon* 251

A paradox in the lateralisation of the visual evoked response — *G. Barrett, L. Blumhardt, A. M. Halliday, E. Halliday and A. Kriss* 253

Synaptic vesicle recycling in synaptosomes *in vitro* — *R. C. Fried and M. P. Blaustein* 255

Extremely low frequency, weak electric fields affect schedule-controlled behaviour of monkeys — *R. Gavalas-Medici and S. R. Day-Magdaleno* 256

Antivenom activity of rattlesnake blood plasma — *R. Straight, J. L. Glenn and C. C. Snyder* 259

LECTINS

As a major producer of lectins, FITC-conjugated lectins and immobilized lectins, we are pleased to announce the development of four new lectins from lentil seed and castor bean. These are available in both the free and immobilized forms as well as the FITC derivatives.

	LECTINS	FITC-LECTINS	AGAROSE-IMMOBILIZED LECTINS
	Code No.	Code No.	Code No.
Lens Culinaris Hemagglutinin A	79-130	79-104	79-133
Lens Culinaris Hemagglutinin B	79-135	79-105	79-138
Ricinus Communis Agglutinin—60	79-140	79-106	79-143
Ricinus Communis Agglutinin—120	79-145	79-107	79-148

ALSO AVAILABLE: In free and agarose-immobilized forms and as FITC-derivatives:

Concanavalin A and Con A Salts
Fucose Binding Protein (from lotus seed)
Soybean Agglutinin
Wheat Germ Agglutinin
Ferritin-Concanavalin A (for Electron microscopy)

AVAILABLE SOON: **Phytohemagglutinin**

More detailed description of these products can be found in our new Biochemicals Catalog. If you don't have one, write the office nearest you for your free copy.

Circle No. 06 on Reader Enquiry Form.

Guide to authors

- Articles are up to 3,000 words in length with at most six displayed items (figures and tables) and may either be reports of major research developments in a subject or broader reviews of progress.
- Letters are brief reports of research of unusual and wide interest, not in general longer than 1,000 words; at most they have three or four displayed items (figures and tables).
- 'Matters Arising' permits occasional short discussion of papers that have previously appeared in *Nature*. There is a limit of 300 words.

Manuscripts may be submitted either to London or Washington. Three typed copies should be submitted, each including lettered copies of figures. Typing (including references) should be double spaced. The title should be brief and informative. Pages should be numbered. References, tables and figure legends should start on separate pages. Experimental detail vital to the paper yet which would interrupt the narrative is best placed in the figure legends. Units should conform to the Système International. Greek characters should be identified in the margin on their first appearance Equations should occupy single lines if possible, exp (a) is preferred to e^a if 'a' is more than one character. Articles should be accompanied by an abstract of not more than fifty words listing the main conclusions.

References are indicated by superscripts in the text. See any contemporary *Nature* for style, but note:

(i) To refer to several references by the same author at once, only one reference number need be given.

(ii) Cite first and last pages.

Abbreviations should follow the *World List of Scientific Periodicals*, fourth ed. (Butterworth, 1963-65). Symposia are often difficult to refer to and only published or soon-to-be-published volumes should be mentioned in references Their publisher and place of publication should be clearly indicated. 'Personal communication' and 'unpublished work' should be incorporated in the text.

Artwork should be sent with the manuscript and clearly marked with author's name and the figure number. Line drawings to be in Indian ink on heavy cartridge paper, tracing paper or similar materials: thin, shiny, torn or folded material should be avoided. Scales for graphs should be chosen such that simple figures will not occupy an inordinate amount of space Most figures are reduced to one column width so originals should be about as wide as a page of *Nature*. To enable figures, particularly maps, to be edited in the same style as the text they should contain only essential material Ideally, an unlabelled original and a labelled copy should be provided: labelling on photographs should, if possible, be avoided entirely. Records, charts etc. which will not reproduce well should be redrawn or simply described in the text We are always glad to see artwork for possible use on the cover, but cannot guarantee its return.

In order to save on postal expenses we return only the top copy and artwork of manuscripts that we cannot publish.

A fuller guide appeared in *Nature* (**246**, 238; 1973).

Strontium–calcium substitution in synaptic transmission in turtle retina — *M. Piccolino* 504
Postexposure serum prophylaxis of neonatal herpes simplex virus infection of mice — *S. Baron, M. G. Worthington, J. Williams and J. W. Gaines* 505
Type C virus in lymphosarcoma in northern pike (*Esox lucius*) — *T. S. Papas, J. E. Dahlberg and R. A. Sonstegard* 506
Virulence of different strains of *Toxoplasma gondii* and host response in mice — *A. Reikvam and A. M. Lorentzen-Styr* 508
Rates of oxygenation and Bohr shift of capillary blood in chick embryos — *H. Tazawa and M. Mochizuki* 509
Correlation between biological potency and biodegradation of a somatostatin analogue — *N. Marks, F. Stern and M. Benuck* 511
Covalently closed circular DNA molecules of low superhelix density as intermediate forms in plasmid replication — *K. Timmis, F. Cabello and S. N. Cohen* 512
Covalently closed circular DNA molecules deficient in superhelical density as intermediates in plasmid life cycle — *J. H. Crosa, L. K. Luttropp and S. Falkow* 516
Role for small nuclear RNAs in "programming" chromosomal information? — *L. Goldstein* 519
Kinetics of triplet–triplet energy transfer and intramolecular distances in enzyme–inhibitor complexes — *W. C. Galley and G. B. Strambini* 521
Stereoselectivity of β irradiation of D,L-tryptophan in aqueous solution — *W. Darge, I. Laczó and W. Thiemann* 522

Corrigendum 524

Matters arising

Solar activity on August 12, 1975 — *B. J. LaBonte* 525
Oscillations in tropical ecosystems — *P. T. Saunders* 525
Evidence for polygenes — *A. Vetta* 525
Reply — *J. N. Thompson* 526

DEAE-Sepharose® CL-6B
CM-Sepharose® CL-6B

Macroporous, bead-formed ion exchangers based on the new high-stability, cross-linked agarose matrix, Sepharose CL

- High resolution and capacity for high molecular weight proteins and other biopolymers
- Exceptionally stable bed volume. Excellent flow rates
- Can be used in polar organic solvents and in solutions of non-ionic detergents
- Can be sterilized repeatedly by autoclaving
- Rapid equilibration. No precycling

Ask for the free booklet with applications examples and other data. From your supplier of Sephadex®, Sepharose® and other separation media.

Class structure in science

SHOULD universities be more responsive to the needs of industry, or is it their job to pursue learning wherever it takes them and to respond to student needs whatever they be? These questions have been asked with increasing insistence in recent months, although probably as a substitute for the more fundamental question: why does industry not appeal more to university graduates, particularly science graduates?

This is hardly simply a British problem; there has been violence in the streets in France recently over moves to direct students into courses with a higher technology content to satisfy French industrial needs. It does, however, manifest itself acutely in Britain. Class distinction and class warfare are an ubiquitous constituent of the British scene, leading to rigid boundaries and ignorant contempt. It is difficult to escape the conclusion that science has its class system too, with universities looking down on the scientific civil service, which in its turn looks down on industry. And mobility, surely the main way of breaking down a class structure, is declining all the time as jobs in universities and the civil service, with their prized security of tenure and excellent pension schemes, become increasingly scarce. Coupled with this, industries based on the physical sciences seem inexorably to be moving away from the research side of their commitment to research and development in the belief that there is not much more in basic science, as we understand it at present, which is convertible into industrial benefit. (This is a view which the Science Research Council (SRC) has also floated recently.) So the outlook is, if anything, for even more broadsides from the ramparts in the future.

It no doubt riles universities to see what they regard as a slackening regard for the pursuit of knowledge in the industrial sector. It no doubt riles industry to see universities continue to regard their best graduates as most suited to academic research. And it no doubt riles the civil service to find itself in the cross-fire and, at present, rather unloved. But the need is for a certain amount of give and take on all sides if the distinctions are not to become more rigid and more bitterly felt.

Manpower planning has a role to play in the rapprochement. Part of the argument in France has been over the payment of differential grants to favour students prepared to take technological courses. A very discrete step in this direction was made by the SRC recently in proposing that at some time in the future it might pay certain postgraduates more than the standard grant. This has brought a predictable response from some student egalitarians, but is a sensible way of trying to raise the quality of graduates in fields where external salaries make the student who sticks to an academic course feel distinctly unequal. Now Mr Gerry Fowler, a minister at the Department of Education and Science, may have stepped back even from such tentative efforts by declaring that the matching of higher education to the manpower needs of the economy is not practicable. Indeed it is not, in a detailed way (and Mr Fowler's arguments seem aimed at detail and precision); but the case for manpower forecasting is not one which admits of too much detail, and meanwhile the half-filled science laboratories, which were built only ten years ago at government urging, are to stay half full.

These low numbers mean that the quality of university science graduates who present themselves for employment in industry is bound to decline, and industry will start to produce its own prescriptions for setting universities to rights. Just as the British workman would love to see the aristocrat reduced to productive manual labour, so industry will, with increasing fervour, call for the university to become more relevant to industrial needs. There have already been salvos from industry about postgraduate education and some of these have at least produced some sensible results. But the sort of ideas floated by Dr Marion McQuillan, of Imperial Metal Industries, in a lecture to the Research and Development Society in London last week, need to be resisted firmly. Dr McQuillan proposes that funding for university research projects should only be approved if the research has a clear economic benefit. Phrases on grant applications stating that the purpose of the work was "a better understanding of . . ." should not be acceptable. Individual universities should be designated as centres of expertise for certain industrial research purposes.

Maybe the idea was presented tongue-in-cheek. Certainly there are university departments that need a vigorous shake, but to seek to distort the function of a university so much (it would be rather like a vice-chancellor urging industry to give up profit making) serves no useful purpose beyond convincing people in universities that there is ignorance outside the walls. Up comes the drawbridge and class warfare takes another step forward.

Dishonesty and grants

Leigh Van Valen, Professor of Biology at the University of Chicago, is Editor of the journal Evolutionary Theory *and is well known for his criticisms of "irresponsible" scientific publishing. Here he comments on an aspect of the American grant system which is also damaging to scientific research*

VARIOUS defects of the system of research grants, as it is practised in the United States, have been discussed extensively. I wish to focus on one which is rarely mentioned, although widely known, and which may well be the most serious. This is the incompatibility, in practice, between honest grant applications and conceptually original work.

The incompatibility is as follows. Any conceptually innovative scientist with some experience knows that there is a good probability that in the next year or two he will have one or more new ideas which will change the direction of his research. In practice, the National Science Foundation and the National Institutes of Health do not tolerate much deviation from the plan of research in the original proposal. The scientist must therefore either adhere to the original proposal at a loss to science, or do his best science while deviating from the conditions under which his grant was awarded.

Two alternatives

Most scientists resolve the situation in one of two ways at the time of applying for grants:

- Original workers who do participate in the granting process use various conscious or unconscious deceits. One kind is a proposal to do research which has just been done or will be done before the grant arrives. This is very common (M. L. Wolbarsht, *Science*, **185**, 399; 1974). Another common kind is a proposal to do research which will be done only if no new ideas come before the grant ends. For both these ploys, and others, it is empirically necessary that the nature of the ploy not be stated This is what creates the dishonesty. When the granting agency explicitly knows of such reservations, or if the application is general enough to be honest, the application is automatically rejected. This is of course the same mentality that required J. D. Watson to falsify his NSF-administered postdoctoral fellowship, where he did part of his Nobel Prize work that he couldn't have done if he had acted honestly.
- Research which really is predictable, at least in outline, is common and is the backbone of most scientists most of the time. There is no problem in such cases. One really can know that one will probably be able to work out the evolution of a group, or test an established hypothesis, or determine whether a known phenomenon applies in a particular case. Because the work is predictable, even though the results may not be, it is usually less than intellectually exciting. It may nevertheless have important results, and it really is necessary for the progress of science. Being easily accountable, it gets funded. Exciting work by honest people does not get funded. This may perhaps take its place among the laws of nature, at least within the boundaries of the United States.

Why should the subject of a grant be adhered to when science is better served by deviation? The administrative answer is accountability: a grant is given for a specific purpose. In applied science this is certainly appropriate. Here the purpose of the money is determined by governmental priorities, by the government's view of national (and occasionally even human) needs, In pure science, however, the aim of giving the money is the advance of scientific knowledge. It is this very advance which is hindered by the present practice. A diversity of approaches is valuable but is not permitted.

The heart of science is new ideas, and their development is discriminated against. This is not true in Europe, whatever the defects of the systems there. My European visitors, who have come from every major country, are uniformly astonished that the United States Government refuses to support creative science. The problem is as real for Szent-Györgyi (*Science*, **176**, 966; 1972), with a Nobel Prize to back him up, as it is for others. I have had several useful ideas in biology and mathematics. None were developed under a government grant, and none could have been. I have also had several grants and eventually realised that the required conformity stultified my research.

Three categories

What to do? I suggest that there be three categories of grants:

- Most grants would be based on specific proposals, as now, but with the explicit understanding that new ideas may be followed at the scientist's discretion. Specific restrictions on such freedom may be necessary in rare cases.
- Specific proposals are inappropriate for much theoretical work; when one knows just what one will do, it is done. This is quite literally true. In such cases grants could be awarded on the basis of research done in the past three years or so, with allowance for extenuating circumstances. The second category would also be appropriate for some scientists who are beginning to work in an area different from their previous work.
- For beginning theoreticians, a modest amount of money for computer costs and the like could be provided for a year or two. These three proposals aim to minimise waste of money while endeavouring to maximise the progress of science.

Many scientists are perfectly comfortable with the present situation. Some of them are the Appollonians of Szent-Györgyi, who "develop established lines to perfection". Others are Dionysians, who know "only the direction in which [they want] to go into the unknown", but who have reconciled their dishonesty with survival. For it is often a matter of survival. Rationalisation of dishonesty is therefore easy.

We recently removed a President because he was dishonest. The norm in our science remains dishonesty, because it is made necessary for the survival of creative research. Often one may be honest or continue in science, but not both. The choice applies mainly to the more creative scientists. We can easily resolve the dilemma if we so want. Do we? □

The Soviet energy balance

Philip Hanson surveys Soviet energy resources and assesses the USSR's energy policy as a factor crucially affecting the prospects for economic growth

OF ALL the countries in the world, the Soviet Union has the most impressive known endowment of non-agricultural natural resources. This is as true of fuel as it is of raw materials. In addition to being the world's second largest gold producer and a leading producer of almost all the useful mineral raw materials, the USSR has all the energy options available from domestic sources: wood, peat, oil shale, coal, oil, natural gas, hydro power and uranium.

In the past few years, however, when energy supplies have become a crucial consideration in economic policy everywhere, the Soviet energy balance has begun to seem precarious. Nobody disputes that the Soviet Union still has vast "potential", or geologically indicated, reserves of the major fuels. Beyond that, however, the Soviet energy position is open to a variety of assessments.

One problem is reserves. The extent of proved reserves, on definitions comparable to those used in the West, is not clearly established. Another problem is costs. The main areas from which increases in fuel supply can come are east of the Urals. Extraction costs in the new oil, gas and coal fields of Siberia vary greatly: for some deposits costs are quite low, for others rather high. But the social overhead costs of bringing roads, housing and amenities to these areas are generally high. Once the fields are being exploited, the cost of moving Siberian energy to the user (by oil and gas pipelines, rail shipments of coal and high-voltage electricity transmission) are generally very high. The alternative of moving the users to the energy supplies is also costly. These high costs are attributable mainly to the harsh natural conditions of most of the area—notably blizzards, permafrost and swamps.

Costs and reserves are not the only contentious issues. There is a good deal of uncertainty about the demand side. How fast will Soviet energy consumption rise in the next five or ten years? Will the Soviet Union remain a net exporter of energy in general and of oil in particular? What are the chances of the West obtaining significant energy supplies from the USSR? The wide spread and frequent revisions of recent forecasts of Soviet energy consumption in 1980 do not inspire much confidence in such forecasts. And the implications for Soviet energy supplies to the West also depend on future Soviet policies in the supply of energy to Eastern Europe, which are not easy to predict beyond 1980.

There is another problem in any assessment of Soviet energy prospects, and this concerns technology. How badly do the Russians need Western technology in order to increase their oil, gas and coal production? Do they need it enough to ensure that some of the more grandiose East-West co-operation projects in Siberia will actually materialise?

Those are the main questions. Some can be answered with reasonable confidence; others are wide open. The accompanying tables summarise recent and planned developments in Soviet energy supply in the 1970s. The plans for 1976–1980 envisage some slowdown in the growth of the primary fuels, except for coal. With petroleum output in some of the older fields in the European USSR expected to fall, this is not too surprising. Oil and gas production in West Siberia (Tomsk and Tyumen provinces) is the main source of growth in the immediate future. West Siberia produced 148 million tonnes of oil and 38,000 million cubic metres of natural gas in 1975 and these figures are planned to reach 300–310 million and 115,000–145,000 million respectively in 1980.

The high costs and sheer physical limits to West Siberian development in the next few years, however, seem to have led the planners to accept a slight deceleration in the growth of oil and gas production. One additional consideration may have been that proven reserves were not rising fast enough. Soviet oil reserves figures are a state secret, but several recent statements by V. Shashin, the Minister for the Oil Industry, imply that new reserves proved have recently been less than the rate of extraction. There is not much doubt that the oil is there; the USSR has 37% of the world's oil-bearing land. But exploration and proving costs are high and the gap between potential and proved reserves is large. A recent US estimate is that the USSR has a relatively modest 12.1% of the world's proved oil reserves. Reserves figures for the other fuels are not secret, though up-to-date official figures are not always available. One estimate of Soviet proved, semi-proved and probable gas reserves (Soviet categories $A+B+C_1$) at the end of 1974 is 23.8×10^{12} cubic metres. This represents 92 years' production at 1974 rates —an impressive position. Nonetheless, the difficulties of exploiting these reserves are considerable, and production has fallen behind plan.

Soviet energy policy has therefore shifted recently in favour of coal and nuclear power. Major increments to coal output are planned from the Ekibastuz and Kansk-Achinsk fields whose low-cost coal, produced in large part by open-cast and strip mining, can be effectively used as a fuel for thermal

Table 1 Soviet Energy Production

	1970	Annual average growth rate (%)	**1975**	Annual average growth rate (%)	**1980** plan (mid-point of range)
Oil (10^6 tonnes)	353	6.9	491	5.2	630
Natural gas (10^9 m^3)	198	7.9	289	7.7	418
Coal (10^6 tonnes)	624	2.4	701	2.7	800
Total energy (10^6 tonnes sfe)[1]	1,238	6.0	1,656	5.5	2,158
Electricity (10^6 MWh)	741	7.2	1,038	5.6	1,360

power stations in the Urals and elsewhere. At the same time the Five Year Plan requires the construction of nuclear power stations in the European USSR and the Urals with total capacity of 13–15 million kW, out of a construction programme of 67–70 million kW of new generating capacity of all types. Soviet installed nuclear power capacity has hitherto been small—3.7 million kW at the end of 1974 compared to 30.4 million in the USA and a total of about 14 million in Western Europe—so this plan would increase the role of nuclear power stations considerably.

This shift in policy has been indicated in a number of Soviet sources over the past two years. It appears to be a response both to higher world energy prices following the Yom Kippur war and to previously unexpected costs and bottlenecks in Siberian oil and gas developments. In his report to the XXV Party Congress in February, Mr Kosygin put the change in quite striking terms: future increases in oil and gas output would be allocated to "technological" needs (for example, feedstocks for the chemical industry), rather than to electricity production. The latter will depend much more heavily on hydro and nuclear power and coal than had previously been planned.

It could well be that the Soviet planners now see energy supply as a bottleneck restricting Soviet economic growth. American recalculations of recent Soviet growth in terms comparable with the measurement of economic growth in the West show an annual growth rate of Soviet real GNP in the first half of this decade of 3.9%. The plan for the latter half of the decade (of a 4.4 to 5.0% annual growth in net material product) probably implies something like a 3½% GNP growth rate. This is admittedly only a modest deceleration, and the plan targets that are finally approved may even show no deceleration at all. But in the light of postwar Soviet plans generally, the 1980 targets look a lot more modest than they do in relation to recent performance; it is likely that they reflect newly-perceived constraints of some severity.

In the early 1970s Soviet electricity and total energy production grew appreciably faster than total national output. In part this reflected the fact that the net export of energy grew in most of the past five-year period. It probably also reflected a tendency for energy consumption to rise somewhat faster than GNP. If Soviet energy consumption continues to rise slightly faster than GNP, the exportable surplus may not grow at all between 1975 and 1980.

A recent study by Jeremy Russell projects a Soviet energy surplus in 1980 of 200–250 million tonnes of conventional fuel equivalent; a surplus of the same order of size on that of 1975. For oil alone the surplus is likely to narrow. Russell's conclusion is that the Comecon group as a whole will still have a surplus of oil production over consumption in 1980 but that a Comecon oil deficit, that is, net imports, is likely fairly soon thereafter.

Soviet long-term oil delivery contracts to Eastern Europe up to 1980 have already been agreed. It is likely that in 1980 only 20–30 million tonnes of Soviet oil (according to Russell), or perhaps 35 million tonnes (according to the Brussels market research organisation, *east-west*), will be available to Western markets. The USSR itself might remain a small net exporter of oil, and some imported Middle East oil might be routed to Eastern Europe through Soviet pipelines.

The position could be quite different as far as natural gas is concerned. Russell projects an annual net Comecon export of natural gas—essentially Soviet natural gas—of perhaps 30–50,000 million cubic metres a year in the early 1980s. Soviet natural gas is already being delivered by pipeline to Austria, Italy, West Germany and France, and Iranian natural gas is being piped through the USSR to West Germany, France and Austria. These are both long term deals and could involve natural gas supplies of the order of 20,000 million cubic metres a year to Western Europe in 1980. The Siberian gas deals that have been discussed with US and Japanese companies in recent years (the Yakutsk and North Star deals) are larger and considerably more problematic. They involve tanker deliveries of liquefied natural gas out of a Pacific coast port and Murmansk, respectively, at a total rate of perhaps 50,000 million cubic metres a year over 25 years. The commercial and political obstacles to the eventual implementation of these deals are formidable. On March 31, however, a Soviet–US–Japanese agreement on joint exploration of the Yakutsk gas deposits was signed, with credits of $25 million each being contributed by the Japanese and US consortia.

The fact that this preliminary agreement has been signed despite all the obstacles indicates the strength of both Soviet and Western interests in the development of Siberian energy supplies. The Western interest requires no explanation, but the Soviet interest is less immediately comprehensible. Why mortgage substantial future energy outputs to the West when energy supplies already form a bottleneck to your own economic growth?

The answer seems to be that Soviet energy production can grow much faster if Western technology is used, and the gains should be enough to repay Western suppliers (in gas) and still have something left over for domestic needs. Soviet technical deficiencies are beginning to show up in a number of key areas. The items which the Russians are unable to produce domestically in sufficient quality and/or quantity in the near future include wide-diameter (1220 and 1420 mm) oil and gas pipeline, pipeline compressor equipment, machinery for deep drilling and secondary oil recovery, submersible pumps, offshore rigs and a wide range of coal mining equipment. It is likely that at least three-quarters of the 20,000 km of wide-diameter oil and gas pipeline laid in 1971–1975 was imported Western pipe. Costly pipe imports continue: in January and February about $500 million worth of new orders were placed in Italy, Japan and France.

The picture of pervasive East-West interpendence which these projects evoke is misleading, however. Soviet natural gas deliveries to West Germany provide less than 15% of West German natural gas consumption. The corresponding figure for the USA in the early 1980s in the event (now remote) of both the North Star and Yakutsk projects going ahead has been put at about 10%.

On the Soviet side, the best assessment seems to be that the Russians will obtain an increase in energy supplies sufficient to support a respectable economic growth rate by a mixture of policies shifting towards fuels less efficient than oil, incurring very large domestic development costs in Siberia, making some use of Western machinery and know-how and perhaps importing significant amounts of Middle Eastern oil. Neither Soviet nor Western energy-supply problems are sufficiently awful to ensure peace on earth and goodwill between Moscow and Washington. □

BRITAIN

Wave energy on

Research in Britain on alternative sources of energy took a step forward last week. Allan Piper reports

THE first real move towards exploiting one of Britain's unconventional energy sources has come with last week's announcement that the Department of Energy (DEN) is to spend £1.01 millions on a 2-year feasibility study of wave-power devices. If the programme is successful further research could lead to the development of such devices to provide up to half of Britain's electrical energy requirements early next century.

News of the venture coincided with the publication of the latest annual report on UK offshore oil and gas resources, which gives estimates that proven reserves of North Sea oil have increased by almost a third over the past year. Although the report revises the production forecast for 1980 slightly downwards, the new estimates are seen as offering the prospect of Britain attaining self-sufficiency in energy by the end of the decade, at the same time providing a stopgap until alternatives such as the wave-power scheme also come on stream.

The decision to press ahead with work on wave-power is based on a National Engineering Laboratory report identifying it as a particularly promising energy resource. Early measurements indicate that the amount of wave energy available around British coasts varies between 40 and 70 kW per metre. The most abundant supplies are offered off north-western Scotland, but areas around the Cornish coast also show considerable potential. One advantage of wave power over other novel energy resources is that the wintertime peak of supply will coincide with maximum consumer demand.

The feasibility study is to assess the relative merits of four possible devices. Three of them, including the "Salter Duck", are British designs; the fourth is Japanese. All use different methods of converting wave energy to a usable form. Each one will be studied at a one-hundredth scale by teams of academic and industrial scientists. While looking principally at operational efficiencies and seaworthiness under varying conditions, they will also estimate approximate costs for any further research and development leading to seagoing trials.

A support programme will cover the collection and analysis of wave data, the long term effects of prolonged wave action on the structures, anchoring and mooring problems, likely environmental and navigational effects of large-scale installations, and possible modes of power generation and transmission. The Central Electricity Generating Board has already started research into ways of integrating the supply into the national grid system.

Commenting on the decision to proceed with wave-power research, Dr Walter Marshall, Chief Scientist at the DEN, said that his department would retain control over the research teams through its Harwell-based Energy Technology Support Unit. The bulk of the £1 million will go towards the principal research programme; it will not be spread equally, but Dr Marshall gave no clues as to whether any of the devices had yet emerged as a clear favourite.

Stressing that the programme represented only an early exploratory phase of wave-power research, Dr Marshall said that further development depends on the findings of the next two years. If all goes well a 10 MW prototype should be in the sea by 1986, with a full-scale model operating by the 1990s, but Dr Marshall declined to forecast a firm date for commercial power production, as past estimates of time-scales on such major projects have generally been "hopelessly optimistic". He did say, however, that commercial installations could be operating during the next century, and DEN figures show that a 600 mile chain of devices around north-western Scotland could eventually provide about half of Britain's present electrical energy requirements even on conservative estimates. Individual devices, each up to about 30 m across, will probably be linked together in 50-km lengths.

International interest in the project has come from the International Energy Agency, which has asked Britain to take the lead in this area of research. The only other country so far seriously involved with wave power is Japan, but Dr Marshall estimated that the total British expenditure—about £1.25 millions including independent research funding—is around four times higher than in Japan. The figure must, however, be seen in perspective: the DEN could spend almost £125 million on nuclear energy this year alone. All the same, at this early stage, Dr Marshall said, any further spending on wave power is unlikely to contract the time-scale of research.

While the wave-power decision represents a significant Government step in a new energy direction, the DEN is also keeping its options open on other alternative sources of energy—solar, tidal, geothermal and wind. It is already engaged on two low-cost areas of research into a possible tidal barrage on the Severn Estuary between Wales and Somerset, and Dr Marshall has expressed a keen interest in solar power.

Even so, it seems clear that the DEN still regards the nuclear, coal, and oil and natural gas options as the mainstays of any future national energy strategy. Dr Marshall believes that the overall cost of wave-power installations could double those of nuclear generators providing comparable power, and his department remains committed to the fast breeder reactor. Additional hopes are pinned on the plan to boost coal production over the next ten years.

As for oil, the new production and reserve estimates are aimed at giving even more room for optimism than previously foreseen. Proven reserves are now placed at 1,350 million tons, compared to last year's, 1,060 million tons, and total reserves could be as high as 3,200 million tons. The production forecast, of 95 million to 115 million tons by 1980, is down slightly on earlier estimates, because of difficulties and delays in commercial development programmes. DEN figures on energy trends, also published last week, meanwhile show that total UK energy consumption fell by 7.5% over the last year. Industrial consumption was down during the last quarter of the year by 17% on the corresponding quarter of 1974. □

A STATEMENT last week from British Nuclear Fuels Ltd (BNFL), which has otherwise captured the public eye in recent months through its nuclear fuel reprocessing activity, disclosed that the UK Ministry of Defence has placed with it a contract for the production of supplies of tritium, the radioactive isotope of hydrogen (half life 12.3 years) which is a key material in the production of H-bombs.

Construction is expected to start in June, following planning permission, of a facility at BNFL's Chapelcross Works, Dumfries, Scotland, where a plant originally built for plutonium production is now operated as a nuclear station supplying power to the national grid. The reactor there will irradiate with neutrons lithium metal which will then be treated in the new plant to separate out the tritium. The plant, which will employ fifty people, should be ready by 1980.

Until now, the Radiochemicals Centre at Amersham has bought from France the tritium Britain uses for civilian purposes, while the Ministry of Defence has obtained its military supplies from the USA. The Ministry now says that a domestic source would be more convenient and would save dollars, but it is not clear whether the civilian imports will continue or whether commercial exploitation of the domestic production for export will be attempted.

BNFL itself has meanwhile faced mixed developments on the reprocessing front. The way ahead for the deal BNFL is sharing with Cogema of France to reprocess Japanese nuclear fuel recently became clearer with the resignation of electricity industry representatives from the Japanese negotiating team which has yet to commit itself following the broadening of the deal to include Cogema.

On the home front, BNFL's Windscale site was recently the location for a gathering of several hundred people protesting against the use of nuclear power and, specifically, the fuel reprocessing carried out there.

● If rabies should enter Britain, the threat would be to wildlife rather than the human population. *Rabies*, a report from the Office of Health Economics, urges surveillance to ensure that pets are not smuggled into the UK or allowed ashore from small boats. The danger results partly from the changing habits of an important vector of rabies, the fox, which as a suburban scavenger now comes into closer contact with domestic animals. For those at risk, meanwhile, the rabies vaccine produced in France and currently on trial in Britain could be both safer and less painful than those previously available.

The vaccine is prepared from the Pitman Moore strain of rabies virus, inactivated with β-propriolactone after being grown in cultures of human diploid cells. The vaccine produces high titres of rabies-neutralising antibodies, and shows promise for immunisation both before and after exposure to the disease. It represents a considerable advance on previous vaccines, produced from viruses grown in animal nervous tissue and duck embryos.

● The fluorocarbon arguments continue, and now the Department of the Environment (DOE) has published the results of a preliminary examination carried out with the assistance of Harwell, the Department of Health, and the Meteorological Office.

Based on studies ranging from the likely effects of fluorocarbons on stratospheric ozone to the health hazards posed by an increased influx of ultraviolet radiation, the findings suggest that the continued use of fluorocarbons at 1973 rates even for another century will ultimately destroy up to 8% of the Earth's stratospheric ozone, resulting in a 16% increase in radiation reaching the Earth's surface. This accords well with the conclusion of a similar World Meteorological Report published earlier this year.

Curbs on aerosols were not recommended, but there was a call for manufacturers and industry to step up the search for serious alternatives to fluorocarbons. The DOE report stresses that with so many uncertainties remaining the need for eventual regulations cannot be discounted, through it is hoped that ongoing research will clear up many of outstanding points within a couple of years.

A Minister in the Environment Department, Denis Howell, said (perhaps arguably) that the predicted increase in radiation levels was about the same as that incurred during a move from northern England to the south coast.

● The fluorocarbon report represents just one aspect of the work of DOE scientists, and along with environmental pollution, this department's research and development teams are also busily engaged with transport planning, building research and work on natural resources. From next August they will find themselves under a new Director General of Research when the present incumbent, Mr D. J. Lyons, steps down after five years in office to make way for Dr Martin Holdgate. Dr Holdgate, currently heading the NERC's Institute of Terrestrial Ecology, has experience leading research teams into South America.

BRITAIN

Drug firm depressant

The Labour Party last week unveiled its discussion document on state participation in Britain's pharmaceuticals industry. At least one argument adduced, concerning research, is likely to be disputed. Chris Sherwell reports

STRONG criticism of the level and direction of private sector pharmaceutical research and development in Britain, which is subsidised by the Department of Health and Social Security (DHSS), is contained in the Labour Party's consultative policy paper "Public Control of the Pharmaceutical Industry". The views form just one plank in the platform from which it argues that, in the public interest, the recently established National Enterprise Board should "as a matter of urgency" acquire "at least one" UK-owned company with a substantial interest in pharmaceuticals and use it as a base for expansion of the public sector within the industry. It also suggests that there should be "research-based planning agreements" between domestic and foreign companies and the national health service to determine, among other things, the amount of research undertaken in Britain.

This amounts to a considerably watered-down version of the original Labour proposals for wholesale nationalisation of the industry. Indeed, the working group compiling the document now describes these proposals as "impractical". Even in their moderated form, though, the latest proposals quickly received a blanket condemnation from Mr Michael Peretz, President of the Association of the British Pharmaceutical Industry.

The research aspects of the argument appear to have a fairly pivotal role: as the 62-page document, which devotes a separate chapter to the subject, says, "the long run future of the pharmaceutical industry in Britain depends on the quality and quantity of its research and development"; the UK-based industry's "greatest asset", it adds, is its group of research scientists. Labour's overall argument for public sector control does not necessarily stand or fall on the case it presents in respect of research and development, of course. But if preliminary reactions expressed last week by researchers themselves are anything to go by, the four identifiable strands of that case do not do much to strengthen the overall argument.

The first, and perhaps most important, strand argues that, while the existing system of profit control encourages research expenditure, it is "impossible to be sure" that all such activity is socially useful. The working group says it is "gravely concerned" that key areas of research can be neglected; there is, it says, "a social case for government funding of research into remedies for conditions which are obscure or occur mainly in developing countries"; it is "open to question whether a wholly profit orientated industry always fully serves a social purpose in long term research".

Only one of the directors of research at industrial and privately-financed research laboratories consulted last week expressed any sympathy with this view—and even he refused to allow himself to be less than 98% against the proposals on this count. Similarly, three professors could see little merit in the second strand, which anticipates the view that a mechanism already exists, through the research councils, for the government to sponsor research in areas where no commercial company would take the risks.

The working group says that even with the implementation of the customer-contractor principle, there has only been a "paper transfer of ongoing work"; there must be "changes of policy over research", not wasteful duplication of administration. The danger, it says, is that "priorities will continue as before". Only one respondent tended to agree with this, and then only because he thought the MRC was "in a mess anyway". But no respondent disputed that the mechanism was indeed there.

The Labour group's objections go further, however. It points out that any long term research effort sponsored by a government department in an area of strong social need would have to be carefully planned; but, it says, this might replicate the very divorce of long term research from industry which is currently a weakness. It admits that closer links could not be better achieved by a public sector company which was commercially orientated. But, and this is the third strand, a long term research effort sponsored by a public sector company would be "more defensible for the government", and might also make it "easier to establish closer structural links" between the DHSS. the research councils and the industry. Research staff might also prefer to work in a publicly-owned where profit-maximisation was not the only force guiding their work, it argues.

These suggestions also fell on stony ground because they seemed so much a matter of opinion. Cooperation already existed, *Nature* was told, and and more bureaucracy was not wanted. As for the final strand of the argument, concerning competition and duplication in research, there was no doubt that both were vital to progress, and in fact even the Labour group acknowledges the advantages without seriously challenging them.

Beyond the idea of closer cooperation between a publicly-owned sector and existing state-sponsored research the Labour group wants wide-ranging planning agreements and a "general system of indirect public accountability and control", the objective being "to change the balance of public and private power within the industry". ☐

USA

Explosions treaty blasted

Colin Norman reports from Washington on the controversy blowing up over the latest US–USSR nuclear agreement

IN JULY 1974, Richard Nixon, then almost engulfed by Watergate, completed one of his last Presidential acts of international statesmanship — the signing of a US–USSR bilateral agreement outlawing the testing of nuclear weapons with yields greater than 150 kilotons. The treaty was greeted by arms control advocates in the USA with utter dismay. They regarded it as a meaningless gesture which would do little to dampen the arms race. Last month, that treaty was extended to cover so-called peaceful nuclear explosions and the reaction has been equally negative.

The Federation of American Scientists (FAS), a liberal organisation whose sponsors include a galaxy of scientific stars, has condemned the joint pact as "worse than nothing". And last week, two former high ranking government officials argued that the treaty is little more than a sham which could seriously impede efforts to prevent the proliferation of nuclear weapsons to countries which do not now possess them. Such powerful opposition could delay, or even scuttle, ratification of the treaty by the Senate.

The 1974 agreement signed by Mr Nixon and Mr Brezhnev was not due to come into effect until March 31 this year, and it covered only weapons testing—the question of peaceful nuclear explosions was left aside for further negotiations. The treaty was soon heavily attacked on the grounds that the 150 kiloton limit is too high, that the two-year delay in implementing the pact would allow both sides to get in as much large-scale testing as they wanted, and that the exclusion of so-called peaceful explosions left a loophole large enough for either military establishment to shoot massive warheads through. Most critics urged the Administration to go back to the negotiating table and come up with an entirely new treaty.

That hasn't happened. Instead, the Administration has negotiated an agreement on peaceful nuclear explosions which essentially sets an upper limit of 150 kilotons for them as well, and which leaves the rest of the 1974 pact unchanged. Though the full text of the new treaty has not yet been released, Administration officials have said that it contains a provision allowing on-site inspection by foreign nationals for peaceful explosions which consist of several blasts whose combined yield is greater than 150 kilotons. Advance warning of such events would also have to be given.

Critics charged last week that the inclusion of the provisions covering so-called peaceful explosions in an already unacceptable treaty makes a bad situation even worse. Aside from the statement from the FAS, criticism came from Dr Herbert Scoville, former chief of research and development in the Central Intelligence Agency, and Adrian Fisher, Dean of Georgetown University Law School and former Deputy Director of the Arms Control and Disarmament Agency (ACDA). Fisher was the chief US negotiator for the historic 1963 Partial Test Ban Treaty which ended atmospheric testing by all nations except France and China. Scoville and Fisher fired off their criticisms during a seminar held by the Arms Control Association.

A central complaint is that the 150 kiloton threshold is so high that it poses virtually no constraint on weapons development. Both the USSR and the USA have crammed many high-yield tests into the two-year period before the treaty was due to take effect. This has enabled the United States to develop a new warhead for the Minuteman missile, and both sides now have such a vast range of tested warheads on the shelf that there's little need to conduct further high yield tests. Moreover, weapons development in the next decade or so is likely to concentrate mostly on low-yield tactical nuclear devices, testing of which would be allowed under the proposed treaty. As an arms control measure, the treaty is therefore viewed as ineffective.

In addition, both Scoville and Fisher suggested that the high limit could impede future negotiations in other areas of arms control. The usual US posture in such negotiations is to argue that limits should be determined by the ability of verification measures to ensure that no treaty violations take place. In this case, however, it is generally agreed that the United States is capable of detecting and identifying explosions in the USSR down to about 15 kilotons. (The actual detection limit is a matter of some dispute, but nobody is arguing that the limit is as high as 150 kilotons.) Thus, Scoville argued last week that "we have lost the principle of verification from our stance on arms control".

The USA and the USSR have twice agreed to seek a treaty banning all nuclear testing—that principle is embodied in the 1963 Partial Test Ban Treaty, and in the Nuclear Non-Proliferation Treaty—but since this treaty doesn't even come close to such a measure, Fisher argued last week that it could eventually torpedo the non-proliferation treaty (NPT). "It is silly to try to get other countries to sign the NPT while the nuclear powers are continuing to test and improve their own weapons", he said.

As for the provision limiting peaceful nuclear explosions, it was negotiated as a separate entity at the insistence of the USSR, which has plans for using nuclear blasts to divert rivers and for other excavation projects in Siberia. When the 1974 treaty was negotiated, the Soviet delegation wanted no limits on peaceful explosions, but the United States eventually insisted that such an agreement would leave a gaping loophole in the threshold test ban, since it would allow large-yield weapons to be tested under the guise of peaceful explosions. The United States, it should be noted, has virtually abandoned its own peaceful nuclear explosives programme.

At least the agreement now puts an upper limit on individual peaceful blasts, but it has nevertheless run into considerable opposition for treating peaceful explosions differently from weapons tests. The FAS statement, for example, notes that "this can only encourage new nuclear powers to justify bombs as intended for peaceful uses", just as India justified its detonation of a nuclear device. Fisher took the same tack: "we could end up with 20 nuclear nations all saying they are peaceful", he argued.

The FAS also regards the inclusion of provisions relating specifically to peaceful devices as an unwelcome prop underneath the 150 kiloton limit. "The linkage between peaceful and military uses makes doubly unlikely any reduction of the 150 kiloton ceiling. After all, such reductions would now require the Russians to reduce their peaceful limit as well", the FAS argues.

One much publicised aspect of the agreement on peaceful blasts is that, for the first time, it contains a provision for on-site inspection. Though the details of what would trigger such inspection, and what it would entail, have not yet been made public, the provision has been termed a major advance in negotiations with the USSR. Thus, Dr Fred Ikle, Director of ACDA, has said that "we consider this as a real breakthrough, from the point of view of arms control, to have been able to negotiate with the Soviets detailed arrangements for on-site verification".

But not everybody agrees. The FAS statement calls on-site inspection "a precedent whose time has passed" since seismic detection methods coupled with normal intelligence gathering "have narrowed, virtually to equivalence, the tests which can be detected but not identified". A source in ACDA also noted that on-site inspection would be limited to non-military regions in the USSR; extension of the concept to arms controls agreements involving military installations is entirely another matter.

Scoville, Fisher and the FAS have all argued that, instead of ratifying this treaty, the Senate should insist that the Administration should return to the negotiation table and come back with a treaty banning all nuclear testing. In a telephone interview last week, Fisher suggested that "in a couple of years, we should be able to negotiate a comprehensive treaty. We haven't really tried so far—and that goes for past Administrations as well".

At present, it is unclear whether opposition to the treaty, which is only just beginning to emerge, will be sufficiently strong to persuade the Senate not to ratify the measure. A check last week with staff people in the offices of several key Senators indicated that so far the matter has not been given close attention, and that few formal statements will be made until the full text of the agreement on peaceful explosions is made available.

It should be noted, however, that ratification will require a two-thirds majority vote in the Senate; in 1973, 30 out of 100 Senators co-sponsored a resolution urging the Administration to negotiate a complete, rather than a threshold, treaty. Senator Kennedy, moreover, has also denounced the terms of the 1974 agreement, which have been left essentially unchanged.

IN BRIEF

Japan's NPT difficulty

The Lower House of the Japanese Diet (Parliament) ratified the Non-Proliferation Treaty last week, but a Japanese nuclear arms ban along treaty lines may still be some way off. Powerful right wing opposition in the Upper House, which must approve the Bill, could see the Bill abandoned when the present Parliamentary session ends on May 24, and there seems little chance that the ratification can remain "on the table" for the necessary 30 days for it automatically to become law, since the crucial decision to extend the session by six days also rests with the Upper House. Hawkish opposition has constantly delayed ratification since Japan signed the treaty six years ago, even though it has passed through the Lower House before.

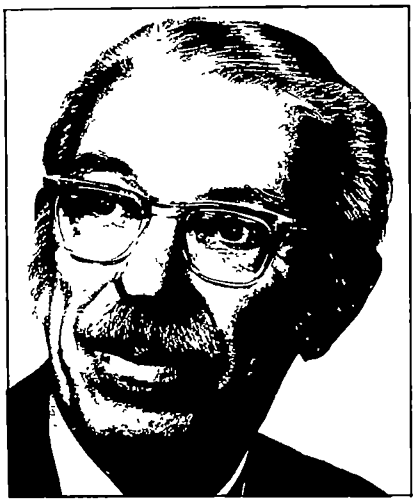
Cancer Institute resignation

In a development which could prove very embarrassing to the US National Cancer Institute, a top official in charge of the institute's environmental carcinogenesis programmes resigned last week, charging that his department is starved of manpower and subsumed under layers of bureaucracy. The official, Dr Umberto Saffiotti, is an outspoken individual who has persistently taken strong stands on the need to remove suspected carcinogens from the environment. His resignation is likely to fuel the growing political debate about whether or not the war on cancer in the United States is paying sufficient attention to cancer prevention.

EEC environment research programme

A five-year research and development programme aimed at introducing better control over the environment and environmental pollution has been agreed by Ministers of the EEC Nine, and to get the £6.7 millions programme under way the Commission has asked for specific research projects from Community interests concerned with most aspects of environmental pollution, reclamation, and ecological problems raised by modern methods of land use. In most cases, successful applicants will share research costs with the community. Laboratories from two UK ministries — Environment, and Health and Social Security—are expected to submit applications.

Federation meetings



THOMAS H. JUKES

THE Federation of American Societies for Experimental Biology includes the major American professional societies of physiologists, biochemists, pharmacologists, pathologists, nutritionists and immunologists. This April, the annual Federation meeting was in Anaheim, California, a short walk from Disneyland. I now wish I had completed the project I thought of starting about ten years ago.

I noted then that registration at the meetings had climbed to more than 15,000, but there didn't appear to be any increase in attendance at many of the numerous scientific sessions. Some were packed, but other meeting rooms were almost empty. Where was everybody? Quite a few were at the exhibits, especially at the free Coca-Cola booth, but it seemed to me that thousands were unaccounted for. I resolved to make head counts systematically in the scientific sessions and compare them each year with the numbers registered, but I got diverted, and in any case, the Coca-Cola booth has been replaced by vending machines. I wondered about the effect of Disneyland this year as a counter-attraction to science, but I was too parsimonious to investigate the matter.

The meetings are a tribal ceremony with a rich folklore. A decent respect for my contemporaries, and a fear of reprisals, prevents me from describing the 1940 Federation meetings in New Orleans. There was a fine scientific programme, and in those lean days a front seat at the floor show in the lively Vieux Carré night clubs could be had for the price of a bottle of beer. Details may be furnished by the President of the National Academy of Sciences, USA, if you can catch him in a reminiscent mood. He was there and it seemed to me that he didn't miss much.

After World War II, the societies grew so large that meetings were often held in the spacious accommodations at Atlantic City. Scientists seemed more serious in those years, and diversions in Atlantic City in April are mostly unappealing. One event stands out. Convention Hall in Atlantic City is designed for major political conventions, at which a band plays on a stage in the main auditorium. The stage is skilfully constructed so that the chairman can press a button and the stage, with the band playing diminuendo, is gradually lowered into the basement by an elaborate system of electric motors and reducing gears. The Candidate, Democrat or Republican, is then introduced to the ecstatic and partisan audience.

At the 1963 Federation meeting there was no band, of course. On stage was an eminent biochemist, Marianne Grunberg-Manago, to give an invited lecture on polynucleotide phosphorylase. Chairing the symposium was the urbane and famous Severo Ochoa, who graciously introduced Marianne. The first slide, showing how nucleoside diphosphates would form RNA-like polymers plus inorganic phosphate, came on the giant screen. The capacity audience was hushed and attentive. The chairman pressed a conveniently-placed button to dim the lights of the auditorium. Slowly and inexorably, platform, chairman, lectern and speaker descended out of sight.

Prominent scientific individualists of a type now unknown used to tread the boards at the meetings. Professor Barnett Sure had a strong dislike of the 15-minute time limitation imposed on regular papers. He would go on talking through the various warning lights and buzzers, through the discussion period, until he found the session chairman tugging at his sleeve. He would then glare at the chairman and say "First slide, please!" Many slides followed.

The American Society of Biological Chemists in 1976 decided to avoid the Federation Meetings, and are meeting separately, in June, at San Francisco, thus rejecting Mickey Mouse in favour of the adult entertainment for which San Francisco is famous. Watch for the report in *Nature*.

Swine influenza

Sir,—The recent description of a human outbreak of influenza virus in an American military camp has justifiably given rise to a great deal of concern. The possibility that the virus involved might cause a severe pandemic must be seriously considered and it is perfectly understandable that vigorous measures be taken to deal with this contingency. Of such measures, the most effective is vaccination with the swine virus and the technology and resources at present available should make possible the production of sufficient quantities of inactivated vaccine for extensive use before the onset of a possible pandemic is anticipated.

Use of such a vaccine on a large scale, however, poses several problems apart from the cost of vaccine production and administration. In the first place, it may be difficult to justify the use of this vaccine for the protection of high risk subjects for whom vaccination is usually recommended, as the majority of such subjects belong to age groups in which antibody (and presumably resistance) to the swine virus is found in a high proportion of individuals due to exposure during 1918 and subsequent years of prevalence of this virus in human populations. Vaccination of younger age groups would be more justified especially considering the possibility of high mortality among young subjects as in the 1918 pandemic. It is difficult, not to say impossible, to estimate the probability of epidemic or pandemic spread of the swine virus.

This uncertainty should not dampen our efforts towards control, but what is to be our future action in the not too unlikely event of epidemics not being observed in the coming season? The risk will still be there in succeeding years and to ignore it will be unwise. If presently feasible inactivated virus vaccine is to be relied upon, the relatively short-lived protection it confers would lead to the daunting prospect of repeated early vaccination against a virus which might not appear at all. A more sensible solution would be to stockpile a strategic reserve of vaccine. Surveillance programmes in operation at present should be more than adequate to detect early signs of epidemic activity of the virus in time to enable the effective distribution and administration of vaccine. Adoption of this policy would make economic sense as the initial investment would be compensated by savings in avoiding the unnecessary use of vaccine in non-epidemic years.

If a strategic reserve of vaccine is acceptable as a potential defence against foot-and-mouth disease of cattle, this would be preferable to the possibly superfluous use of vaccine on the massive scale anticipated in the USA or to the vaccination of already resistant subjects as proposed in this country.

Alternative refrigerants

Sir,—F. A. Cotton's letter (Correspondence, March 25, page 280) is an oversimplification although not, perhaps, a serious one. The fluorocarbon manufacturers estimate that the mean life of a fluorocarbon between manufacture and release to the atmosphere is about six months for an aerosol propellant and about two years for a refrigerant. The latter statement is surprising but is perhaps explained by the fact that a proportion of refrigerants is used in freeze drying and released immediately to the atmosphere, and also that in North America, at any rate, a considerable quantity is used in the air conditioning systems of cars which, perhaps sooner rather than later, are involved in head to tail collisions and release their fluorocarbons as a result.

Birks and Leck (Correspondence March 4, page 8) omitted to state that already in North America about 50% of total refrigerant used is refrigerant 22 which is unsuitable as an aerosol propellant This contains a carbon-hydrogen bond and, for reasons not completely understood but probably because this bond is destroyed by OH radicals which it can encounter in the lower atmosphere, its lifetime in the atmosphere is rather short, probably around three years, as compared with the 80–100 year life of refrigerant 12. It thus appears that refrigerant 22 is unlikely to cause a problem as far as stratospheric ozone is concerned.

The reason commonly given by the chemical manufacturers for not using refrigerant 22 exclusively is that this would leave manufacturing capacity unused as it is not possible to manufacture R-22 in a plant designed for R-12 However, I have been informed by a particular manufacturer that he routinely switches his plants from R-22 to R-12 according to demand. I was not previously aware that an R-22 refrigerant plant was much more expensive but, if this is so, it is difficult to understand why already half the refrigerant used is R-22.

There thus seems to be no valid reason why we should not dispense with the expensive, trivial and possibly dangerous convenience of the aerosol spray can—remembering that fluorocarbons are used almost exclusively in "personal care" products such as hair sprays and deodorants—and still retain the benefits of refrigeration.

Human anatomy

Sir—Kenneth Mellanby (February 19, page 523) remarked that model was a term capable of abuse, and that in Soho the word probably would not lead to useful scientific research. A week or two earlier the asymmetry of the scrotal sac of male homo sapiens had been discussed using artistic models as criteria.

Both these publications reveal the curious reluctance of scientists to research into human anatomy and relate it to function, disease and sociology. Such studies might usefully be termed gross morphological enquiries, in contrast with the vague constitutional studies which had a short flowering in the late nineteenth century and mid-twentieth century

I have found, for instance, that asymmetry is commonplace in the human physique. The circumference ratios (right/left) of thirty right-handed women in the 18–22 years age group were measured, and averaged 1.02 (ankle), 1.06 (calf), 1 05 (thigh), 1.09 (biceps). The volume of the mammary glands also differs, although supportive garments do not allow for this fact; the result is that the right mammary gland, if supported well, implies a looser support for the left. The explanation of these asymmetries is presumably in the greater use of the muscles underlying the right hand limbs.

No evidence for this asymmetry can be found in the paintings of Titian or Rubens in the National Gallery, London or in Rodin's The Kiss.

Revival of Milankovitch

from George J. Kukla

To support a century-old controversial theory that no one has yet been able to prove or disprove convincingly is an unrewarding business. Obviously though, something great must be in the making if the head of the UK Meteorological Office, certainly not one to suspect of holding irresponsible revolutionary views, ardently re-approves the Milankovitch theory of glaciations (see *Nature,* **260,** 396: 1976). According to the report, Mason was impressed by the coincidence in the length of orbital periodicities with those found by Hays, Imbrie, and Shackleton (unpublished) in the ^{18}O records of some deep-sea cores. Geologists will be pleased but hardly surprised by the convincing answers of the computerised correlation. Fifty years ago, Eberl (*Die Eiszeitenfolge im Nordlichen Alpenvorlande,* 1930) demonstrated that the number of alpine Pleistocene terraces coincides with Milankovitch minima and 10 years ago, Broeker, (*Science,* **151,** 299; 1966) summarised available isotopic chronologies of Late Pleistocene and reported a remarkable resemblance to insolation curves. As for the energy involved, Mason sees the quantities in the "right ball park" which contradicts a view held by Shaw and Donn (*Science,* **162,** 1270; 1968). Now Weertman in this issue of *Nature* (page 17) demonstrates that Milankovitch variations are large enough to set the continental ice sheets into motion. But this is possible only if precipitation in high latitudes is much greater than today.

Here is where the problem begins: to find the details of the mechanism through which insolation changes climate. Although today the astronomical part of the Ice Age theory is fairly reliable, Koppen and Wegener's original ideas on the direct impact of insolation on glaciers are, in the light of modern climatology, naive at best. Redistribution of energy in the Earth–atmosphere system, which operates through a number of delicate feedbacks makes the problem extremely complicated (Kellogg and Schneider, **186,** 1163; 1974).

The largest effect of orbital perturbations is in the changes of seasonal and geographical distribution of radiation over the globe. In order to influence the climate, sensitive areas and seasons must be affected by insolation to a greater degree than in the rest of the year (Kukla, *Nature,* **253,** 600; 1975). Finding these zones and intervals is critical for understanding climate dynamics. No valid explanation of past climates or successful seasonal forecast is possible without first solving this key problem. Subdivision of yearly insolation into only summer and winter segments or simple global circulation models incapable of handling subtle feedbacks, can hardly provide an answer.

Suarez and Held (of Princeton University's Geophysical Fluid Dynamic Laboratory) used an energy balanced model which simulates the seasonal cycle and produces a large change in the extent of permanent snow and ice when past insolation structures are applied.

Berger (*EOS,* **57,** 254; 1976) has provided us with insolation values at twelve mid-month intervals in ten degree latitudinal belts for the past million years. His calculations of August irradiation on top of the atmosphere indicate a peak (744 Ly d^{-1}) 8,000 years ago at 60°N and a minimum of 679 Ly d^{-1}, 19,000 years ago. The difference of 65 Ly d^{-1} is undoubtedly large enough to affect the surface heat balance even without the volcanic dust triggers proposed by Bray (*Nature,* **260,** 414; 1976). On the other hand, the glacial–interglacial difference of 65 Ly d^{-1} is relatively small compared with the annual amplitude of irradiation to 60°N latitude. Insolation drops and rises by that amount in less than 10 days every October and April.

Despite millions of data bits on every element of the Earth–atmosphere system we still know lamentably little on the weather system response to this 10 day insolation shift. Can we expect to find the answers from spotty geological evidence accompanying the same irradiation change occurring over ten thousand years? Can we hope to understand glaciation and deglaciation without understanding fall and spring? With the wealth of data already at hand shouldn't we start to look seriously into the mechanism of the seasonal cycle? ☐

Control of transcription of the ovalbumin gene

from Pamela Hamlyn

THE well-characterised eukaryotic mRNAs have all been isolated from cells in which they are the predominant mRNA. The mRNA for ovalbumin is no exception being the major mRNA species in part of the hen oviduct, however, it is of particular interest since its production can be induced in immature chicks by treatment with the hormone oestrogen. On administration of the hormone there is a concomitant proliferation of tubular gland cells in the oviduct. When the treatment ceases (withdrawal) the number of these cells drops to 10–15% and ovalbumin synthesis becomes undetectable. This system is of interest to endocrinologists and also to molecular biologists, who have used it as a model system to study the control of protein synthesis (Palmiter, *Cell,* **4,** 189; 1975).

It has been known for some time that oestrogen, after diffusing into cells, combines with a protein, and that the complex migrates to the nucleus where it remains bound to the chromatin This is a specific reaction; it has been shown that the hormone–receptor complex will not bind to the chromatin of non-target cells Since the oestrogen appears to bind (by way of the receptor) to the genetic material, and since one of the observed effects is the synthesis of the protein ovalbumin, the study of the mRNA was an obvious next step.

Initially ovalbumin mRNA was

detected in RNA preparations by its ability to direct the synthesis of ovalbumin in cell-free protein synthesis systems. This method has now been superseded, however, by preparing a 'probe' for ovalbumin mRNA by transcribing the messenger with reverse transcriptase to obtain a radioactively-labelled complementary DNA. The cDNA is used to measure the concentration of mRNA sequences in immature chick oviduct cells before, during and after stimulation with oestrogen (Harris, Rosen, Means and O'Malley, *Biochemistry*, **14**, 2072; 1975). Before stimulation, ovalbumin mRNA was undetectable in oviduct cells, whereas several days' administration of oestrogen resulted in tubular gland cell formation and a build-up of ovalbumin mRNA to approximately 50,000 molecules per cell. Ovalbumin mRNA synthesis stops when the hormone is withdrawn and within 12 days the level of mRNA has dropped to 0-10 molecules per cell. These results have been used to suggest that the primary regulation of ovalbumin synthesis by oestrogen occurs at the level of mRNA transcription, that is, that the oestrogen–receptor complex on binding to the chromatin activates or 'derepresses' the ovalbumin gene so that it can be transcribed Other interpretations of these data are possible however. Cox *et al.*, for example, have pointed out the possibility that the effect of oestrogen could be to prevent the very rapid degradation of ovalbumin mRNA (Cox, Haines and Emtage, *Eur. J. Biochem.*, **49**, 225; 1974).

To investigate further whether the oestrogen–receptor complex has a direct effect on transcription, O'Malley's group have measured the number of RNA polymerase initiation sites on chromatin isolated from oviduct nuclei at various stages of oestrogen treatment (Tsai *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **72**, 4228; 1975). They have shown that during primary stimulation the number of RNA polymerase initiation sites increases, whereas withdrawal results in a drop in the number of initiation sites.

And now O'Malley and his coworkers have asked whether the RNA synthesised *in vitro* from isolated chromatin has the same tissue specificity as the RNA isolated from whole cells over the range of ovalbumin stimulation conditions. Using a cDNA probe for ovalbumin mRNA they were able to show that in their *in vitro* system only RNA transcribed from chromatin isolated from ovalbumin target cells contained ovalbumin mRNA sequences. They have also shown that RNA polymerase was necessary to produce RNA to which the cDNA would hybridise. (This is the usual control to eliminate the possibility that ovalbumin mRNA in the cell has been isolated as a contaminant in the chromatin preparation) Their results indicate that in general the presence of sequences transcribed *in vitro* which contain ovalbumin mRNA mimics the pattern of *in vitro* transcribed RNA with respect to hormone dependence The authors do point out one difference however During withdrawal there are between 0–10 molecules of ovalbumin mRNA per tubular gland cell but the chromatin isolated from the oviduct of withdrawn chicks could support the transcription of up to 5,000 molecules per cell. The authors suggest that the cells may fail to do this *in vivo* because of deficiencies in the RNA polymerase (or associated factors). Alternatively it may be (as Cox *et al.* also suggest) that low levels of mRNA are produced but are rapidly destroyed in the absence of post-transcriptional stabilisation which is in some way brought about by oestrogen.

O'Malley and his colleagues plan to use this *in vitro* system—to separate it into its components and reconstitute it —in order to study more directly how the oestrogen receptor interacts with chromatin. The continuation of this series (this latest paper is number eleven) will be awaited with interest.

Jovian magnetotail stretches past Saturn

from John Gribbin

In one of those surprising discoveries that, with hindsight, should not have been a surprise at all the Pioneer 10 sensors have detected the influence of Jupiter's magnetotail some 690 million km behind the planet, beyond the orbit of Saturn. This is just about the same distance from Jupiter as the Sun is on the other side—but since the magnetosphere surrounding Jupiter has a diameter of more than 14 million km it is not so surprising that the magnetotail stretches so far—about 50 magnetospheric diameters. After all, the Earth's magnetotail has been detected 500 planetary diameters 'downstream'.

Pioneer 10 passed through this extended magnetotail in mid-March, taking a full 24 h to complete its passage through the region of space influenced by Jupiter's magnetic field, according to NASA reports. Having passed the orbit of Saturn early in February, Pioneer 10 is now well on its way out of the Solar System, while its sister craft, Pioneer 11, re-targeted by its swing past Jupiter, is crossing the Solar System to encounter Saturn in three years time The evidence for the presence of Jupiter's magnetotail beyond Saturn's orbit comes from the Pioneer 10 solar wind detector, which registered zero during the time that the Jovian field 'shut out' the solar wind; the possibility that a genuine lull in the solar wind coincided with the spacecraft being exactly in Jupiter's magnetic shadow remains, but hardly looks plausible.

On the face of things, the observations imply that there is a roughly cylindrical volume of space influenced by Jupiter's magnetic field stretching across a sizeable fraction of the Solar System, and probably expanding slightly at greater distances from the Sun, since the solar wind density decreases as the square of the distance from the Sun. One of the most intriguing implications is that Saturn itself must pass through Jupiter's magnetotail every 20 yr, the next occasion being in April 1981 (unfortunately, just about 18 months after Pioneer 11 reaches Saturn). John Wolfe, Pioneer project scientist at NASA's Ames Research Center, comments that "this should produce some interesting magnetic phenomena".

One puzzle is that Pioneer 10 is now six degrees above the plane of Jupiter's orbit, and if the solar wind blows radially the magnetotail should be a couple of degrees, at least, below the spacecraft. But as earlier data from both Pioneer 10 and Pioneer 11 have shown, the solar wind blows gustily even at the distance of Saturn, and this turbulence could explain the tail being blown 'upwards' by six degrees temporarily.

The continuing irony of the new discoveries about Jupiter is, of course, the way in which space probes have shown that in many ways the most similar planet to the Earth is not Venus or Mars but the giant of the Solar System, a planet which contains three-quarters of all the Solar System's planetary material and which just missed, on some theories, becoming a star. ☐

Nations and numbers, 1975

from Robert M. May

For the past few years, the Environmental Fund in Washington DC has published an annual chart giving a country-by-country summary of the best contemporary estimates of population magnitudes, growth rates, and other demographic parameters. Some of these figures are familiar to most people, and some are not

Because of the many sources of uncertainty and delay in obtaining and reducing census data, the figures for

1975 do not simply derive from 1975 censuses. Rather they are extrapolations from the 1973 UN *Demographic Yearbook,* itself based on data up to 10 years old; the Environmental Fund's projections forward from 1973 derive from actual growth in numbers of people (from Table 4 of the 1973 UN *Demographic Yearbook*), rather than the more theoretically derived birth and death rates given in the latest UN estimates (April 1, 1975). The most significant uncertainty is in the figures for China.

In mid-1975, the total world population stood at around 4,147 million, growing at an annual rate of 2.2%. The dominant contribution was from Asia, whose 45 countries contributed 2,407 million people, with an overall growth rate of 2.5%; the growth rates of individual countries were scattered about this weighted average rate with a standard deviation of about ±0.7%. Other major geographical regions are Africa with 50 countries, 420 million people, growth rate 2.8%; and Latin America with 30 countries, 328 million people, and growth rate of 2.9%. The more developed regions are the 27 European countries, comprising 474 million people with an overall average growth rate of 0.8%; North America with 242 million and growth rate 1.0%; the USSR with 254, and 0.9%; and Oceania (comprised mainly of Australia) with 21 million people growing at 2.1% per annum. In each of these major regions, the growth rates of individual countries are scattered around the weighted mean value with standard deviations in the range 0.6–0.7; thus European rates span a range from −0.4 to 2.6, Latin American from 1.0 to 3.5, African from 1.2 to 3.8.

Of the larger countries (and henceforth I shall use "larger" to mean in excess of 10 million inhabitants), the top 1975 growth rate was Pakistan, at 3.6%. Despite its tribulations, South Vietnam was a close runner-up at 3.5, followed by Iraq and Kenya with 3.4%. In the open division of this event, regardless of the country's population, the clear winner was Kuwait with 4.8% (produced in part by immigration), from Libya on 3.8 and Rhodesia on 3.7. At the other end of the scale was East Germany with a negative population growth rate of −0.4%, followed by Portugal with −0.3, Hungary with 0.1, and Sweden and the United Kingdom on 0.2.

These different growth rates, past and present, make for great sociological differences in the countries. One important index of this is the fraction of the population which is under 15 years of age. In the world as a whole, 37% of people are under 15. By region, this breaks down into 44% in Africa, 43 in Latin America, and 40 in Asia, in systematic contrast with 26% in Europe, 27 in North America, 29 in the USSR, and 33 in Oceania. The top numbers are held by Iraq and Mexico, with a staggering 48% of the population below the age of 15; a dozen other countries (mainly in Latin America) follow with 47%. At the opposite end, Hungary has 20%, and East Germany and Sweden 21%. This ratio, which may crudely be thought of as a ratio of "tax consumers" to "tax producers", has a multitude of obvious implications for the social organisation of a country, some of which have been explored by Watt (*Principles of Environmental Science,* McGraw-Hill, New York, 1974) and others.

Maudlin (*Studies in Family Planning*, **6**, 30–36; 1975) has catalogued the developing countries according to the official government position regarding population growth or support of family planning. It is encouraging that 34 of these 118 countries, accounting for 2,083 million people (or 74% of the total among developing countries), have an announced policy to reduce population growth rates. In the case of India, the policy reaches back to 1952; 23 others date from the 1960s, and the remaining 10 from the 1970s. The average 1975 rate of population growth in this first category of developing countries was 2.6%. A second list of 32 countries (total population 454 million, representing 16% of people in developing countries) have official support for some form of family planning activities for reasons other than reducing population growth. The average growth rate in this category of "less alarmed" countries is 2.8%. A third category, including 52 countries (although only 270 million people, or 10% of those in developing countries) does not even have support for family planning.

It is notable that so large a fraction of the developing countries has adopted policies aimed at reducing

Natural selection and evolution

KREBS and May's account of social insects and the evolution of altruism (*Nature,* **260,** 9; 1976) is excellent, but the first paragraph raises a controversial issue. They attack statements of the type 'adaptations evolve because they are of benefit to the species (or population) as a whole'. They go on to point out, rightly, that natural selection acts on individuals, not on populations, but they then say: "Natural selection is a matter of differential survival and reproduction of individuals (or to be precise of genes), not of species". Evolution occurs over many generations, however, and genes do not exist in isolation but are part of gene complexes to which they must be adapted. Since most organisms reproduce sexually there will be many different gene complexes in the population over several generations. So for a gene to maintain its differential survival (that is, to increase its frequency or be selected) it must be adapted to many gene complexes, in other words to the entire gene pool of the population. This is what is meant by saying that an adaptation evolves because it benefits the population as a whole.

This point is important because a number of authors, particularly American ones, interpret 'adaptations benefitting populations' as implying group selection as defined by Wynne-Edwards (*Animal Dispersion in relation to Social Behaviour,* Oliver and Boyd, 1962). I have myself recently been criticised on these grounds (Dingle, *Science,* **188,** 1105; 1975), yet I never once mentioned group selection. There is an important distinction between natural selection, which relates to individuals or gene complexes, and evolution, which relates to changes in populations or in gene pools. When people write about adaptations evolving because they benefit the population or the species, this should not be thought to imply that they do not understand Darwinian natural selection, but rather that they are stressing the integration of the genes responsible for the adaptation into the gene pool.

MALCOLM EDMUNDS

JOHN KREBS REPLIES: Edmunds is correct in pointing out that good genes are ones which not only code for good characters, but also get on well with their fellow genes. However, selection does not act on large gene complexes, because they do not survive long enough as single units. Genes last a long time, so they are the units which survive in the process of natural selection. Where genes are very closely coadapted, they evolve very strong linkage so as to become one supergene.

Well adapted gene pools and gene complexes are obviously a consequence of natural selection for good genes, but this does not mean that gene pools and complexes are the basic unit of natural selection.

population growth. As stressed by Korten (*Studies in Family Planning*, **6**, 178–187; 1975), there are few other ideas in human history that have been transformed from taboo to official government policy in little more than a decade. Even so, the picture is not encouraging. The survey of aims and accomplishments with respect to population growth in the 14 largest developing countries (in order, China, India, Indonesia, Brazil, Nigeria, Bangladesh, Pakistan, Mexico, Philippines, Thailand, Turkey, Egypt, Iran, Korea) by Stewart (in *Population and the New Biology*, Academic Press, New York, 1974) reveals a consistent pattern of targets which, although modest enough, are not being met India's two-thirds cut-back in the 1974 budget for its family planning programme is the sort of economy it can least afford.

Another interesting demographic statistic is the percentage of a population that is classed as urban. This statistic is made a little fuzzy by virtue of the definition of an "urban" locality differing from country to country (see *Trends and Prospects in Urban and Rural Populations, 1950–2000*, UN, New York, 1975). Nonetheless, this figure shows interesting trends, particularly when the estimates for 1975 are put beside those for 1950.

In 1950, 29% of the world population was urban, as against 39% in 1975. Broken down into geographical groupings, these figures (expressed as percentage urban in 1950 and in 1975, respectively) are 23 and 44 for southwest Asia; 16 and 21 for middle south Asia, 13 and 22 for southeast Asia, 17 and 31 for east Asia; 13 and 25 for Africa; 41 and 60 for Latin America; 55 and 67 for Europe, 39 and 61 for the USSR; 64 and 77 for North America; and 65 and 72 for Oceania. Concealed within these aggregated numbers are such dramatic transformations as 28% urban growing to 63% over 25 years in Martinique, 11 to 37% in Zambia, 21 to 50% in Algeria, and many other examples of a more than 200% change in the urban fraction, particularly in Africa. Very little of this differential growth in urban populations is the result of planning. The absolute lowest urban fractions in 1975 come from Nepal (5%), followed by Tanzania (7) and Uganda (8). The most urban large country in both 1975 and 1950 was Australia (with 86 and 80%, respectively), slouch-hat jackeroo image to the contrary. □

Conservation of microbial genetic resources

from S. P. Lapage

The Third International Conference of Culture Collections (ICCC III), was held in Bombay, from March 15–19, 1976 and was attended by 290 scientists from 29 countries. It was organised by the World Federation of Culture Collections and local organising committee, under the auspices of UNEP, Unesco, ICRO and the UNEP/Unesco/ICRO panel, IUBS, The University of Bombay and other Indian organisations.

ICCC III provided a useful forum for discussion on the role and development of culture collections in developing countries. Emphasis was placed on the preservation of strains for local use and the preservation of those local strains which might otherwise be lost to science; on the relation of culture collections to the UN agencies and to the proposed development of regional microbial resource centres, with associated culture collections that would maintain the relevant strains of microorganisms, (for example suitable strains for nitrogen fixation or food fermentation in the particular region).

Also discussed were the value of national and regional federations of culture collections, the World Data Center and its relation to other data centres and their services in providing information on the location of the microbial genetic resources held in culture collections. The related problems of standardisation of data handling and of data coding for groups of microorganisms were also considered extensively, and it was thought necessary that the agreement of the relevant international authority for each group of microorganisms concerned (such as the International Committee of Systematic Bacteriology and International Committee on the Taxonomy of Viruses) be obtained before any system of data coding was universally recommended or adopted. The deposit of microorganisms for patent procedure in culture collections and an International Treaty proposed under the sponsorship of the World Intellectual Property Organisation were also discussed, as were the problems of identification in culture collections, and the value of culture collections in many other fields—medical, veterinary, industrial and others.

The technical aspects of preservation were also dealt with T W. G. Rowe (Edwards High Vacuum, Crawley, UK) announced some recent work of D. Greiff (Medical College of Wisconsin, Milwaukee) who has shown that ice and DMSO can be simultaneously sublimated under vacuum from a protein solution to leave a water-soluble 'cake', which opens up a prospect for the successful freeze-drying of microorganisms and possibly tissue cultures that do not survive freezing without a cryoprotectant. Rowe and Greiff have also shown the persistence of minute open channels in the heat sealed ends of Pyrex glass ampoules through which air and water vapour may percolate leading to deterioration of the contents. These channels can be closed simply by coating the sealed end with the synthetic rubber, neoprene. □

Drug action at the molecular level

from S. Neidle

A symposium on this topic was held on April 12–13 at the Middlesex Hospital Medical School, London, organised by the Co-ordinating Committee for Symposia on Drug Action, under the auspices of the Biological Council.

MOLECULAR pharmacology as an area of study encompasses a wide range of disciplines, from X-ray crystallography through membrane transport kinetics, to bio-organic chemistry. This diversity of approach was well illustrated at the recent symposium on drug action. Although the contributions covered a number of different problems, it became clear however, that many of these approaches are indeed to a large extent interdependent. Thus, "hard" results from say, kinetic studies concerning a biological receptor and the drugs which bind to it are best obtainable when the receptor itself has an established molecular structure. This point was exemplified by P J. Goodford (Wellcome Research Laboratory), who described recent attempts to design a drug to fit a known receptor. Haemoglobin, whose three-dimensional structure is well understood, was used as a model Diphosphoglycerate, a natural inhibitor of oxygen uptake by haemoglobin, fits into a geometrically well-defined binding cleft in the protein. Instead of synthesising series of diphosphoglycerate analogues, Goodford and his colleagues simply decided to manufacture a molecule that would fit exactly into the cleft, and have appropriate groupings to confer hydrogen-bonding donor and acceptor properties Biological testing of the inhibitor properties of their synthetic substrates have provided results which auger well for this novel approach.

The classical approach to systematic drug design was described by C. R. Ganellin (Smith, Kline and French). The simple concepts of structure–activity relationships, such as Hansch analysis using linear free-energy relationships, have been widely used. The limitations of these methods are now well known; however, Ganellin showed that dynamic structure–activity relationships are capable of analysing quite complex situations, such as relative ionic populations in a prototropic equilibrium mixture, and hence identifying the ionisation sites of the pharmacologically active tautomer of, say histamine. The relevance of this approach (and indeed of most others) to the identification of active conformers and tautomers was questioned by W. G. Richards (University of Oxford), who reported on his recent quantum mechanical calculations on histamine. He also emphasised the importance of considering the topography of both nuclei and electrons of drug and receptor in an active environment, in order to determine the essential conformation of the drug. The active conformation of histamine, as determined from conformational probability maps, seems to be neither that determined in the solid state by X-ray crystallography, nor that present in solution, and furthermore there is no obvious positive charge centre in the active molecule. Although these results have to be treated with caution, their implications are of some importance.

A hundred years ago

THE forty-seventh anniversary of the Zoological Society was held on Saturday last, Viscount Walden, F.R.S., the President, being in the chair. Mr. P. L. Sclater, F.R.S., the Secretary, read the report, which showed that the income (28,738*l*.) was greater than it had been in any previous year since the foundation of the Society. The total number of visitors in 1875 had been 699,918. The new lion house had been, as far as its main portions were concerned, completed and opened to the public. The building contains fourteen dens, the larger of which measure 20 ft. by 12 ft., the smaller being 12 ft. square. The out-door cages are to be completed by the end of July next; they will measure 44 ft. by 29 ft. Mr. Sclater desired it to be known that of the larger Felidae, the Ounce (*Felis uncia*) was a desideratum. The adoption of the report was moved by Prof. Huxley, seconded by Prof. Tennant, and carried unanimously.

from *Nature*, **14**, 15–16; May 5, 1876

Unsurprisingly, they provoked a lively discussion, during which some experimental support was suggested for essential conformations from structural studies on enzyme–substrate complexes. The audience, which consisted mostly of experimentalists, was doubtless relieved to hear that theoretical calculations of drug conformation are by no means infallible—indeed it is a characteristic experience that increasing sophistication in *ab initio* calculation often parallels increasingly poorer quality of results.

Magnetic resonance techniques for probing drug–receptor conformations in solution are currently enjoying a considerable vogue. Thus, J. Feeney (National Institute of Medical Research) showed how he has applied them to studies of hormonal peptides, such as oxytocin and gastrotetrapeptide. Although no direct information can be obtained about their conformations when bound to receptor sites, useful data indicating preferred modes of flexibility and intramolecular hydrogen-bonding organisation are more readily accessible. From this, Feeney and his associates have developed a "zipper" theory for the mechanism of receptor binding, whereby attachment is stepwise to a series of subsites, with each step giving a reorientation of the substrate conformation. G. C. K. Roberts (National Institute for Medical Research) presented a progress report on inhibitor bindings studied by NMR to the biosynthetically important enzyme dihydrofolate reductase. Although definitive conclusions must await an X-ray analysis, it is apparent that binding of, for example, the anti-leukaemic drug methotrexate (which is a competitive inhibitor for the natural substrate) is a complex process, which is accompanied by dynamic changes in the enzyme conformation.

Drug binding to nucleic acids, especially DNA, as receptors, has for long been a favoured field of study, doubtless partly because so much is known about the detailed structures of the nucleic acids. M. J. Waring (University of Cambridge) emphasised some of the challenging and unsolved problems in this area, particularly those concerned with binding to preferred lengths of sequence. Studies of binding with the antibiotic echinomycin, a cyclic octapeptide with two quinoxaline rings attached, have shown that this compound acts as a bifunctional intercalating agent. The two planar quinoxaline rings are believed to slot in between two base pairs, that is, with a gap of 10.2 Å. The problem of, *inter alia*, apparent violation of the neighbourhood exclusion principle at high binding levels has, however, hindered a detailed understanding of echinomycin binding to DNA so far.

It is not surprising that the complexity of membrane-bound receptor proteins has meant that knowledge of them at the molecular level is relatively sparse. Thus, the achievements of E. A. Barnard (State University of New York at Buffalo; now at Imperial College) and his associates in purifying the acetylcholine receptor (molecular weight 330,000) from denervated cat muscle, were the highlight of the session on these systems. It is worth remembering that the receptor, which was purified by binding to the snake venom α-bungarotoxin, exists in nanomolar concentrations in the tissue used. Results mentioned by Barnard from several laboratories have indicated the sites of receptor attachment to be the postjunctional membrane. The individual receptors are on the crest of the fold facing the presynaptic sites, and there appear to be roughly 20,000 individual molecules of protein per fold, arranged somehow within about 2,000 particles, as seen in freeze-etched electron micrographs. Clearly, this area of molecular pharmacology is destined for considerable advance in the near future. ☐

Solar system origin

from David W. Hughes

An advanced study institute on the Origin of the Solar System was held in the Institute of Lunar and Planetary Sciences of the University of Newcastle-upon-Tyne between March 29 and April 9, 1976 under the sponsorship of NATO.

COSMOGONY, the study of solar system origin processes is bedevilled by the fact that only one solar system is observable. The origin and evolution of stars (which are thousands of times further away and immeasurably less accessible than the planets) is much better understood simply because the sky is full of them—of different sizes and mass and at different stages in their evolution—and comparisons between them produce an abundance of clues to the physical processes responsible for their birth, life and death. The wavy paths of Barnard's star and Epsilon Eridani as they move across the celestial sphere indicate that they probably have planetary companions. Their remoteness, however, makes it completely impossible for us to measure the mass or orbits of the planets at present. An observer on one of the planetary companions of Epsilon Eridani, for example, looking towards the Sun would see Jupiter at greatest elongation 1.6″ away from the Sun and as an object 10^{10} times less bright. Jupiter's image would thus be completely swamped by the glare of the Sun. The centre of the Sun moving around the centre of mass of the Solar System would produce an astrometric wave of peak-to-peak amplitude 4×10^{-3}″ which is well below present-day detection limits. So a solar system such as ours orbiting a nearby star would be undetectable. The companions of Epsilon Eridani and Barnard's star must be much heavier and/or much closer to the central star than our Jupiter or Saturn.

Bearing these difficulties in mind a group of cosmogonists (a "nebulosity" of cosmogonists might be the better collective noun considering the scant common ground between their theories) met for two weeks at the University of Newcastle-upon-Tyne to discuss their latest theories and to explain them in detail to the many research workers in related fields who had also assembled there.

The best resumé of the problem was given by H. Reeves (CNRS, Saclay) who expanded on his recent paper (*La Recherche*, **6**, 807; 1975). Cosmogonic theories were divided into four groups dependent on whether the Solar System was formed at the same time or later than the Sun and on whether the Solar System was formed out of interstellar material which has the same chemical composition as present-day interstellar material or from material that has been altered chemically as a result of being at one time inside a star and being heated up to temperatures near 10^6 K. Observational facts are used to help decide between the above options.

The facts that the deuterium/hydrogen ratio is about 2×10^{-5} in planetary and interstellar material but less than 3×10^{-7} in the Sun, the lithium/silicon ratio is 200 times smaller in the Sun than in the planets, whereas the iron/silicon ratio is reasonably the same, indicate strongly that the Solar System is made of unaltered material, thus ruling out two of the options.

Ratios between the abundances of parents and decay products in radioactive series indicate that the Earth, Moon and most meteorites solidified about 4.6×10^9 yr ago The ^{12}C/^{13}C ratio has halved over the past 5×10^9 yr and measurements of this ratio in cometary gas and the atmosphere and surface rocks of planets indicate that the Solar System was formed quickly, and at the same time as the Sun. So the nebulosity, parts of which condensed to form the planets, was dense and short lived. The cosmochemistry of the Solar System, which accounts for the mean composition of the planets and its variations with heliocentric distance, again requires a massive nebula (~10% of the solar mass), opaque to radiation, with temperatures varying from 1,500 K at about 0.3 a.u. from the Sun to 200 K at 40 a.u., and pressures of between 10^{-3} and 10^{-6} atmospheres. This temperature variation accounts for the rocky nature of the terrestrial planets and the icy and gaseous nature of the outer planets. It must also be remembered that only about 1% of the original nebula finally coalesced into planets, 99% being lost from the system.

The Reeves scenario rules out all theories which call on cloud capture long after solar system formation, interstellar collisions and binary star origins and leaves one with the basic Laplace nebula which was first propounded in 1796. All other theories have to be carefully scrutinised in the light of the above observations.

A. G. W. Cameron (Harvard College Observatory) and H. Alfvén and G. Arrhenius (University of California) were protagonists in a fascinating debate starting from positions 5×10^9 yr apart. Cameron concentrated on star formation (that is, birth of the Solar System), invoking a pressure-induced collapse of an interstellar cloud caused by a recent encounter with a galactic spiral arm and a nearby supernova explosion. This cloud forms a cool, turbulent, dense disk out of which large protoplanets condense and subsequently disrupt leaving, as debris, the present planets. Magnetic fields and plasma effects play no part.

Alfvén and Arrhenius pledged allegiance to the 'actualistic' principle, the present state of the Solar System in conjunction with the physical processes now acting being progressively wound backwards so that older and older times are reconstructed. In the resulting theory the Solar System condenses slowly out of a low density nebula which is partially ionised and controlled by magnetohydrodynamic processes. At this stage in the debate problems of angular momentum raised their heads. These are that a one solar mass cloud of average galactic density (1–10 hydrogen atoms cm^{-3}) and differential rotation would, if it condensed to form a star, form a star which was spinning too quickly, was too hot and too highly magnetised; the planets contain 0.14% of the mass but 98% of the angular momentum of the Solar System; and conversely satellites of planets only contain 10–20% of the planet's angular momentum.

Alfvén transfers angular momentum from the Sun to the planets using Birkeland currents similar to those acting in the ionosphere and magnetosphere. Cameron's Sun is originally spinning quickly and is braked over the 5×10^9 yr by solar wind drag. D. C. Black (NASA–Ames Research Centre) makes use of the apparent rarity of star formation and the fact that stellar rotation axes are orientated randomly with respect to the galactic plane to conclude that gas clouds only collapse if the galactic corotational angular momentum is almost completely cancelled out by the turbulent angular momentum of the cloud. M. M. Woolfson (University of York) does not have this problem as in his theory the gas pulled from a protostellar cloud when the Sun passes close by has an independent angular momentum to the Sun's.

G. Herbig (Lick Observatory, California) reviewed observations of the young T Tauri type stars and indicated how their high shrinkage rates, large-scale mass ejections, variability and apparent nebula envelopes were of considerable relevance to planetary formation.

A. J. R. Prentice (Monash University, Australia) was the only contributor to introduce directly the Titius–Bodes law. His "Laplacian" theory predicted rings of planetismals at the presently observed heliocentric distances but this again leaves the problem of how and why these planetismals accrete to form one, and only one, planet from each ring. The accretion and fragmentation processes taking place between these planetismals were discussed in detail by A. W. Harris (Jet Propulsion Laboratory) and J. K. Kerridge (Institute of Geophysics, University of California). W. H. McCrea (University of Sussex) suggested that Earth–Moon–Mars and Venus–Mercury were just fission products from earlier larger planets.

Diverse ideas and suggestions were put forward by many people but the list of unanswered questions remains uncomfortably long. What do meteorites have to tell of the conditions in the nebula during the early Solar System? Opinions differed greatly as to their significance. Why didn't the Asteroids form a planet? Is the planarity and orbital directness of the present Solar System just the result of 4.6×10^9 yr of gravitational perturbation? Is there anything apart from comets beyond Pluto? Why did meteorites undergo a second heating after formation? Just how common are solar systems like our own? The remaining questions are legion, and the debate will go on far into the future; however, this study institute at Newcastle gave the problems a good airing and introduced many people to the fascinations of this intriguing subject. Two weeks of stimulating mental activity was had by all. □

Milankovitch solar radiation variations and ice age ice sheet sizes

Johannes Weertman

Department of Materials Science & Engineering, and Department of Geological Sciences, Northwestern University, Evanston, Illinois 60201

The fluctuations in the size of ice age ice sheets are calculated using glacier mechanics and the Milankovitch solar radiation variations. The calculations are greatly simplified by considering only two-dimensional ice sheets with profiles that would be appropriate if ice obeyed the flow law of a perfectly plastic solid. The solar radiation variations seem to be large enough to account for ice ages.

The Milankovitch theory of the ice ages[1,2] is based on the long term variation in the solar radiation received at presumed critical northern latitudes during certain seasons of the year. This variation is produced by changes in the magnitude of the eccentricity of the Earth's elliptical orbit around the Sun, the precession of the Earth's axis, and by changes in the value of the tilt of the Earth's axis. The eccentricity varies between the limits of 0 and 0.06, with an average period of 93,000 yr; the angle of tilt of the Earth's axis varies between 22.1° and 24.5° with an average period of 41,000 yr; and the average, precessional period is 21,000 yr (ref. 1). Ice ages are assumed to occur when the total solar radiation for the half year that contains spring and summer at certain northern latitudes is at a deep minimum value. Interglacial periods are assumed to occur when the solar radiation has a high maximum value.

Figure 1 shows the variation, ΔQ, over the past 300,000 yr and the next 80,000 yr of the solar radiation, Q, averaged over the high radiation half of the year at 50°N (ref. 1). Today the value of Q, measured in langleys d^{-1} (1 langley (ly) = 41.85 kJ m^{-2}), at the latitudes of 60°N, 50°N, and 40°N is 787, 847, and 892 respectively for the high radiation half of the year[1]. Thus the variation ΔQ that is shown in Fig. 1, which is between the limits of $+50$ ly d^{-1} and -35 ly d^{-1}, is the same as that produced by shifting the land mass upon which an ice sheet may be resting southwards by up to 9.5° latitude (or $\sim$ 1,000 km) and northwards by up to 6.7° (or $\sim$ 750 km).

No attempt has been made so far to apply the theories of the mechanics of ice age ice sheets[3] or of the rates of growth and reduction of ice sheets[4] to determine whether the Milankovitch solar radiation variations are indeed large enough to produce the very large changes in the dimensions of ice age ice sheets. The half width L of these ice sheets varies with time between the limits of about $0 < L < 1{,}000$ km. Barry, Andrews, and Mahaffy[5] have attempted to calculate how fast a continental ice sheet nucleated in eastern Canada might form, but they made no comparison with the Milankovitch theory. Calder[6] calculated fluctuations of the volume of ice age ice sheets but did so with no consideration at all of glacier mechanics. He simply assumed that the rate of increase or decrease of the ice volume was proportional to the Milankovitch variation in radiation.

An attempt is made here to see if the Milankovitch solar radiation variations are sufficient to produce large variations in the size of ice age ice sheets.

The model

To make things simple I will consider a two-dimensional ice sheet that rests on a land surface that was flat before the ice sheet formed on it. Figure 2 shows the ice sheet in profile. The lower ice surface is not flat because of isostatic depression of the land surface. The northern edge of the ice sheet, at the border of the Arctic Ocean, is situated at $x = -L$ and the southern edge is at $x = L$. The total width of the ice sheet is therefore $2L$. The elevation of the upper ice surface above the original position of the land surface is $h(x)$ and the depression of the lower ice surface is $h'(x)$. When isostatic conditions prevail and the density of rock is taken to be three times that of ice, $h'(x) = \frac{1}{2}h(x)$. The total thickness of the ice is equal to $(3/2)h(x)$.

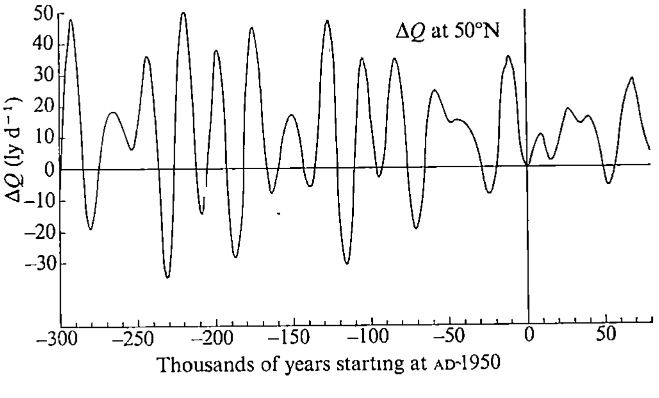
Let the ice sheet profile be approximated by that determined with the flow law of a perfectly plastic solid. The profile of an actively flowing ice sheet is given by the equation

$$h(x) = h(-x) = [\lambda(L-|x|)]^{1/2} \qquad (1)$$

Here $\lambda = 4\tau/3\rho g$, where τ is the yield stress which is equal to the basal shear stress ($\sim$ (0.5–1)$\times 10^5$ Pa)(1 Pa = 10^{-5} bar), ρ is the density of ice, and g is the gravitational acceleration. The value of the constant λ is $\sim$ 7–14 m.

To remain in existence the ice sheet must be nourished by snowfall. Let $h_s(x)$ represent the snowline elevation. At elevations on the ice sheet $h(x) > h_s(x)$ there is, over the year, a net accumulation of ice and at elevations $< h_s(x)$ there is a net

Fig. 1 Milankovitch radiation variation[1].



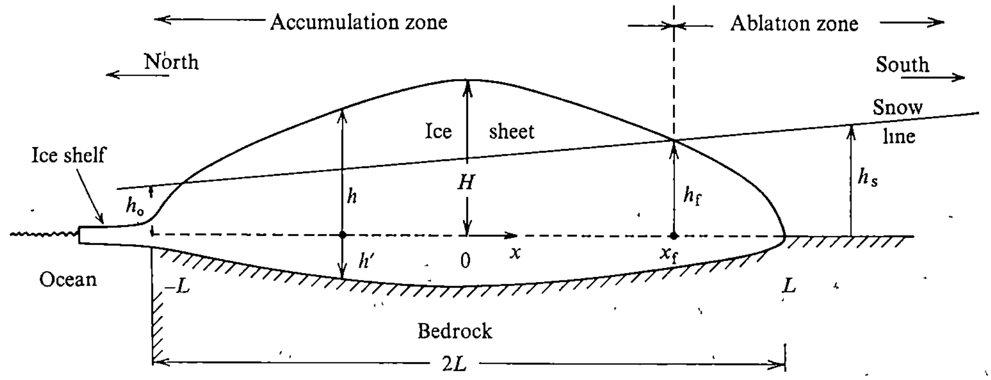


Fig. 2 Cross section of ice age ice sheet.

ablation of ice. Assume that the snowline elevation above the original land surface can be approximated by a simple linear relationship

$$h_s(x) = h_0 + s(x+L) \tag{2}$$

where s is the slope of the snowline and h_0 is the snowline elevation at the northern edge of the ice sheet. The snowline to be used in any calculation is the one that would be found by placing successively larger ice sheets on the land surface and observing on these ice sheets the elevation $h(x_f)$ at the firn line position x_f that separates the accumulation zone from the ablation zone (see Fig. 2). This snowline, which exists in the presence of an ice sheet, will be lower than the one that exists now.

Equilibrium ice sheet

All the ice accumulated on the northern half of the ice sheet will flow out in ice shelves into the ocean as ice today flows out of the Antarctic Ice Sheet. In the southern half of the ice sheet the ice gained in the accumulation zone eventually must be lost in the ablation zone. The average accumulation rate $\langle a \rangle$ over the whole southern half of the ice sheet is equal to

$$\langle a \rangle = [a x_f - a'(L - x_f)]/L \tag{3}$$

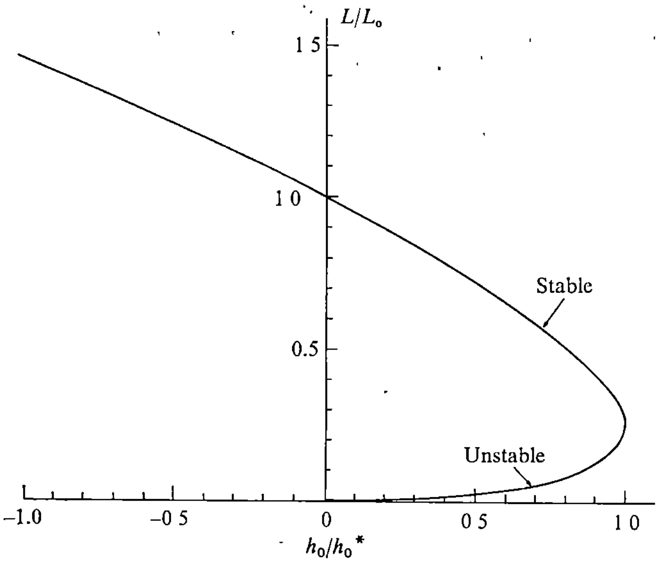
where a is the average accumulation rate within the accumulation zone and a' the average ablation rate in the ablation zone. Both a and a' are positive quantities.

Obviously an ice sheet is in equilibrium only if $\langle a \rangle = 0$. The half width L of an equilibrium ice sheet is found by setting $\langle a \rangle = 0$ in equation (3) and then combining that equation with equations (1) and (2). The result is

$$(L/L_0)^{1/2} = \tfrac{1}{2}[1 \pm (1 - h_0/h_0^*)^{1/2}] \tag{4}$$

where $L_0 = \lambda(1+a'/a)/s^2(1+2a'/a^2)$ and $h_0^* = \lambda/4s(1+2a'/a)$. Figure 3 shows a plot of L/L_0 against h_0/h_0^*. Obviously no equilibrium ice sheet can exist if $h_0 > h_0^*$. The plus sign in equation (4) gives the half width L of a stable equilibrium ice sheet and the minus sign the half width L of an unstable equilibrium ice sheet. If $h_0 < 0$, only the solution of the stable equilibrium ice sheet is physically meaningful. A stable equilibrium ice sheet over time approaches its equilibrium size if its dimensions are perturbed. An unstable equilibrium ice sheet either shrinks until it disappears or grows until it reaches the stable equilibrium size if its dimensions are perturbed. The change in size of a non-equilibrium ice sheet is a consequence of the fact that $\langle a \rangle \neq 0$.

Fig. 3 Normalised plot of equilibrium ice sheet size against normalised snowline elevation at northern edge.



It should be noted that the half width L of the equilibrium ice sheet is independent of the actual values of a and a'. It only depends on the ratio a'/a. This result is not valid if a power-law creep equation is used to determine the ice sheet profile. The resulting dependence of L on a and a' is, however, relatively weak[3].

The magnitude of terms L_0 and h_0^* should be noted. For the not unreasonable values $a'/a = 2.75$, $s = 10^{-3}$, and $\lambda = 14$ m one finds $L_0 = 1{,}245$ km and $h_0^* = 0.54$ km. Now suppose h_0 were to fluctuate in value between limits > 0.54 km and < 0 km because of Milankovitch variations in radiation. The value of the stable equilibrium half width L of the ice sheet would alternate between 0 km and a limit $> 1{,}245$ km.

Time variation of ice sheet size

The variation in time, t, of the volume, V, of the southern half of the ice sheet is simply

$$\mathrm{d}V/\mathrm{d}t = a x_f - a'(L - x_f) \tag{5}$$

For an active ice sheet $V = (\lambda L^3)^{1/2}$ and the rate of change $\mathrm{d}L/\mathrm{d}t$ is given by

$$\begin{aligned}\mathrm{d}L/\mathrm{d}t = (2a/3\lambda^{1/2}L^{1/2})\{L - [(1+a'/a)\lambda/4s^2] \times \\ \times [-1 + (1 + 4s[h_0 + 2sL]/\lambda)^{1/2}]^2\}\end{aligned} \tag{6}$$

This equation is found by combining the preceding equations. Since for an active ice sheet $h(x) = h(-x)$ the northern half of the ice sheet changes its size at the same rate as does the southern half.

Equation (6) applies only if the ice sheet is actively flowing, that is, the basal shear stress is equal to the yield stress. Now it could happen that the snowline is raised so that the whole ice sheet is in an ablation zone. In this situation the removal of ice reduces the basal shear stress to below the yield stress and ice no longer flows. The ice sheet is stagnant. The rate of wastage of the ice sheet can be quite rapid in this situation[4]. The rate of

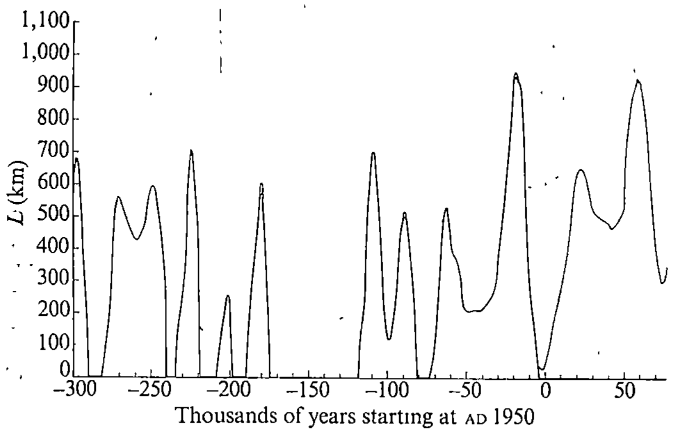


Fig. 4 Half width, L, of ice sheet as a function of time calculated with $\lambda = 14$ m, $\Delta Q_0 = 10$ ly d^{-1}, $s = 0.001$, $\alpha = 0.021$ km ly^{-1} d, $a = 1.2$ m yr^{-1}, $a'/a = 2.75$ (thick line) and 2.745 (thin line).

change dL/dt whenever $h_s(0) > h(0)$ will be approximated by the equation

$$dL/dt = -2a'(L/\lambda)^{1/2} \tag{7}$$

This rate of shrinkage is three times faster than that found by assuming that the ice sheet is active.

A growing ice sheet can also be stagnant. Suppose that the snowline is suddenly lowered and h_0 has a negative value. If $-h_0/s > 2L$, snow will accumulate on the ground ahead of the ice sheet, or an ice sheet will nucleate if $L = 0$. In this situation it will be assumed that either a is large enough or the term $-h_0/s$ is sufficiently small that no serious error is introduced by setting $L = -h_0/2s$ and $h(x)$ the value given by equation (1).

Connection with the Milankovitch radiation variation

We saw earlier that the Milankovitch variation in the solar radiation ΔQ is similar to that produced by shifting the land surface north and south by distances ~ 1,000 km. If the snowline were fixed in space but the land surface were shifted north and south by such distances the effect would be the same as keeping the land surface fixed and moving the snowline elevation up and down. In other words the value of h_0 would be given by the equation

$$h_0 = \alpha(\Delta Q + \Delta Q_0) \tag{8}$$

where ΔQ_0 is a constant and

$$\alpha = s/(dQ/dx) \simeq (21 \text{ km ly}^{-1}\text{d}) \times s.$$

We assume that in this naive way the solar radiation variations can be related to changes in the elevation of the snowline.

The Milankovitch radiation variations undoubtedly cause changes in the value of a, a', the ratio a'/a and possibly in the slope s. Only the change in size of the ice sheet produced by changes of the snowline elevation given by equation (8) will, however, be considered because there seems to be no good way of estimating how the other quantities are altered by the variations of the radiation.

I have calculated the variation of L using equations (6), (7) and (8) and the Vernekar tables[1]. The Vernekar tables list the value of ΔQ at 1,000-yr intervals over the past 2 Myr and for the next 120,000 yr. The computer calculations were made incrementally by calculating $\delta L/\delta t$ where δt was taken as 1,000 yr. The values of ΔQ chosen were for 50°N. The value of L 2 Myr ago was set equal to zero. (For Fig. 6 at 1 Myr ago.)

Figure 4 shows two plots of L over the past 300,000 yr and for the next 80,000 yr for $s = 10^{-3}$, $\lambda = 14$ m, and $a = 1.2$ m yr^{-1}. Two values were chosen for a': $2.75a$ and $2.745a$. The value of ΔQ_0 was taken to be 10 ly d^{-1}, which gives $h_0 = 0.2$ km at the present time. The value of h_0 over the past 300,000 yr varies between the limits of 1.3 km and −0.5 km. Figure 5 shows the same plot, for $a' = 2.745a$, carried back to 2 Myr and superimposed on the Milankovitch curve.

I believe that Figs 4 and 5 demonstrate that the Milankovitch radiation variations are potent enough to be the prime cause of ice ages, although these plots by no means prove that the Milankovitch ice age theory is correct. The magnitude of the highest peaks, ~ 1,000 km, is of the right order of magnitude. The position and relative magnitudes of the peaks and troughs over the past 130,000 yr correlate well with sea-level fluctuations over the same period (see Fig. 7 of ref. 7). The main criticism that can be directed at Figs 4 and 5 is the use of a rather large, but not impossibly large, accumulation rate as well as ablation rate. At the present time the precipitation in north-eastern Canada is about half this level.

If a much smaller ratio a'/a is used the value of h_0^* becomes so large that once an ice sheet is formed it never disappears.

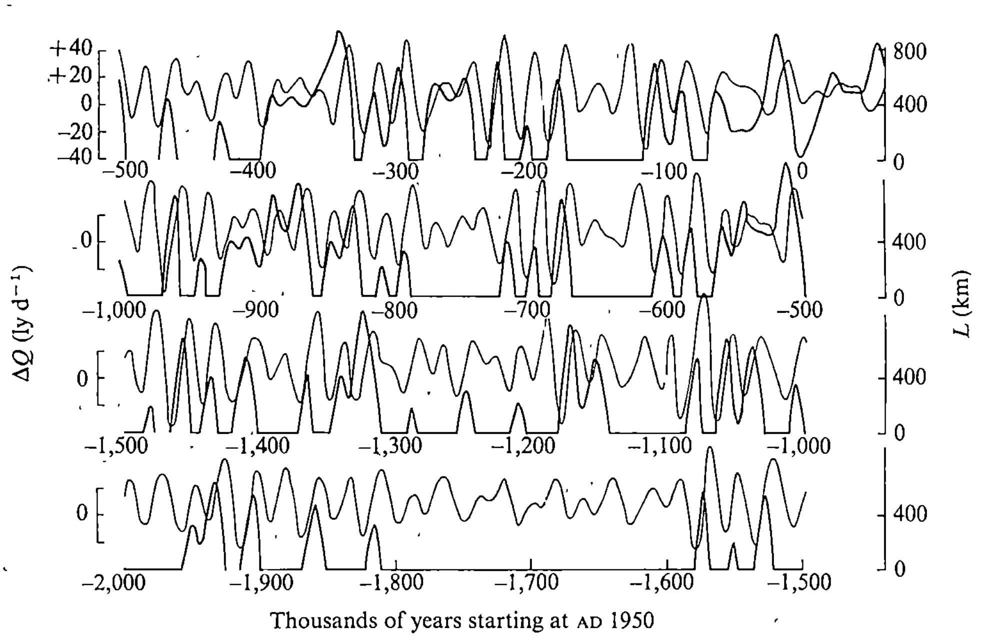

Fig. 5 Same plot as Fig. 4 for the case $a'/a = 2.745$ but for a longer time period. Also shown is the radiation variation.

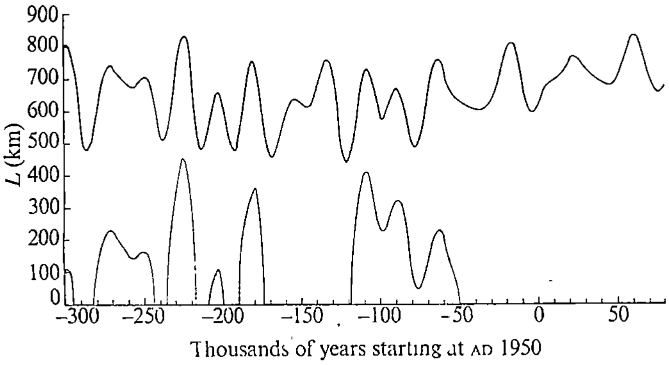

Fig. 6 Same plot as Fig. 4 but with $\lambda = 14$ m, $\Delta Q_0 = 10$ ly d^{-1}, $\alpha = 0.02625$, $a = 0.3$ m yr^{-1}, and $a'/a = 2.2$ (thick line) and 2.4 (thin line).

If a much larger ratio is used the ice sheet never grows to a large size. If smaller values of a as well as a' are chosen, the peak size of the ice sheet is reduced. Figure 6 shows an example of reduced peak size. This figure also illustrates a case of non-disappearance of an ice sheet. The use of $a = 0.6$ m yr^{-1} can produce peaks $\sim L = 700$ km.

The smaller value of a produces smaller peaks in L, not because the equilibrium size of the ice sheet is small, which it may not be, but because the rate of build up of the ice sheet is smaller. The ice sheet does not approach a large equilibrium size before the value of ΔQ changes and causes the ice sheet to waste away.

Figure 4 also demonstrates the hazard of using a Milankovitch curve to predict future ice ages as well as to determine when past ice ages must have occurred. According to Fig. 4 and data not plotted, depending on whether $a'/a = 2.750$ or $a'/a = 2.745$, there will be no ice age for the next 120,000 yr or one actually is starting to build up right now. (Note that the value of L for the thin line curve at $t = 0$ is $\sim L$ of existing ice caps in the Arctic.) By assuming different values of the constant ΔQ_0 new peaks can be made to appear in the plots or old peaks can be made to disappear.

Conclusion

I believe that it has been demonstrated that the solar radiation variations that are the basis of the Milankovitch theory are large enough to have produced ice ages. To make the large ice age ice sheets that are known to have occurred, however, it is necessary that high accumulation and ablation rates existed at least on the southern half of the ice sheets—rates that are substantially higher than occur today in Greenland and Antarctica. These calculations demonstrate the rather unusual position the northern land masses must have for it to be possible for ice ages to come and go over the past 1–2 Myr. If the northern land masses were all shifted southwards by $\sim$ 500 km it would be equivalent to increasing ΔQ by $\sim$ 25 ly d^{-1}. Suppose all other factors remained constant (precipitation is not changed, for example, in spite of the altered water circulation into and out of the Arctic Ocean). After such an increase in ΔQ it would be very difficult to give predictions for ice ages with large ice sheets using our model while at the same time requiring the model to predict alternating ice ages and interglacials with the land masses in their present position. Similarly if the land masses were shifted northwards by $\sim$ 500 km it would be difficult to make the model predict anything other than a perpetual ice age.

Thermal radiation produced by the expansion of the Universe

Leonard Parker

Department of Physics, University of Wisconsin-Milwaukee, Milwaukee, Wisconsin 53201

I show here that the expansion of the Universe can create particles with a black-body distribution. I give a simple model in which the creation of particles in an initially empty spacetime leads at very early times to a Friedmann expansion dominated by hot relativistic particles (probably including gravitons) having a black-body spectrum, even before classical thermalising processes have had a chance to act. If the particle creation occurs near the Planck time, the entropy produced is consistent, in order of magnitude, with that required by the Einstein equations. The conditions in which one achieves consistency with the observed 3K black-body radiation are also discussed.

THE model we discuss in detail here assumes a Robertson–Walker (isotropic) space time which expands from a possibly singular state characterised by the universal constants G, $\hbar$, and c. The metric is treated classically, whereas the matter and radiation are quantised. The equations of the quantised particle fields are the simplest (minimally coupled) generalisations of the special relativistic free-field equations. We assume that other interactions have a negligible effect on the particle creation process near the singularity, compared with gravity. No particles are present initially. Near the singularity, the particle field equations for spins other than 0 and 2 are conformally invariant (the masses can be neglected because of the high energies involved), so that they lead to no particle creation in the isotropic model[1–3]. Mesons obeying the minimally coupled spin-0 field equation will, however, be created in abundance near the singularity. We show that these mesons have the remarkable property that they are created with a black-body spectrum, and hence will be in thermal equilibrium *ab initio*, even in regions of space time which are not causally connected[4]. The same can be said of gravitons obeying the linearised Einstein equations given by Grishchuk[3], since each component $h_i{}^k$ obeys our equation (2) when the τ-time defined below is used. Entropy is generated because the particles are created in pairs, and correlations between members of a pair are unobservable on account of subsequent interactions and decays. Although these results do not make use of the Einstein equation which implies that the density at t_p is of the order of the Planck density, they are consistent with it[5,6], and further provide a mechanism for producing the necessary entropy. It should be noted that in the model considered here, one starts with very simple initial conditions (empty Minkowski space) and obtains a black-body spectrum at a very early time, independent of classical thermalising mechanisms. (Our results are not necessarily inconsistent with a 'bouncing' model, as in refs 6 or 7, if appropriate boundary conditions are imposed at the minimum of $a(t)$.)

Any mechanism consistent with the Einstein equations which yields uniform black-body radiation before t_e, the time at which the matter and radiation densities become equal, will lead to an expression for the present black-body temperature which depends on t_e raised to the one-sixth power. We interpret this expression as giving the present temperature to be approximately equal to the redshifted temperature of the initially created particles.

To obtain the present matter density, and thus t_e, from this model, one could use a matter–antimatter separation mechanism (possibilities are reviewed in ref. 19), or an interaction which did not conserve baryon number. One could also introduce the excess baryon number in the initial state, without significantly affecting the temperature. We make no attempt here to predict the entropy per baryon.

In anisotropic expansions with similar boundary conditions on the minimally coupled scalar field, we find that the particles are created with a direction dependent distribution resembling Doppler shifted radiation in an anisotropically expanding thermal cavity with perfectly smooth reflecting walls and no dust. As in the latter case, one would expect interactions to bring out a true black-body spectrum, while, as suggested by Zeldovich, the expansion itself was isotropised through the gravitational interaction of the created matter. Our results should be similar to those of ref. 8, the main modification being in the initial particle distribution. A special case of such a distribution was found by Berger[9] in the degenerate Kasner universe. We, however, view our present boundary conditions, incorporating $\hbar$, c and G, as corresponding to a physical process occurring only when the curvature is sufficiently large, and not near a pseudo-singularity, as in the degenerate Kasner.

From a fundamental viewpoint, the thermal production of particles may point towards a generalisation of the association of entropy and temperature with black-hole space times[10,11] to cosmological space times, or to singularities themselves. In that connection, the cosmological thermal emission may have a role analogous to the thermal emission by black holes discovered by Hawking[12].

The spectrum and probability distribution of the particles created by the isotropically expanding universe have been given before[1,2], but the detailed form of the coefficients $|\beta/\alpha|$ involved, and the connection with black-body radiation, is given here for the first time. More details, together with a treatment of the anisotropically expanding model, will be published elsewhere.

Isotropic model

For simplicity, we consider the spatially flat Robertson–Walker metric

$$ds^2 = dt^2 - a^2(t)\sum \delta_{ij} dx^i \, dx^j$$

The presence of spatial curvature will not significantly alter the result. As noted earlier, there is significant particle creation only by the minimally coupled spin-0 (and spin-2) field equation $\nabla_\mu \nabla^\mu \varphi = 0$, where ∇_μ denotes the covariant derivative. (We use units with $\hbar = c = 1$.) The mass can be neglected because the energy of the created particles which contribute to the present black-body spectrum is very large compared with elementary particle rest masses. Canonically quantising the field in the usual way, we write

$$\varphi(\mathbf{x},t) = (2\pi)^{-3/2} \int d^3k [A_{\mathbf{k}} e^{i\mathbf{k}\cdot\mathbf{x}} \psi_k(t) + \text{H.C.}] \qquad (1)$$

where $k = |\mathbf{k}|$, and the $A_{\mathbf{k}}$, $A_{\mathbf{k}}{}^\dagger$ obey the usual commutation relationships. For simplicity, we are considering the neutral field. In ref. 1 we showed that charged particles are also created (in particle–antiparticle pairs) with the same probability distribution. The functions $\psi_k(t)$ satisfy

$$d^2\psi_k/d\tau^2 + a^4 k^2 \psi_k = 0 \qquad (2)$$

with

$$\tau = \int^t a^{-3}(t')dt'$$

The Wronskian condition is $\psi_k(d\psi_k{}^*/d\tau) - \psi_k{}^* (d\psi_k/d\tau) = i$.

Boundary conditions

We assume that for t large with respect to t_p, the expansion parameter $a(t)$ is given by the general relativistic solution for a universe dominated by relativistic particles and radiation, namely $a(t) = Ct^{\frac{1}{2}}$, where C is a constant which does not enter our final results. As t approaches t_p, we let $a(t)$ join smoothly to a constant value a_1 given, approximately, by $a_1 \simeq Ct_p{}^{\frac{1}{2}}$. In terms of τ time, the approach of a towards a_1 will be greatly stretched out and very gradual, since as $t \rightarrow t_p$ (and a becomes small) τ approaches very large negative values. The results will be independent of the detailed behaviour of $a(t)$ near the 'singularity', but will depend on its being characterised by G, $\hbar$, and c. We regard the smooth joining of $a(t)$ to a constant a_1 as the simplest means of constructing unambiguous initial conditions incorporating the Planck dimensions, and not necessarily as a true representation of the universe 'before' the expansion began (just as 'turning on' an interaction between particles does not imply it was ever absent in nature).

As an initial condition we suppose that for large negative τ

$$\psi_k \Big|_{\tau \rightarrow -\infty} = (2ka_1{}^2)^{-1/2} \exp(-ika_1{}^2\tau)$$

so that the $A_{\mathbf{k}}$ are the usual special relativistic annihilation operators corresponding to physical particles in the initial Minkowski space ($a = a_1$). (The quantity k/a is the magnitude of the momentum.) We assume that no particles are present initially, $A_{\mathbf{k}} \, |0\rangle = 0$ for all $\mathbf{k}$, where $|0\rangle$ is the state of the system (Heisenberg picture). After $a(t)$ has settled down to the form $Ct^{\frac{1}{2}}$ there will be essentially no particle production resulting from the expansion, because, as we showed in ref. 2, or as can be directly verified from equation (2), the WKB expressions for ψ_k are exact solutions for that particular form of $a(t)$.

Fundamental approximation and solution

The key characteristics of $a(t)$ are that, viewed as a function of τ, the quantity a^4 in equation (2) gradually approaches a constant value $a_1{}^4$ for large negative τ and grows smoothly to a value large with respect to $a_1{}^4$. It is furthermore mathematically convenient (but does not affect the result, since the particle creation is negligible when a is large) to let a^4 approach a constant value $a_2{}^4$ for large positive τ, so that one has a final Minkowski space in which to unambiguously determine the results. Then, following a method which has been used in treating the reflection of radio waves and quantum mechanical reflection from a potential barrier in the regime where the WKB approximation would yield no reflection[13,14], we approximate a^4 in equation (2) by

$$a^4 \simeq a_1{}^4 + \mathrm{e}\zeta [(a_2{}^4 - a_1{}^4)(\mathrm{e}\zeta + 1) + b] (\mathrm{e}\zeta + 1)^{-2} \qquad (3)$$

where $\zeta = \tau s^{-1}$, s is a constant giving the range in τ time over which the transition from a_1 to a_2 takes place, and b is a positive constant. Our final result will be independent of b and a_2. One easily sees that for the present problem $s \simeq a_1{}^{-3} t_p$ (for example, in an expansion with $a \propto t^{\frac{1}{2}}$ starting at t_p, the τ interval for a^4

R387

to grow from a_1^4 to $16a_1^4$ is $\Delta\tau = a_1^{-3} t_p$, whereas the τ interval for a to grow to infinity is $2a_1^{-3} t_p$).

For large τ, we have

$$\psi_k\Big|_{\tau\to\infty} = (2ka_2^2)^{-1/2}[\alpha_k \exp(-ika_2^2\tau) + \beta_k \exp(ika_2^2\tau)]$$

where α_k and β_k are complex constants. The Wronskian condition requires that $|\alpha_k|^2 - |\beta_k|^2 = 1$. The annihilation operators $a_{\mathbf{k}}$ for particles at late times are given by $a_{\mathbf{k}} = \alpha_k A_{\mathbf{k}} + \beta_k^* A_{-\mathbf{k}}^\dagger$. The exact solution of equation (2) with a^4 given by equation (3) is discussed in refs 13 and 14, where it is shown that

$$\left|\frac{\beta_k}{\alpha_k}\right|^2 = \frac{\sin^2\pi d + \sinh^2[\pi sk(a_1^2 - a_2^2)]}{\sin^2\pi d + \sinh^2[\pi sk(a_1^2 + a_2^2)]} \tag{4}$$

where d is a real number involving the constant b. For any k significant for the highly red-shifted radiation observed in the present universe, the quantity ska_2^2 is very large compared to unity (for example, if $a_2 \simeq C t_2^{\frac{1}{2}}$ with $t_2 \simeq 10^{-28}$ s, then $ska_2^2 \gg 1$ for all k contributing to present frequencies > 1 Hz). Therefore, to an excellent approximation

$$|\beta_k/\alpha_k|^2 = \exp(-4\pi ska_1^2) \tag{5}$$

This result is independent of b and a_2 in equation (3), and depends mainly on the gradual and smooth joining to a_1 which takes place at very early times. These considerations, together with general results[15,16] about the behaviour of $|\beta_k/\alpha_k|$, suggest that an expression of the form of equation (5) holds whenever the approach of $a(\tau)$ to a_1 is sufficiently smooth. (We are not yet sure whether the exponential approach of $a^4(\tau)$ to a_1^4 as $\tau \to -\infty$ is essential; it may only be necessary that a^4 and all its derivatives be continuous and that $a_2 \gg a_1$.) The result in equation (5) is certainly independent of the (reasonable) behaviour of a when it becomes large with respect to a_1. It should hold for the actual expansion (equation (3) was introduced for mathematical convenience) by the time $|\beta_k/\alpha_k|$ ceases to change significantly (certainly no later than 10^{-20} s, and probably much closer to t_p).

Energy distribution of created particles

We have shown[1,2] that production takes place in particle pairs, and have given the probability distribution of the created particles. From equation (51) of ref. 2, we conclude that the probability of observing n pairs, where one particle is in mode **k** and the other (antiparticle) in mode -**k**, is

$$P_n(\mathbf{k}) = |\beta_k/\alpha_k|^{2n}|\alpha_k|^{-2}$$

Equation (52) of ref. 2, on the other hand, gives (in the discrete representation) the average number of particles in mode **k** in a coexpanding volume element as $\langle N_{\mathbf{k}}\rangle = |\beta_k|^2$. The correlations between particle and antiparticle of a pair are effectively destroyed by decay processes and other interactions. In this way entropy is generated by the particle creation process, and the particles (or antiparticles) alone are described by a density matrix or mixed state with the above probability distribution. Using equation (5) and $|\alpha_k|^2 - |\beta_k|^2 = 1$ in the expressions for $P_n(\mathbf{k})$ and $\langle N_k\rangle$, one readily finds that

$$P_n(\mathbf{k}) = \exp(-n\mu k)[1 - \exp(-\mu k)] \tag{6}$$

and

$$\langle N_k\rangle = [\exp(\mu k) - 1]^{-1} \tag{7}$$

where $\mu = 4\pi sa_1^2 \simeq 4\pi a_1^{-1} t_p$. This is black-body radiation with a temperature at time t given by

$$T(t) \simeq (4\pi k_B)^{-1} t_p^{-1}(a_1/a(t)) \tag{8}$$

where k_B is Boltzmann's constant, and the time dependence arises because the wavelength at time t is $(k/a(t))^{-1}$. This unexpected result permits us to associate uniform temperature and entropy with the initially created particles, even in causally unconnected regions.

This result is consistent with the Einstein equation

$$a^{-1}\mathrm{d}^2a/\mathrm{d}t^2 = -8\pi G\rho/3 \tag{9}$$

where we have used $p = \rho/3$. Putting $\rho = (\eta_a/2)\sigma T^4$, where η_a is the number of different kinds of particles produced initially (counting each state with different quantum numbers (spin and charge) separately), and $\sigma = \pi^2 k_B^4/15$ is the Stefan–Boltzmann constant, one finds from equation (9) with $a(t) = Ct^{1/2}$ and $a_1 = Ct_p^{1/2}$

$$T(t) = 2(45\pi)^{1/4}\eta_a^{-1/4}(4\pi k_B)^{-1} t_p^{-1}(a_1/a(t)) \tag{10}$$

at early times (t_p occurs here because $G = t_p^2$). This is the same as equation (8) to within a factor of $\sim 7\eta_a^{-1/4}$. This agreement is satisfactory, considering that equation (8) was obtained using rough, order of magnitude estimates, and that a dependence on η_a could appear in the expressions for s and a_1 if the early behaviour of a depends on quantum effects involving the number of fundamental fields (we are using a model with a limited number of such fields).

Consistency with observations

Finally, it is worth noting that the temperature in equation (10) (or equation (8)) can be connected to the present temperature. As the Universe expands, the original particles decay, interact, and annihilate, leaving η_b components of the present black-body radiation (counting each spin and charge state separately, and each fermion as 7/8 of a boson in forming the entropy below). Assuming that the entropy

$$S = \eta(t)(2/3)\sigma T^3(t) a^3(t)$$

in a comoving volume, $a^3(t)$, is conserved, one finds[17-19]

$$T_b \simeq (\eta(t)/\eta_b)^{1/3}\, T(t)\,(a(t)/a_b) \tag{11}$$

where subscript b refers to the present time, and $\eta(t)$ is the number of elementary constituents at time t. Assuming that the factors involving η are ~1, since powers like 1/3 or 1/4 are involved, one finds from equations (10) and (11) that (in c.g.s. units)

$$T_b \simeq 7(4\pi k_B)^{-1}\,\hbar t_p^{-1}\,(a_1/a_b) \tag{12}$$

Denoting the earliest time at which the universe becomes matter-dominated by t_e (so that $a \propto t^{2/3}$ for $t > t_e$), one finds $a_1/a_b \simeq (3/2)^{2/3}(t_p/t_H)^{1/2}(t_e/t_H)^{1/6}$, where $t_H = a(\mathrm{d}a/\mathrm{d}t)_b^{-1} = 3t_b/2$ is the Hubble time[20], $t_H = 5.8 \times 10^{17}$ s. This gives

$$T_b \simeq (t_e/t_H)^{1/6}\,(30\ \mathrm{K}) \tag{13}$$

which equals 3 K when $t_e \simeq 2 \times 10^4$ yr, but is within a factor of 10 of 3 K for all possible values of t_e > 8 d. To determine t_e in our model one would have to predict the baryon number density (or entropy per baryon).

Any theory consistent with Einstein's equations and leading to black-body radiation before t_e will yield equation (12) and (13), since equation (10) (with η_a replaced by $\eta(t)$) follows from the Einstein equation (9) at a time t shortly before t_e. The particle creation process occurring near t_p leads naturally, however, to the interpretation of T_b in equation (12) as the redshifted temperature of the particles created with a temperature of the order of the Planck temperature ($k_B^{-1}\hbar t_p \simeq 10^{32}$ K). In that sense, a model of the present kind (or possibly starting with an anisotropic expansion) seems to point towards a plausible explanation of the origin of the density and entropy of the black-body radiation. Our model is perhaps the simplest of those involving particle creation near the Planck time.

Abundance and membrane association of elongation factor Tu in *E. coli*

Gary R. Jacobson & Jürg P. Rosenbusch

Biozentrum, University of Basel, Klingelbergstrasse, 70, 4056 Basel, Switzerland

Elongation factor Tu is present in a fourfold excess over the amount seemingly involved in protein synthesis. It is identical to a major protein which we have found associated with the plasma membrane. The possibility of a specific role in that location is considered.

In a recent study of envelope-associated proteins, we have described the properties of a homogeneous polypeptide of which there are 70,000 molecules per cell (5% of the total cellular protein)[1]. Several observations, particularly its release from the cell by osmotic shock but not by the conversion of cells to spheroplasts, suggested that this polypeptide is probably associated with the inner face of the plasma membrane *in vivo*. We could not identify the function of this protein with a molecular weight of 44,000. We now report that it is identical with elongation factor Tu (EF Tu) which through cyclic association and dissociation with another factor, EF Ts (ref. 2), is an essential component in protein synthesis (for review, see ref. 3). We demonstrate that EF Tu is present in substantial excess over EF Ts, and therefore over ribosomes[4]. This abundance and the suggested association with the membrane led us to ask what function EF Tu could exert in that location.

EF Tu and the protein released from the cell by osmotic shock are identical

The relationship between the protein we have described[1] and EF Tu is shown by the following observations. Electrophoresis in sodium dodecyl sulphate (SDS) of authentic EF Tu, purified according to Miller and Weissbach[5], and of the major protein released by osmotic shock yielded identical mobilities for the two proteins (not shown). The amino acid compositions of the two proteins are very similar[1,5], and well within the variations usually observed between laboratories. The amino terminal ends of both proteins are blocked (ref. 1 and Wade *et al.*, unpublished, cited in ref. 6). We have confirmed this for authentic EF Tu by the method of Weiner *et al.*[7]. No aminoacyl residue modified in its α-amino group was found after dansylation and hydrolysis of the undegraded polypeptide and after each of three successive cycles of Edman degradation. The spectra of the membrane-associated protein before and after extensive dialysis[1] are identical with the corresponding spectra of EF Tu (ref. 5). The functional identity of the released protein with EF Tu was tested by measuring both GDP binding[5] and stimulation of the *in vitro* polymerisation of phenylalanine[8] in osmotic shock supernatants. The results (Table 1) show that the activities characteristic for EF Tu vary according to the amount of the major protein released into the shock fluid. To determine whether the two proteins are in fact the same, we prepared tryptic peptide maps of the purified membrane-associated protein and of EF Tu. The fingerprints obtained were very similar (Fig. 1*a* and *b*). Double-diffusion tests of antibodies specific to one

Table 1 Correlation between release of EF Tu and of the major membrane-associated protein released from *E. coli* by osmotic shock*

Shock medium	Phe polymerisation† (pmol polymerised ml^{-1})	GDP binding‡ (nmol bound ml^{-1})	Amount of membrane-associated polypeptide§ (% total cell protein)
Water			
Supernatant¶	74 (80%)‖	4.0 (51%)‖	3.6 (74%)‖
Pellet¶	18 (20%)	3.8 (49%)	1.3 (26%)
0.5 mM $MgCl_2$			
Supernatant¶	21 (25%)	0.76 (9%)	0.4 (8%)
Pellet¶	62 (75%)	7.4 (91%)	4.4 (92%)

*Cells (*E. coli* K12, derivative BHB 960) were grown to a density of 6×10^{8} ml^{-1} and osmotically shocked using the procedure of Nossal and Heppel[9] with H_2O or 0.5 mM $MgCl_2$ as shock medium. Equal aliquots of the supernatants and pellets, taken up in the original volume and sonicated, were assayed as indicated below. Total activities were determined for all experiments by assaying sonicated, but unfractionated, cells. These were always within 10% of the sum of osmotic shock supernatants and pellets. Cell lysis was monitored by measuring β-galactosidase activity[10] in supernatants and pellets, and was always $\leqslant$20% with water and $\leqslant$10% with $MgCl_2$.

†Phenylalanine polymerisation[8] using ^{14}C-phenylalanine tRNA and washed ribosomes as described previously[11] was measured for 5-min periods at 30 °C. EF Ts (purified as described in Fig. 2) and EFG free of EF Tu activity (an S-100 of *E. coli* BE was treated at 55 °C for 15 min, ref. 12) were added in excess. Purified EF Tu polymerised 0.80 nmol Phe per 5 min per mg protein in these conditions, close to the value of 0.88 calculated from ref. 8.

‡Binding was measured with 5 μM ^{14}C-GDP (Amersham) by filtering the reaction mixture after 15 min at 25 °C through nitrocellulose filters (Sartorius, 0.45-μM pore size).

§Estimated by quantification of the peaks representing the membrane-associated polypeptide in densitometric scans of stained polyacrylamide slab gels, as described previously[13].

¶Protein concentrations were: 0.6 and 8.5 mg ml^{-1} in the shock fluid and the residue, respectively, in the presence of magnesium ions, and 2.5 and 7.5 mg ml^{-1} in its absence.

‖Figures in parentheses indicate the percentage of the total activity or of the total membrane-associated protein, respectively.

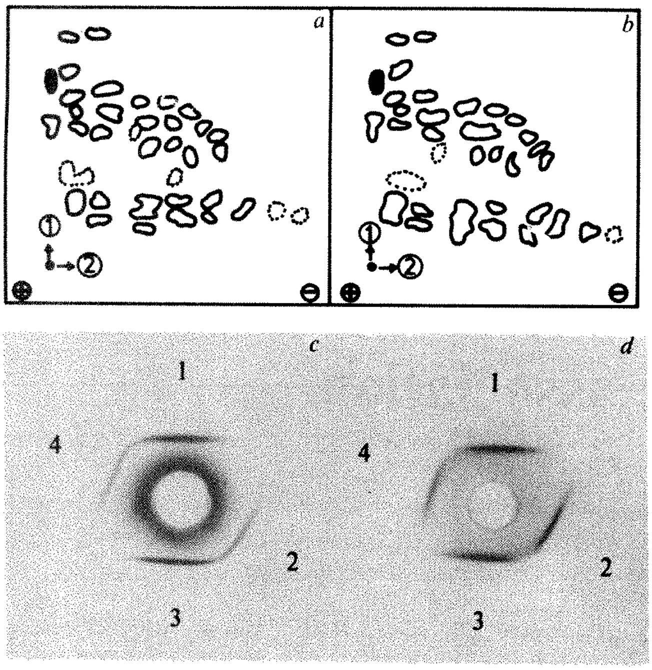

Fig. 1 Comparison of osmotically released polypeptide and EF Tu. The two peptide maps represent the patterns after ninhydrin staining (*a*) and an autoradiogram (*b*) of the same chromatogram. *E. coli* BE cells were grown as described previously[13] and labelled with a ^{14}C-amino acid mixture at a cell density of 10^8 ml^{-1}. Cells were collected at 6×10^8 ml^{-1}, washed and subjected to osmotic shock. Concentrated shock fluid was subjected to gel electrophoresis in SDS. The major band (44,000) was eluted, and the concentration of detergent lowered by dialysis overnight at low ionic strength. A tenfold excess of pure, unlabelled EF Tu (ref. 5) was then added. The mixture was digested with TPCK-treated trypsin and subjected first to chromatography (dimension 1) and then electrophoresis (dimension 2) on silica gel thin layer plates (Kodak 6061) with solvent systems as described previously[14]. The minor differences of the maps, if they are not artefactual, may be due to the fact that there are two genes coding for EF Tu (ref. 15), and that the two gene products have been enriched to different extents in the preparation procedures for EF Tu and the protein released by osmotic shock. From the number of spots (34) and the sum of arginyl and lysyl residues in the two proteins[1,5], the possibility of a mixture of two non-identical proteins can be excluded. The Ouchterlony double-diffusion test shows the reaction of antibodies specific for the osmotically released protein with EF Tu (wells 1 and 3) and an osmotic shock supernatant (wells 2 and 4), (*c*); and the reaction of antibodies specific for EF Tu with the same samples in the outer wells (*d*).

protein yielded precipitin lines continuous with that of the other (Fig. 1*c* and *d*).

Excess of EF Tu over EF Ts in the cell

It has been reported that EFs are synthesised in stoichiometric amounts with ribosomes, and that their quantities in the cell vary with the growth rate of bacteria[4]. In the case of EF T, this observation should be restricted to EF Ts, since the antibodies, used for the quantifying of the factors, were specific for EF Ts, and did not interact with EF Tu (ref. 16). In view of the fact that there are 70,000 molecules of EF Tu per cell[1], and that we found little variation in the different growth conditions used, we re-determined the proportions of EF Tu and EF Ts in the cell.

First, we determined the amounts of the two factors in the three fractions from an ammonium sulphate precipitate, which represented an intermediate step in the purification procedure[17]. Table 2 shows that almost two-thirds of the total EF Tu was contained in fraction C. Activity determined in that fraction by the phenylalanine polymerisation assay, however, is considerably less[17], an observation explained by the virtual absence of EF Ts in that fraction. This result was confirmed by gel filtration chromatographic analyses of extracts A, B and C (Fig. 2). EF Tu is therefore presumably underestimated when an activity assay designed to detect the function of the complexed factor (EF T) is used, but is revealed by gel electrophoretic analyses of the various fractions.

From the data in Table 2 and Fig. 2, it can be estimated that approximately 80% of total EF Tu occurs in the non-complexed form. The ratio of EF Tu to EF Ts would be 5 : 1. To confirm this result, we used an independent method. The estimation of the amount of protein in the bands on SDS gels with mobilities corresponding to EF Tu and EF Ts (Fig. 3) yielded a ratio of 3.6±0.4 (Table 3). Although we have already determined that the band corresponding to EF Tu consists of at least 90% of this factor[1], we do not know whether other proteins comigrate in the position of EF Ts; a value of 3.2 is therefore a minimal estimate. It is reasonable to conclude, therefore, that the two factors occur in a ratio of approximately 4 : 1, independent of the growth conditions used.

Table 2 Quantification of EF Tu from stained gels and EF Ts by activity assays in ammonium sulphate fractions*

Extract (% $(NH_4)_2SO_4$)	EF Tu† (% total)	EF Ts‡ (% total)
A (27.8% eluate)	7.8	25
B (24% eluate)	28.2	75
C (19.6% eluate)	64.0§	None detected

*A crude extract of 100 g *E. coli* BE was carried through the ammonium sulphate fractionation step[17] in the purification of EF T and EF G. No EF Tu or EF T was found in the residue after the 19.6% extraction.

†Estimated from densitometric scans of stained SDS–polyacrylamide gels[13] of the three fractions.

‡Measured by exchange[18] of ^{14}C-GDP with purified EF Tu–GDP.

§Our finding of large quantities of non-complexed EF Tu is in agreement with results of Arai *et al.*[19], who purified EF T, EF Tu and EF Ts by ion exchange chromatography in the presence or absence of GDP. They also found a large fraction of free EF Tu in cell extracts.

Also presented in Table 3 are the growth rates obtained for *Escherichia coli* BE cells in different media and the corresponding values for the proportion of total cell protein represented by EF Tu. Cells growing very slowly synthesised about half the amount of EF Tu as those grown in richer media. Since the ratio of the two factors remains the same (3.4), there is approximately half as much EF Ts in cells grown on the poorer medium. Although with the strain used in this study, minimal media containing glucose still yielded short generation times (Table 3), our results are consistent with the previously published variation of the level of EF T with growth rate[4]. The synthesis of EF Tu thus seems to be coordinated with that of ribosomes and EF Ts, but at a much higher level.

Possible functions for EF Tu at the membrane

Since EF T occurs in an approximately equimolar ratio to ribosomes[4], and this complex is known to contain EF Tu and EF Ts in stoichiometric amounts, 20–30% of the total complement of EF Tu seems to be involved in protein synthesis at any given time. The simplest explanation for the 'excess' of EF would be that the binding of aminoacyl-transfer RNA to the acceptor site in the ribosomes is inefficient, and that a large excess of the protein responsible for this process is required for effective protein synthesis. Alternatively, or in addition, EF Tu may be responsible for other functions in the cell. It is well known that when *E. coli* is infected with RNA phages such as Qβ, this protein becomes a subunit in the enzyme responsible for RNA replication[23]. It may further exert a control function in transcription, in conjunction with the effector

Table 3 Stoichiometry of EF Tu and EF Ts

Method	Medium	Generation time (h)	EF Tu (% total protein)*	EF Tu/EF Ts (mol per mol)†
Quantification by Sephadex G-100 chromatography of ammonium sulphate fractions	M9 (minimal)	0.87	—	5.1‡
Stain quantification from gels	M9 (minimal)§	0.87	5.1	3.3
	M9+1% casamino acids mixture (Difco)	0.48	4.6	4.0
	Tryptone broth (Difco)	0.48	4.5	3.8
	Acetate (1%)	4.5	2.7	3.4
Determination of radioactivity¶ eluted from gels	M9 (minimal)	0.87	—	3.5

*Calculated from densitometric scans of SDS gels (see Fig. 3).

†Bands corresponding to EF Tu and EF Ts were cut from stained gels. The stain was eluted with dimethylsulphoxide and the A_{600} of eluates measured (for details, see ref. 22). Each value is the average of at least four determinations.

‡Calculated from data given in Table 2 and the integrated peaks in Fig. 2.

§Cells were grown to densities of 6×10^8 ml^{-1} in the media indicated, collected, dissolved directly in SDS, and subjected to gel electrophoresis in the detergent.

¶Cultures in M9 medium were labelled at cell densities of 10^8 ml^{-1} with 0.25 μCi-ml^{-1} U-^{14}C-amino acid mixture (Amersham). At densities of 6×10^8 ml^{-1}, they were collected and electrophoresed as described above. Bands were dissolved in 30% H_2O_2 at 60 °C overnight and counted as described previously[22]. The value given is the average of four determinations.

guanosine tetraphosphate[24,25]. It is unclear, however, whether these functions could account for the large amount of EF Tu, and for the high ratio of EF Tu to Ts.

We have shown[1] that 50–80% of EF Tu is released from the cell by osmotic shock (data corrected for cell lysis). We have suggested that the released fraction is associated with the inner face of the plasma membrane, suggesting that a specific function is carried out in that location. Membrane association of many processes involved in macromolecular synthesis in bacteria has been suggested[26], and some of these, in turn, may be related to EF Tu (see above).

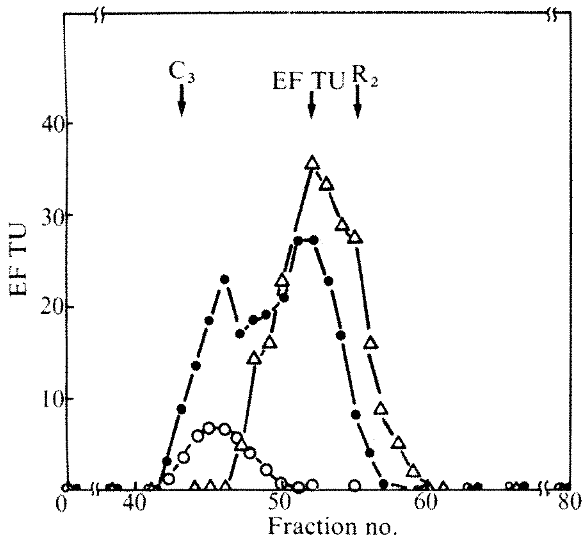

Fig. 2 Gel filtration chromatographic analyses of the three extracts from an ammonium sulphate fractionation (see Table 2). Eluates A, B and C were dialysed into 50 mM Tris-HCl, 10 mM $MgCl_2$, 1 mM dithiothreitol and 0.1 M KCl, and chromatographed on a calibrated Sephadex G-100 column in the same buffer. All fractions containing material absorbing at 280 nm were subjected to electrophoretic analysis in SDS. The gels were stained with Coomassie blue. From the patterns obtained, the amount of EF Tu was quantified by integration of the peaks obtained by scanning densitometry (for details, see ref. 13). Units on the ordinate are arbitrary. ○, Extract A; ●, extract B; △, extract C. C_3 and R_2 indicate the catalytic and regulatory subunits of aspartate transcarbamylase, with molecular weights of 100,000 and 34,000, respectively[20]. All EF Tu in extract A and 40% of it in extract B chromatographed with a distribution coefficient (K_d) corresponding to a molecular weight of 80,000. The remaining 60% in extract B and all in extract C had a K_d identical to that of purified EF Tu (arrow). The composition of the complexed form of EF Tu (80,000) was determined by rechromatography of the pooled fractions (43–46) in the presence of 1 mM GDP in the column buffer. In these conditions, EF Tu eluted quantitatively at the position indicated. The only other polypeptide to shift position in this second dimension was one with a mass of 32,000. The protein is present in approximately stoichiometric amounts with EF Tu. Its identity to EF Ts was confirmed by separating the two proteins which change their elution position in the presence of GDP using ion exchange chromatography[5]. Determination[19] of EF Ts activity yielded 2.7×10^5 U mg^{-1} in the peak containing the 32,000 polypeptide. We have used this two-dimensional procedure to purify EF Ts.

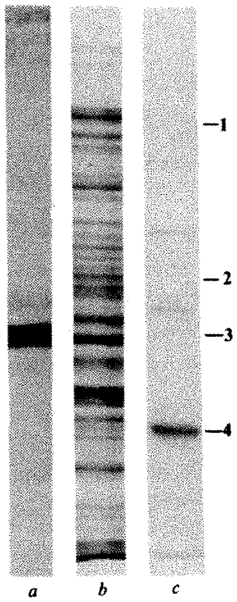

Fig. 3 Gel electrophoretic patterns in SDS of pure EF Tu (*a*), whole cells directly dissolved in sample buffer[21] (*b*) and EF Ts, purified according to the two-dimensional procedure given in Fig. 2 (*c*). Scanning densitometry indicated that the main band of gel *c* constitutes 80% of the total protein applied. Determination of EF Ts activity in the GDP-exchange reaction[18] yielded a value 20% smaller than that found for the pure factor[18]. It can therefore be concluded that the major band is pure EF Ts. The growth conditions and the method for estimating the intensities of the bands corresponding to EF Tu and EF Ts in gel *b* are described in Table 3. Molecular weight standards indicated were: 1, phosphorylase *a* (95,000); 2, catalase (58,000); 3, ovalbumin (45,000); 4, C chain of aspartate transcarbamylase (33,000).

The protein may, of course, also be functional in the synthesis of proteins on membrane-bound ribosomes[27]. The evidence for a compartmentalisation of ribosomes in bacterial cells, however, is not fully convincing; according to recent estimates[28], it would account for only one-third of the ribosomes and therefore for less than 10% of EF Tu.

One observation may be of value in determining whether EF Tu provides a link between several cellular processes in the membrane, or whether it may have other functions there. Morrissey *et al.*[29] have reported that the ribosomal proteins L7/12, known to interact with EF Tu on ribosomes (see ref. 30 for references), also occur in the non-ribosomal fraction of the cell in amounts similar[29] to those of 'excess' EF Tu. It would be interesting, therefore, to determine whether these proteins also interact with EF Tu at other cell sites, and if so, whether the function of the complex may be more amenable to analysis than that of either component alone.

Yet another possibility is suggested by our observation that the membrane-associated fraction of EF Tu is partially precipitated by calcium, and quantitatively by vinblastine ions. We have considered the possibility that these and related observations may indicate a structural role for this protein at the bacterial membrane[1]. Finally, Jaskunas *et al.*[15] have reported that at least two genes code for EF Tu. Although the products of these genes seem to be very similar[15], this observation opens up the possibility of a genetic approach to investigating the functions of EF Tu in the cell.

Supported by the Swiss National Foundation for Scientific Research. G.R.J. is a postdoctoral fellow of EMBO and a recipient of a supplementary grant of the American Swiss Foundation for Scientific Exchange. We thank Dr T. Bickle for discussions.

Note added in proof: Furano[31] has also reported a high excess of EF Tu over ribosomes. According to his interpretation, the excess of the elongation factor allows binding of the entire aminoacyl-tRNA pool in the cell.

Production of yeast alcohol dehydrogenase isoenzymes by selection

Christopher Wills

Department of Biology, University of California, San Diego, La Jolla, California 92093

Mutants of yeast alcohol dehydrogenase have been produced that protect the cell against the poisonous aldehyde acrolein by increasing the NADH–NAD ratio. The altered properties include changes both in binding constants and in cooperativity. Such mutants may be useful in exploring the nature of adaptation at the molecular level.

WORK in the field of molecular 'evolution' in the laboratory has so far been directed towards the selection of mutant enzymes with a high affinity towards unusual substrates[1–3]. I report here on a specific selective system that produces mutants of yeast alcohol dehydrogenase (ADH, EC 1.1.1.1) in which other functions have been altered. The kinetic alterations are sufficiently marked to justify the view that these mutant gene products are new isoenzymes. There is at this locus a potential for great diversity in adaptational response, which may cast some light on the fine details of the evolutionary process.

The selection procedure has been set forth in detail elsewhere[4], and relies on two observations. The first is that petite yeasts (those unable to respire aerobically) synthesise only one of the two isoenzymes found in the cytoplasm. This form, ADH-I (ref. 4), is normally constitutive under laboratory conditions, has a high K_m (Michaelis–Menten constant) for ethanol, and seems to be chiefly responsible for the production of ethanol from acetaldehyde in cells grown anaerobically[5]. The other cytoplasmic isoenzyme, ADH-II, is coded by an unlinked locus[6], has a much lower K_m for ethanol, and has a relative mobility at *p*H 8.6, with ADH-I taken as 100%, of 110%. ADH-II is found only in aerobically grown grande yeast. A primary function of ADH-II is to convert ethanol accumulated during anaerobic growth to acetaldehyde, with the concomitant reduction of NAD. ADH-I can also accomplish this task, though presumably less efficiently; grande mutants (those able to respire aerobically) free of ADH-II have been produced in several laboratories[4,7] and grow satisfactorily on ethanol as the sole carbon source.

The second observation on which the selection scheme is based is that grande cells lacking cytoplasmic ADH activity cannot be induced to become petite. They die instead, indicating

Table 1 Concentrations of NADH and NAD in crude extracts of wild-type and mutant cells

Strain	μg NADH per mg protein	μg NAD per mg protein	NADH–NAD ratio
XW517-2D (ADH-I)	0.035	0.568	0.062
XW520-2A (ADH-II)	0.152	0.913	0.166
XW517-S-AA-1	0.296	0.781	0.379
XW517-S-AA-5	0.196	1.038	0.188

Protein was determined by the method of Lowry *et al.*[15]. Cells were grown in YEPD+2% EtOH. Average of two determinations.

that ADH activity is essential for the survival of petite cells. Reinforcing this conclusion, it has proved impossible to select petite strains to yield cells lacking ADH activity. It seems likely that glycolysis cannot proceed without the presence of ADH to catalyse the production of ethanol as a final step, although grande cells lacking ADH activity can survive by means of oxidative phosphorylation alone.

Cells lacking ADH activity and ADHs with altered kinetics were selected by an elaboration of the scheme originally used by Megnet[8]. Allyl alcohol, CH_2CHCH_2OH, is readily oxidised by yeast ADH to acrolein (acrylaldehyde). Acrolein is highly toxic to yeast cells, although the mechanism of its toxicity is in doubt[9]. Selection on a specific sequence of media with increasing allyl alcohol concentrations resulted in the production of grande yeast strains lacking both cytoplasmic and mitochondrial ADHs (ref. 3). These strains could survive in allyl alcohol concentrations up to 1.6 M, compared with 1 mM for the wild type, which was a strong indication that allyl alcohol by itself was harmless to the cell. These were the strains that could not be converted to petite, demonstrating that petites lacking ADH activity could not survive.

Table 2 Acetaldehyde and ethanol in medium of cells grown anaerobically to log phase

Strain	Acetaldehyde (mM)	Ethanol (M)
XW517-2D (ADH-I)	1.2	0.096
S-AA-1	4.84	0.05
S-AA-5	1.2	0.12

Concentrations were measured enzymatically with commercial ADH (Sigma). Cells were grown in a New Brunswick Bio-Flo chemostat, model C-20, modified by the addition of a closed-circuit pump passing medium and cells from the instrument through a photocell monitor connected by a feedback loop to the chemostat's medium pump. The concentration of cells in the chemostat chamber could therefore be kept constant and at log phase. All strains were grown to a level of 3×10^7 cells ml^{-1}, without aeration, since introduction of air rapidly removes acetaldehyde from the medium by evaporation. Thus, the pattern of excretion of the strain producing ADH-II could not be checked accurately since in anaerobic conditions it also produced only ADH-I.

The rationale for producing mutant enzymes with altered kinetics was therefore straightforward. Selection was carried out on petite strains grown on complete medium with increasing amounts of allyl alcohol. The assumption was that petite strains could not simply escape by mutating to ADH$^-$, since they required ADH activity. Only those cells containing an enzyme that could somehow discriminate between the normal substrate, ethanol, and the potentially dangerous one, allyl alcohol, would survive. It was assumed initially that the mutant enzymes thus obtained would show marked kinetic differences between the two substrates, but this was not the case and in retrospect it can be seen to be unlikely because of the similarity between the two molecules. Instead, the mutant enzymes changed the intracellular environment so as to shift the equilibrium between allyl alcohol and acrolein in the direction of the harmless alcohol. This was done by shifting the NADH–NAD ratio.

Selection and physiological effect of mutant enzymes

The mutants were selected from a wild-type cytoplasmic petite, XW517-2D, *a* mating type, by plating on YEPD (1% yeast extract, 2% Bacto-peptone, 2% dextrose, all w/v, all from Difco) to which 2% ethanol (v/v) and allyl alcohol had been added. Spontaneous mutants were selected that grew well at 20, 40 and 60 mM allyl alcohol, cloned at each stage and plated at the next highest concentration. Vigorous clones from the highest concentration of allyl alcohol were used.

Two independently derived mutants were chosen to be investigated thoroughly, XW517-S-AA-1 and XW517-S-AA-5. Each migrated electrophoretically more slowly than the ADH-I from XW517-2D at *p*H 8.6, 93% and 85% respectively. Both were shown to be allelic to ADH-I and not to ADH-II by the appropriate crosses. When tetrads from crosses of the mutant to the wild type were made petite, resistance to 60 mM allyl alcohol segregated 2:2 in the tetrads and was invariably found to be associated with the mutant enzyme.

A further useful spontaneous mutation occurred in one of the segregants from a cross involving S-AA-1. This strain, which was thought to be petite, was found to produce ADH-II, and grew very slowly on glycerol as the sole carbon source. The strain had been converted to petite using ethidium bromide[10], but the conversion was incomplete. This enabled us to investigate the physiological properties of ADH-II on a genetic background that was almost petite, and to compare them with the properties of the mutant enzymes and of ADH-I. This strain was designated XW520-2A.

Kinetic studies of the mutant enzymes showed that there was no pronounced change in their affinity for allyl alcohol. Indeed, the kinetic changes were slight and did not involve a large increase in K_m for this substrate. This was puzzling until we realised that neither allyl alcohol nor acrolein is likely to be metabolised further by the cell. In vivo therefore, they should eventually reach some approximation of their apparent thermodynamic equilibrium

$$K'_{eq} = \frac{[\text{Acrolein}]\,[\text{NADH}]}{[\text{Allyl alcohol}]\,[\text{NAD}]}$$

complicated by the possibility that substrate and product may be acted on differentially by active transport systems.

This equilibrium could not be determined precisely because of side reactions entered into by the acrolein, but it approximates that for ethanol and acetaldehyde (1.15×10^{-4} at *p*H 7.0 (ref. 11)). Thus, an increase in the NADH–NAD ratio in the cell will produce a corresponding decrease in the acrolein–allyl alcohol ratio. Since the last compound is harmless, this should protect the cell. I therefore investigated changes in the ratio and changes in the physiology of the mutant cells.

Oxidised and reduced NAD were measured in whole-cell preparations by the Everse *et al.*[12] modification of the method of Greengard *et al.*[13] (Table 1). All three mutants, including the near-petite that produces primarily ADH-II, showed a pronounced increase of reduced relative to oxidised NAD.

Such a shift should be associated with a shift in the relative amounts of ethanol and acetaldehyde excreted by the mutant cells. The amounts of acetaldehyde and ethanol in the medium, measured enzymatically, are shown in Table 2. The two mutants show different patterns, with S-AA-5 producing more ethanol and S-AA-1 producing more acetaldehyde than the wild type. As we shall show, this was consistent with the kinetic changes.

If a shift in the NADH–NAD balance in the cell is responsible for resistance, growing the cells in conditions designed to restore the original balance should abolish the resistance, and that is what happened. It had been observed that acetaldehyde is lost rapidly from aerated but not from non-aerated cultures. The reaction should therefore be driven in the direction of ethanol in a closed system, but not in one in which the acetaldehyde is given a chance to escape. Further, addition of ethanol, even in anaerobic conditions, should drive the reaction back towards acetaldehyde, restoring the resistance. S-AA-1 and the ADH-II mutant showed the expected pattern, growing well under aeration in the presence of 20 mM allyl alcohol, but not without aeration. The resistance was readily restored in anaerobic cultures by the addition of ethanol. S-AA-5, however, showed some growth at 20 mM allyl alcohol without aeration. Ethanol also increased the resistance of this mutant. It thus seemed likely that the resistance of these mutants could be directly traceable to an enzyme-mediated shift in the proportions of reduced to oxidised pyridine nucleotides. Detailed kinetic studies bore this out, and cast some light both on the mechanisms of the wild-type isoenzymes and on how these mechanisms have been altered in the mutants.

Kinetics of wild-type and mutant enzymes

Table 3 gives the kinetic measurements of the ethanol–acetaldehyde reaction for the two wild-type isoenzymes and the two mutants. Allyl alcohol kinetics were also obtained, and showed differences analogous to those for ethanol, but it has so far proved impossible to obtain consistent acrolein kinetics because of side reactions. A number of kinetic parameters were obtained, as detailed in the legend to Table 3. K_A and K_B are the K_ms for substrate at infinite cofactor concentration and cofactor at infinite substrate concentration respectively; K_{AB} is the K_m for substrate and cofactor.

The kinetic data can be considered on two levels: the differences in K_m and V_{max}, and the differences in cooperativity. Both are approximately consistent with the physiological data and with the working hypothesis concerning the nature of allyl alcohol resistance.

ADH-I and ADH-II do not differ greatly in the V_f/V_b ratio, but show markedly different K_ms. ADH-II exhibits an extreme reduction in both K_{ABf} and K_{ABb}, which is what one would expect with an isoenzyme primarily concerned with oxidation of ethanol to acetaldehyde. In aerobic conditions, acetaldehyde must swiftly be converted to acetyl CoA, so the very low K_{ABb} does not normally prevent the reaction from proceeding towards acetaldehyde. The almost petite strain XW-520-2A allows accumulation of acetaldehyde and NADH, however, which explains why this strain is resistant to allyl alcohol.

S-AA-1, which excretes four times the usual amount of acetaldehyde and loses its resistance to allyl alcohol in anaerobic conditions, shows a twofold reduction in the velocity of the back reaction coupled with a twofold reduction in the K_{ABb}. S-AA-5, which excretes more ethanol than the wild type, shows a fivefold reduction in both K_{ABf} and K_{ABb}. Although the kinetic alterations in S-AA-1 might themselves be enough to explain the shifts observed in the NADH–NAD ratio and in the pattern of excretion, they do not seem to help in the case of S-AA-5. It is also possible that some of the NADH–NAD shift has been caused by enzyme-mediated *p*H changes, and this is under investigation.

It is possible to obtain a rough estimate of the size and direction of cooperativity in these enzymes by calculating the ratios of K_{AB} to the product of K_A and K_B. The approximate ratios are summarised in Table 4. A ratio greater than one indicates positive cooperativity, with a greater ease of catalysis as the concentration of substrate or cofactor rises. The primary plots show an increasing K_m with decreasing substrate and decreasing cofactor concentration. A ratio less than one, on the other hand, indicates negative cooperativity[14], marked by a decreasing K_m with decreasing substrate or cofactor concentration. The direction of cooperativity observed in the two wild-type isoenzymes, ADH-I and ADH-II, helps to explain their preferred direction. ADH-I shows positive cooperativity for the forward reaction, and thus at low substrate and cofactor concentrations will exhibit a reduced velocity in this direction. ADH-II shows negative cooperativity for this same reaction, and this, coupled with the greatly reduced K_m, must considerably enhance its forward reaction rate at low concentrations.

The cooperativities of the two mutants have been altered in

Table 3 Kinetic constants for the four enzymes

Enzyme	Activity*	V_f/V_b	K_{ABf} (M²)	K_{ABb} (M²)	K'_{eq} (calculated) × 10³
ADH-I	352	0.14	10^{-5}	5.0×10^{-7}	6.8
ADH-II	358	0.215	1.4×10^{-7}	1.1×10^{-9}	9.4
S-AA-1	296	0.35	10^{-5}	2.4×10^{-7}	7.2
S-AA-5	79	0.122	1.8×10^{-6}	1.1×10^{-7}	7.2

Enzyme	K_{EtOH} (M)	K_{NAD} (M)	$K_{\mathrm{EtOH}}\cdot K_{\mathrm{NAD}}$ (M²)	K_{Acet} (M)	K_{NADH} (M)	$K_{\mathrm{Acet}}\cdot K_{\mathrm{NADH}}$ (M²)
ADH-I	2.4×10^{-2}	2.4×10^{-4}	5.8×10^{-6}	3.4×10^{-3}	1.4×10^{-4}	4.7×10^{-7}
ADH-II	2.7×10^{-3}	1.4×10^{-4}	3.8×10^{-7}	4.5×10^{-5}	2.8×10^{-5}	1.3×10^{-9}
S-AA-1	4.2×10^{-2}	3.1×10^{-4}	1.3×10^{-5}	1.1×10^{-3}	1.2×10^{-4}	1.3×10^{-7}
S-AA-5	2.4×10^{-2}	6.0×10^{-5}	1.4×10^{-6}	2.2×10^{-3}	6.0×10^{-5}	1.3×10^{-7}

* Units mg^{-1} purified enzyme, where one unit reduced 1 μM NAD min^{-1} at 25 °C (*p*H 8.8) in the presence of 0.3 M EtOH (ref. 16).

Enzymes were purified by treatment with protamine sulphate, a heat step and ammonium sulphate fractionation. The active fraction was redissolved in 0.01 M KPO_4 (*p*H 7.0) and passed through an affinity column of DEAE–Sephadex conjugated with 8-(6-aminohexyl)-amino-NAD (ref. 17). Elution was with a pulse of NAD, and the enzyme was further purified by passage through a small DE11 column. Purity was checked by thin-layer sodium dodecyl sulphate slab acrylamide electrophoresis. Yield was typically about 80% of the activity in the crude extract All kinetic measurements were made at *p*H 8.8 and 23 °C. NAD and NADH, purchased from Sigma, were dissolved in 0.005 M phosphate buffer, *p*H 6.0 and 8.5 respectively, put on a 2×35-cm DE11 column and eluted with a 0.005–0.2-M gradient of the same buffer. The NAD purification was essentially the same as that of Dalziel[18]; the NADH purification yielded cofactor of excellent purity with an absorbance ratio (A_{260}/A_{340}) of only 2.25. In both purifications, other peaks were observed in the gradient Purified cofactors were kept in the refrigerator in tightly-stoppered bottles and used within a week. No changes in their absorption properties were noted. Actaldehyde was distilled before use and stored at −70 °C. The enzyme was dialysed extensively before use to remove any traces of mercaptoethanol. Kinetics were measured by monitoring the change in absorbance at 240 nm recorded at the maximum sensitivity (0.1 absorbance unit full-scale) of a Gilford 2400S spectrophotometer. Velocity readings were taken for eight different substrate and six different cofactor concentrations, each 2/3 the concentration of the preceding one. The reaction was measured in 3-ml cuvettes, using 0.032 M pyrophosphate buffer. It was found that zinc greatly enhanced the velocity of the back reaction (acetaldehyde to ethanol), while not affecting the forward reaction All back reaction velocities were therefore obtained in the presence of 5×10^{-5} M $ZnCl_2$. Measurements were made in duplicate. It soon became obvious that the enzymes did not exhibit simple Lineweaver–Burk kinetics, though a Lineweaver–Burk assumption was used in the analysis. Kinetic constants were obtained by the method of Florini and Vestling[19]. A program written in BASIC for the Hewlett–Packard 9830 mini-computer was used to fit the eight constant-substrate lines and six constant-cofactor lines by least squares to Lineweaver–Burk plots. Then, secondary plots were derived from the inverses of the Vs calculated from these primary plots to obtain K_A and K_B, the Michaelis–Menten constants for the substrate at infinite cofactor concentration and cofactor at infinite substrate concentration respectively. V_{max} for the reaction was also obtained from these secondary plots. Theoretically, it should be possible to derive K_{AB} (in mol²), the Michaelis–Menten constant for substrate and cofactor, since the intersection of the lines in the primary plot has the coordinates $-K_B/K_{AB}$, $(K_{AB}-K_AK_B)/K_{AB}V_{max}$. A K_{AB} different from the product of K_A and K_B indicates the presence of interactions. The lines on the primary plot never intersected at a single point, however, showing instead a complex pattern of several intersection points The computer was instructed to print out values of K_{AB} derived from the x and y coordinates of each of the 15 constant-cofactor line intersections and the 28 constant-substrate line intersections. The two values of each pair rarely agreed with each other, but when they did, each pair that was in agreement was also found to be close to the same value. This value was taken to be K_{AB}, and could be compared with the product of the values of K_A and K_B derived from the secondary plot This procedure might seem arbitrary, since so much information was discarded, but fortunately a further check existed. Since kinetics for both the forward and the back reaction were available, it was possible to substitute them into the Haldane equation[20] $K'_{eq} = (V_fK_{ABb})/(V_bK_{ABf})$ where V_f and V_b are the maximum velocities of the forward and back reactions respectively, and K_{ABf} and K_{ABb} the Michaelis–Menten constants for the forward and back reactions. As can be seen from the table, the K_{AB}s fit the K'_{eq} derived from equilibrium measurements[11] quite well, the derived value being 7.25×10^{-3} at *p*H 8.8.

different ways. In S-AA-1, positive cooperativity has been introduced into the back reaction, which has the effect of decreasing its relative rate at low concentrations. The net result, when coupled with the K_m and V_{max} changes, will be less ethanol and more acetaldehyde excreted. In S-AA-5, the positive cooperativity of the forward reaction has been reduced or lost, which should make the reaction proceed more readily at low concentrations, yet this mutant is observed to excrete relatively more ethanol than the wild type. This shift in excretion may somehow be linked to the reduced K_ms, but the link between the kinetic changes and the NADH–NAD shift is not as clear as in S-AA-1.

It seems likely from the kinetics that the cooperativity exists between subunits rather than between binding sites within a subunit (or the Florini and Vestling plots would all proceed through a single point), but precise values for the cooperativity await the completion of equilibrium dialysis studies. The situation is complicated by the fact that both substrate and cofactor seem to take part in the cooperativity. An attempt has been made to fit Hill exponents to the data, but a consistent picture has not emerged, presumably because of this complication.

Table 4 Approximate ratios of K_{AB} to $K_A \times K_B$ for the four enzymes

Enzyme	$K_{ABf}/(K_{\mathrm{EtOH}} \cdot K_{\mathrm{NAD}})$	$K_{ABb}/(K_{\mathrm{Acet}} \cdot K_{\mathrm{NADH}})$
ADH-I	2	1
ADH-II	0.5	1
S-AA-1	1	2
S-AA-5	1	1

It is easy to see how such kinetic alterations would lead to a shift in the reaction towards acetaldehyde, provided that there is a very efficient mechanism for removing acetaldehyde from the cell. The precise magnitude of the shift in the NADH–NAD ratio cannot be determined, since any differences between intracellular compartments are lost in our whole-cell preparations.

Future prospects

These two mutants show specific alterations in function that can be traced to a particular selective pressure. It is likely that the present mutants and others like them can be used to probe the mechanism of cooperative interactions in subunit enzymes. The effect of allyl alcohol selection is to alter the kinetics of one isoenzyme towards an approximation of the kinetics of the other. In neither mutant has any improvement been noted in the velocities of the reactions; a 'better enzyme' has not been produced by these (at the most) two or three mutational steps.

Several questions of evolutionary interest can be approached using this system. Among them are: in how many ways can the molecule be altered to give kinetic changes similar to those seen in these two mutants? What fraction of the molecule has the potential to be involved in this particular adaptive change? Is there a high probability of mutational changes occurring in a particular sequence, or are there many possible sequences? And what is the distribution of amino acid substitutions bringing about these changes? One is not limited here, as is the case with the haemoglobins, to examining a sample of mutations heavily biased towards those that change the charge of the molecule: in this system, it seems highly probable that any alteration in the amino acid composition of the ADH is the result of selection and not of chance.

I thank Julia Phelps and Anne Saunders for technical assistance, Chi-Yu Lee for help with the affinity chromatography and Johannes Everse for discussions. This work was supported by a grant from the US Public Health Service.

Infrared profile of Milky Way at 2.4 μm

THE diffuse component of galactic radiation has been observed in various wavelength ranges, but few observations are yet available in the near infrared range. Since the interstellar extinction is rather weak in this wavelength range, one can obtain an overview of the galactic structure, such as the distributions of infrared sources and of absorbing matter from this region of the spectrum. We have therefore attempted a balloon observation of infrared radiation at the wavelength 2.4 μm with a band width 0.1 μm, avoiding intense OH airglow.

The telescope comprised a silicon of 10 cm (F=0.8) and an array of three PbS detectors attached to the focal plane, each of which had a 3°×3° field of view. The whole optical system was cooled by liquid nitrogen to reduce the background thermal radiation and improve the detector sensitivity. The absolute sensitivity was checked in flight by observing α Her which was simultaneously observed at Agematsu Infrared Observatory of Kyoto University. Relative sensitivity was calibrated in flight by means of calibration light.

The Milky Way was raster scanned in the range $23° \leqslant l \leqslant 75°$ $|b| < 20°$. The isophoto of the infrared surface brightness thus obtained is shown in Fig. 1. The galactic plane was found to be as much as 6° wide (f.w.h.m.) nearly independent of longitude. The surface brightness decreases as longitude increases, as shown in Fig. 2. The flux at the galactic equator is 6×10^{-10} W cm^{-2} μm^{-1} at l=23° and decreases to 8×10^{-11} W cm^{-2} μm^{-1} at l=75°. The longitude dependence of the infrared brightness also shows humps in the tangential directions

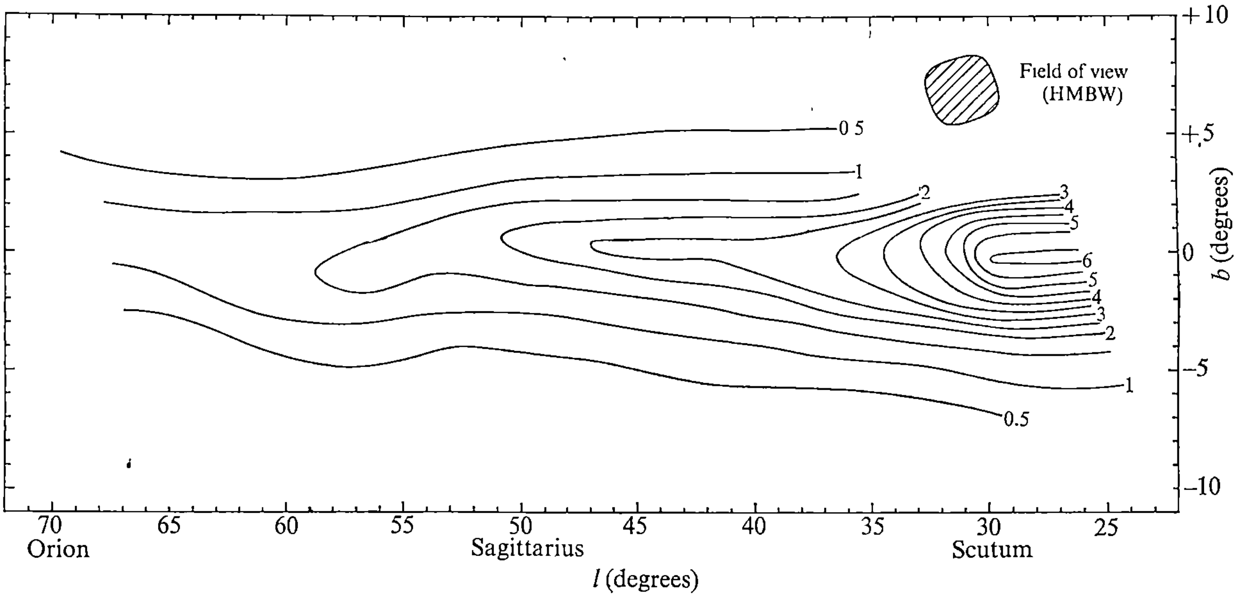

Fig. 1 Isophoto of the 2.4-μm infrared surface brightness The lines are drawn in steps of 0.5×10^{-10} W cm^{-2} sr^{-1} μm^{-1}.

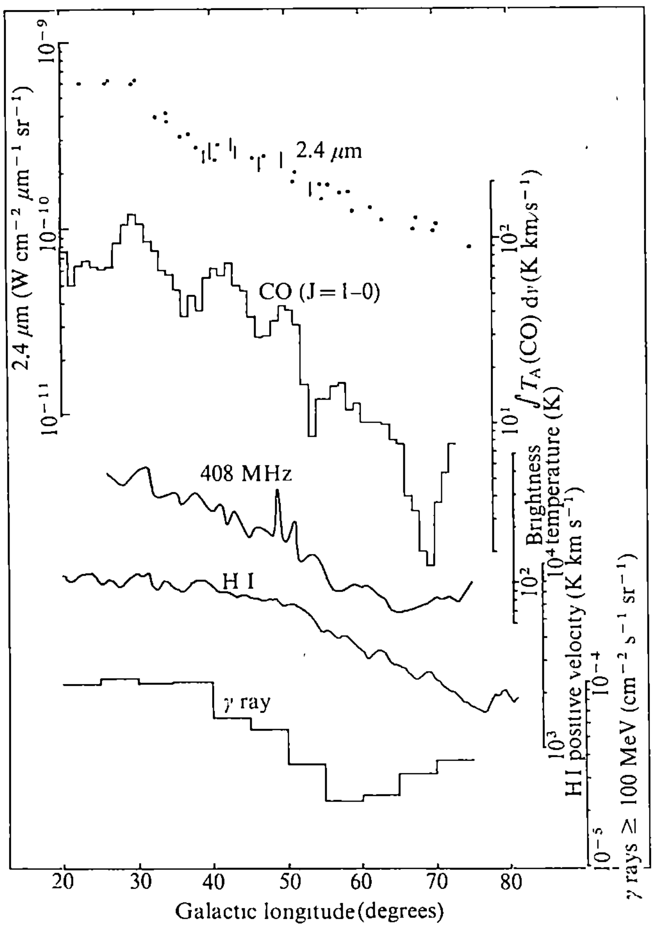
of the spiral arms, $l \simeq 30°$, $50°$. This implies that some fraction of infrared sources are associated with particular objects in the spiral arms.

As a class of such objects, the 2.6-mm line intensity of CO molecules[1] is given in Fig. 2 for comparison. Its longitude distribution shows several peaks at the positions of the infrared humps. Since the CO line intensity represents the surface density of dense molecular clouds, the association of infrared sources with the dense clouds is suggestive. The less steep longitude dependence of the infrared brightness indicates that a considerable fraction of infrared sources is distributed over the Galaxy in a similar manner to normal stars.

Fig. 2 Longitude dependences at the galactic equator of the 2.4-μm intensity (W cm^{-2} sr^{-1} μm^{-1}), the 2.6-mm CO line antenna temperature integrated over velocity (K km s^{-1}), the 408-MHz brightness temperature (K), the 21-cm brightness temperature integrated over positive velocity (K km s^{-1}), and the 100-MeV γ-ray intensity (photons cm^{-2} s^{-1} sr^{-1}).



There may be several other objects which consist of a concentrated component and a diffuse component, the latter showing a distribution similar to general galactic matter. Of those showing longitude dependences similar to the infrared brightness over a considerable longitude range, the intensity of the radio continuum is the most remarkable example. The brightness temperature at 408 MHz (ref. 2) is also shown in Fig. 2. (The brightness temperature at 820 MHz (ref. 3) shows a similar behaviour.) The two spikes seen at ~ $l=50°$ at 408 MHz would have been too sharp to be resolved with our infrared detector. Since the radio continuum is mainly of thermal origin, this correlation indicates an H II region source. In fact, the surface density of H II regions[4] does correlate qualitatively with the infrared brightness.

In contrast to the distribution of H II regions, that of hydrogen atoms shows a much shallower longitude dependence. If, however, only hydrogen atoms with positive velocities are taken into account, the longitude dependence fits exactly with that of the infrared brightness for $l \geq 40°$. The brightness temperature of the 21-cm line integrated over positive velocity[5] is given in Fig. 2. This would suggest that the infrared radiation observed at 2.4 μm is emitted mainly from the region inside the solar circle. A deviation seen for $l < 40°$ may arise partly from the large optical depth (~1 in the low longitude region) so that the column density is not proportional to the brightness temperature.

Finally, comparison is made with the intensity of 100-MeV γ rays[6]. Since the γ rays are produced by collisions of cosmic rays with interstellar matter, their intensity is proportional to the product of densities of cosmic rays and interstellar matter integrated over the line of sight. Thus the distribution is correlated in part with the 21-cm line intensity and also with the density of cosmic ray sources.

It is interesting to see that the longitude dependences observed for the 2.4-μm radiation, the 2.6-mm CO line, H II regions, the 21-cm hydrogen line of positive velocities and the 100-MeV γ rays are, at least in part, correlated with each other. Their interrelationships have been discussed, for example, in connection with the 5-kpc ring, and thus infrared emission provides another means of investigating galactic structure.

Erosion and the rocks of Venus

THE remarkable photographs of the surface of Venus returned by the Venera 9 and 10 spacecraft have revealed the presence, in two different sites, of a variety of rocklike forms, some angular and some smooth. Press reports[1] express surprise at the absence of very efficient erosional mechanisms. It may be useful to point out instead that it is the presence, not the absence, of erosional mechanisms on Venus which is surprising. The degree of erosion of surface rocks on Venus is determined by an equilibrium between the rate of production and the rate of destruction of surface rocks. The principal causes of erosion of terrestrial rocks—running water, diurnal and seasonal temperature changes, particularly in deserts, and aeolian abrasion—are all absent on Venus. The surface temperature of 750 K is above the critical point temperature of water. Ground based radioastronomical measurements, a comparison of the temperatures measured by Venera spacecraft at a variety of solar zenith angles, together with the high heat capacity of the massive Venus atmosphere, all clearly demonstrate that the diurnal temperature differences are a few degrees K at most[2,3]. The obliquity of the rotation axis of Venus is so small that there are effectively no seasons on the planet. The efficiency of aeolian abrasion depends on the velocity to a power $\geqslant 3$; since both theory and observation show the velocities in the lower atmosphere of Venus to be about an order of magnitude less than at comparable regions in the Earth's atmosphere, it follows that sandblasting on Venus is at most 10^{-3} as efficient as on Earth[4].

The problem is to find a suitable source of erosion of surface rocks—a problem somewhat similar to that raised by the radar discovery of large, presumably impact, basins which, when compared with their lunar, martian and mercurian equivalents, are remarkably shallow. Two mechanisms for the erosion of crater ramparts on the surface of Venus can be suggested[4]; I propose that they may also be important for the erosion of the rocks photographed by Venera 9 and 10. The atmosphere of Venus contains hydrochloric acid at a mixing ratio of $\sim 10^{-6}$, hydrofluoric acid at $\sim 10^{-8}$ and sulphuric acid at larger mixing ratios which, however, are as yet undetermined for the lower atmosphere of the planet[5]. Chemical weathering for lengthy periods by such a mixture of strong acids, even in very dilute concentrations, may be quite adequate to erode angular projections of siliceous rocks.

A second possibility arises from the high surface temperature of Venus. Although these temperatures are not sufficiently high to melt silicates, they are high enough to bring many rather common geochemical materials (for example, NaOH, KOH, HgS and KNO_2) near or to their melting points. If the rocks of Venus are comprised of such materials, even in abundances of a few tenths of a percent, the rheological properties of their low melting point components may, over long periods, be adequate to soften the contours of surface rocks. Deformation of the walls of large basins will occur over long periods, even if the lowest melting point of abundant constituents is considerably above 750 K.

With typical terrestrial values of the subsurface temperature gradient, the high surface temperature of Venus implies that the melting points of silicates should be reached a few tens of kilometres subsurface. The 'granitic' values of the uranium–potassium–thorium radioisotope ratios[6], as determined by Venera 8, suggest that a terrestrial value to the subsurface temperature gradient may be a good first approximation. In this case, access of magmatic material from the interior of Venus to its surface should be considerably easier than on Earth and significant fractions of the surface may be frozen lava fields, having reached thermal equilibrium at the low temperature of 750 K. This may provide both a source of rocks too young to have been eroded and a means of filling large craters and impact basins.

Venera 9 and 10 are the first spacecraft to obtain *in situ* photographs of the surface of another planet and photographs which they have obtained open a new field of very high resolution comparative planetology.

Airborne ultraviolet studies of Venus

BECAUSE of the high atmospheric extinction in the ultraviolet at ground level, an airborne platform offers distinct advantage for planetary optical measurements in the wavelength region below 3,500 Å. The joint NASA–ESO Space Shuttle simulation programme (ASSESS) provided an opportunity for conducting such measurements aboard NASA's Convair 990 jet aircraft, at an altitude of ~ 40,000 feet. The following summary of these measurements is a supplement to the published report on the ASSESS experiments[1].

The experimental setup for airborne planetary ultraviolet studies consisted of a two-dimensional gyro-stabilised plane mirror (a heliostat) placed near a quartz side window in the aircraft. Objects outside the aircraft could be viewed at elevations between 10° and 40°. A 14″ diameter Cassegrain telescope was fitted with an image position analyser star tracker which fed electrical signals to the movable secondary mirror in the telescope for stabilisation of rapid changes in image position and also to the heliostat to compensate for slow changes that were not compensated for by the gyros of the heliostat. Once an object was acquired, this system automatically tracked it within the elevation and azimuth ranges through which the heliostat could be driven to look at an object through the aircraft window.

Our primary objective was to observe Venus in the ultraviolet region. The telescope image size diameter was ~ 0.5 mm. A quartz lens magnified this to a 5-mm disk in the slit plane of a 1-m Ebert–Fastie spectrophotometer.

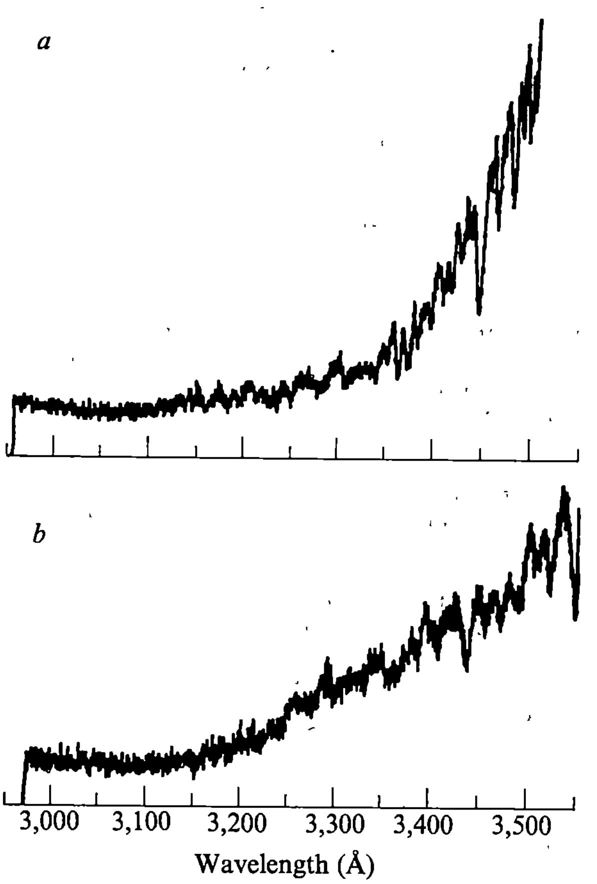

Fig. 1 Solar (*a*) and Venus (*b*) ultraviolet spectra between 2,970 and 3,540 Å at 4 Å resolution.

The primary wavelength region monitored was between 2,950 and 3,350 Å in the third order, with a resolution of ~ 4 Å. A cooled S20 photomultiplier tube fitted with a quartz window, and operating in pulse counting mode, was used as a detector. A mini-computer, a digital multiplexer, a digital tape recorder and an interactive graphic system permitted data organisation for real time analysis and display of the results on a scope and a chart recorder, as well as for magnetic tape recording for subsequent detailed analysis. A D/A converter provided independent records of raw data on both chart and analog magnetic tape recorders. The entire optical and electronic system was adequately automated for single operator control in keeping with the guidelines of the shuttle simulation mission requirements.

Measurements of the solar radiation reflected from Venus were obtained on five flights at elevation angles of 15°–30°. An hour and a half of data were acquired by the experiment operator during the confined portion of the mission and two 0.5-h periods were acquired by the principal investigators later in the programme. Direct solar and lunar spectra were obtained for the same elevation angles and wavelength resolution during two of the flights. Figure 1*a* and *b* illustrates typical solar and Venus spectra. Further analysis requires normalisation of these spectra at one wavelength before obtaining the difference spectrum or ratio spectrum to remove the solar Fraunhofer and terrestrial O_3 absorption features from the Venus spectrum. In a previous set of Venus observations from another expedition using the NASA Convair 990, some absorption features appeared in the wavelength regions of the SO_2 bands. We will analyse our current observations, which are at higher wavelength resolution, to look for conclusive evidence of these bands as well as other features, such as the NH band at 3,357 Å, which might be present.

In addition to these Venus data, we acquired sufficient information to deduce the total O_3 column densities in the Earth's atmosphere. We also monitored the ultraviolet spectra of Jupiter and terrestrial airglow O_2 Herzberg and OH Meinel emissions. In summary, these flights have produced much scientific data which will be helpful to our understanding of the composition of planetary atmospheres. In addition, the evaluation of the simulated shuttle mission should be useful in the planning of scientific missions on board the space lab–shuttle system.

We thank NASA for support.

Glaciations and dense interstellar clouds

McCREA has revived the idea that the Earth's ice ages may have been caused by the interaction of the Sun with dense interstellar clouds[1]. In this theory, originally formulated by Hoyle and Lyttleton[2], the solar luminosity is temporarily increased by the accretion of gas on to the Sun when the Solar System passes through a dense interstellar cloud. The increased insolation is assumed to cause an increase in precipitation and ice accumulation. McCrea suggests that the recurrence and duration of ice epochs can be attributed to the passage of the Solar System through compression lanes in the spiral arms. Relative velocities between the Solar System and the clouds range from 5–20 km s^{-1}, but cloud densities of 10^5–10^7 hydrogen molecules per cm^3 are called for by the model. A study of the character and grain size distribution of texturally mature lunar soils supports this model[3]. Here we examine several consequences of the passage of a dense cloud through the Solar System and find severe problems for this glaciation mechanism.

Since the most recent glaciation ended only $\sim 10^4$ yr ago, we expect to find a dense interstellar cloud at a distance $\sim 1/5$ pc, and in what follows we assume the minimum possible density for the cloud ($\sim 3.3\times10^{-19}$ g cm^{-3}) unless otherwise stated. The duration of the last glaciation was $\gtrsim 7\times10^4$ yr, indicating that the cloud dimensions must be $\gtrsim 1$ pc. Regardless of the relative velocity of the cloud, the solid angle subtended must be nearly 2π steradians, or almost half the sky. Hoyle and Lyttleton acknowledged that their model implied the existence of such a dense nearby cloud, but this could not be ruled out with the observations available at that time (1939).

It is now straightforward to eliminate the possibility of the cloud being atomic or ionised hydrogen. The optical depth in the 21-cm line of atomic hydrogen is $[n/(4\times10^{18}\,T_s)]\Delta X$, where ΔX is the cloud thickness, n is the number density of hydrogen atoms, and T_s is the spin temperature. For a reasonable value of the spin temperature of 100 K, we obtain $\tau_{\mathrm{HI}}\gtrsim 750$. If the cloud is completely ionised, then the optical depth from free–free transitions is

$$9.8\times10^{-21}\,\frac{n^2\Delta X}{\nu^2 T_e^{3/2}}\ln\left[49.5\times10^{-3}\,\frac{T_e^{3/2}}{\nu}\right]$$

where ν is the frequency in GHz, and T_e is the electron temperature[4]. For $T_e\sim10^4$ K and $\nu=1$ GHz, we have $\tau_{\mathrm{HII}}\gtrsim 2{,}000$. Clearly, no significant fraction of the cloud mass can be in the form of atomic or ionised hydrogen.

The usual possibility referred to[1,2] is that the cloud consists

The soft X-ray background has been observed in shaded regions, with upper limits obtained in hatched regions. X-ray observations are not available in the clear areas. Symbols show column densities of H_2, and for those cases in which $N_{H_2} > 10^{19}$ cm^{-2}, the areas of the circles are proportional to the column densities. The column density predicted by the model for approximately half of the sky is illustrated by the large circle.

of molecular hydrogen. Indeed, an H_2 cloud of such density would not require a significant proportion of dust for shielding since it would primarily shield itself against ambient ultraviolet radiation[5]. In addition, the postulated cloud is completely optically thick to X rays with energy $\lesssim 3$ keV (ref. 6). In Fig. 1 we have combined published observations at 0.28 keV of the soft X-ray background[7-9]. At this energy the optical depth of the cloud is $\gtrsim 1{,}300$. Superimposed on these observations we depict column densities of interstellar H_2, derived from satellite observations of H_2 absorption lines in the ultraviolet spectra of selected stars[10,11]. The largest column density reported from the ultraviolet measurements is $N_{H_2} \simeq 4 \times 10^{20}$ cm^{-2}, whereas the model calls for $N_{H_2} \geq 2 \times 10^{22}$ cm^{-2}, with $N_{H_2} \simeq 4 \times 10^{23}$ cm^{-2} being a more typical value. From the lack of extensive absorption of the soft X-ray background, and the lack of sufficient H_2 column densities, we can rule out the existence of such a dense molecular cloud of large angular size.

The observational constraint that the cloud be transparent to visible light implies that for a cloud of solid particles the mean free path for mutual collisions is comparable with, or greater than, the cloud dimensions. Such a cloud cannot be appreciably accreted on to the Sun since mutual collisions are required to destroy the systematic velocity of the cloud material as it sweeps behind the Sun. Thus, the proposed cloud could not consist of dust.

The transparency to visible light also implies that, for micron-sized dust grains, the dust–gas mass ratio $< 10^{-4}$. This is at least 2 orders of magnitude lower than the usual value.

We now consider the dissipation of the orbits of small particles in the Solar System, because of the relative motion between the particles and the cloud. Neglecting the initial velocity of the cloud relative to the Solar System, this force will significantly disrupt the orbits on a timescale:

$$t \simeq l(\rho/\rho_c)(a/GM_\odot)^{1/2}$$

where l is the radius of a particle, ρ is the mass density of a particle, ρ_c is the cloud density, and a is the orbital radius For the zodiacal dust cloud we take $a \simeq 1$ AU, and $l \simeq 1$ µm, and obtain $t \simeq 4$ yr—even centimetre-sized particles would have been removed from the Solar System during the last glaciation. At present, much weaker dissipation mechanisms are operative, and the replenishment of the zodiacal dust cloud requires $\gtrsim 10^5$ yr (ref. 8) as against the $\sim 10^4$ yr since the last glaciation.

The possibility of replenishment by the dense cloud itself cannot be dismissed. Any such consideration must, however, account for the formation of the planar distribution of the zodiacal dust since the last ice age and the remarkable coincidence of the plane with the ecliptic.

We also find that this same dissipative force can remove particles of ~ 1 cm from Saturn's rings during the $\sim 7 \times 10^4$-yr glaciation period. Pollack *et al.*[9] interpret existing observations of the rings to indicate a mean particle radius of ~ 1 cm. They hypothesise that small particles are continually created through meteoroid impacts. Particles considerably smaller than 1 cm are quickly removed by the Poynting–Robertson drag.

The McCrea model links purportedly periodic glacial phenomena with regular astronomical occurrences. The constraints discussed present grave difficulties in explaining at least the last glaciation in this way. These constraints, as pointed out by McCrea, are of interest since the Solar System must occasionally pass through interstellar clouds.

Another possibility is that this mechanism acts merely as a rapid trigger for a longer lived glacial episode. This tends to complicate the conjecture regarding the climatic phenomenon somewhat. The observational data constrain the angular size of the cloud $\lesssim 30°$, indicating that the ice must persist for $\gtrsim 5$ times the trigger duration. In this case, the optical depth of the cloud, though still severe, is reduced by a factor of five. X-ray observations in those directions not yet examined will probably restrict the possibilities even further. Although the smaller cloud would wipe out the zodiacal dust in ~ 20 yr, the zodiacal dust would have had a longer time for replenishment. The 6×10^4 yr since its passage is a sizeable fraction of the replenishment time.

Proterozoic oceanic crust at Bou Azzer

THE precise nature of the last great Precambrian orogeny (~600 Myr BP) is the subject of controversy, and views diverge as to whether it was a collision orogeny[1–3] or whether *in situ* deformation of an intracratonic orogenic belt occurred[4–6]. Geological evidence is given here, indicating the former presence of an oceanic domain along the northern margin of the West African Craton.

The Precambrian basement of the Anti-Atlas comprises two major structural units: the northern border of the West African Craton to the south-west, and a portion of the Pan-African Orogenic Belt to the north-east (Fig. 1). The linear Bou Azzer Complex[7], composed of ultrabasic to acid, plutonic and volcanic rocks in a greenschist metamorphic environment, is located along the edge of the craton in the central part of the Anti-Atlas. Younger than the craton, which stabilised around 1,800 Myr BP, it was affected by Pan-African metamorphism (~ 640 Myr BP).

A vertical section, 4–5 km thick, the Bou Azzer Complex comprises, in ascending order: upper mantle peridotites (harzburgites, dunite with some diallagites), ultrabasic cumulates (dunite–werhlite–clinopyroxenolite sequences), basic cumulates (layered gabbros), large stocks of quartz diorite, submarine lavas (diabases and spilites often displaying pillow structures) overlain by spilites, keratophyres, quartz keratophyres, and tuffs accompanied by greywackes, siltstones, limestones and jaspilites (Fig. 2). All the ultrabasic rocks have been serpentinised, in several stages; so the contact between residual mantle peridotites and overlying utrabasic cumulates is not clearly defined. Ultrabasic and basic cumulates are the result of evolution in a magmatic chamber under a roof of tholeiitic basic lavas, in a shallow and hydrated environment undergoing distension, as shown in the layered gabbros by presence of magmatic breccias, diabases, and keratophyre sills in the lower part, which fed dyke swarms at a higher level. At the top of the layered gabbros, beneath the tholeiitic lavas, intrusion breccias comprising angular fragments of diabase enclosed in leucogabbro occur. Most of the quartz–diorite stocks, displaying flaser structures, are located between the gabbros and the overlying basic lavas. Late quartz diorites have been intruded syntectonically into keratophyres, with resulting contact metamorphism.

The Bou Azzer Complex is a typical ophiolite[8] assemblage displaying the same rocks facies, the same vertical sequence, and the same thickness as those of the classical Palaeozoic (Ballantrae, Newfoundland) and Mesozoic (Oman, Troodos, Vourinos) suites. In accordance with current concepts of ophiolite as oceanic lithosphere[9–11], the Bou Azzer Complex is here interpreted as a sheet of allocthonous, Proterozoic oceanic lithosphere.

During the major phase of folding of the Pan-African Orogeny, which produced recumbent isoclinal folds towards the WSW and greenschist metamorphism, two palaeogeographical domains collided. The oceanic crust (ophiolite) was thrust, locally in an inverted position, over the northern border of the West African Craton, itself characterised by epicontinental limestones, quartzites and basic lavas with alkaline trend.

Also in the Pan-African Belt, 2,000 km from the Anti-Atlas, on the eastern edge of the West African Craton, in the Adrar of Iforas (Mali), disturbed ophiolite (upper mantle metaperidotites, gabbros, basic lavas, keratophyres, tuffs, jaspilites) are obducted into an epicontinental sedimentary unit.

The discovery along the margins of the West African Craton of typical ophiolites, interpreted as vestiges of Middle or Upper Proterozoic spreading oceanic crust, shows that a model based on plate tectonics, not necessarily of

Preparation and properties of rubber dislocations

The purpose of this note is to describe the construction and properties of a Volterra[1] edge dislocation made from two sheets of smooth rubber. A simple theoretical analysis illustrates the key features of the model and illuminates its interesting and unexpected behaviour.

A smooth transparent rubber sheet was manufactured by cross linking ethylene–propylene copolymer against a glass plate in a heated press[2,3]. After cutting the rubber into strips and removing it from the glass, two smooth pieces were brought into contact to form a laminate containing a single reversible adhesive interface (Fig. 1*A*). The Volterra dislocation of Burgers vector *b* was then formed by peeling one end of the laminate, displacing it rigidly, and re-adhering at the interface (Fig. 1*B*)[4]. Clearly, dislocations can exist in an essentially amorphous material[5,6].

Viewed in the geometry of Fig. 1*B* the vital features of the dislocation are obvious! The dislocation is composed of two, opposite facing cracks, each capable of moving reversibly along a special weak plane in the body. These cracks differ from conventional cracks in that they can heal, where the surfaces come close together, to produce an interface comparable in strength with that before fracture. Other close similarities between cracks and dislocations have been noted[7,8].

I now consider the condition for the existence of the dislocation. The dislocation persists in spite of the attractive surface forces continually striving to close the cracks and collapse the structure. These attractions are counteracted by elastic forces in the bent rubber. In equilibrium, the dislocation reaches a length *z* which can be calculated using a simple energy argument.

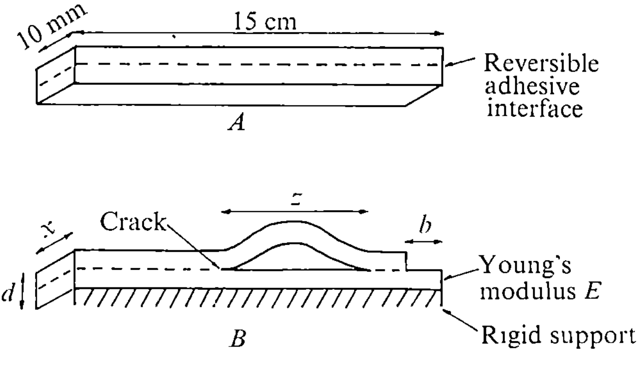
The free energy of the rubber surfaces is zRx where R, the interfacial energy, is the work needed to separate unit area of the interface. The elastic energy in the bent strip, treated as a strut collapsing at constant force[9], is approximately $\pi^2Exd^3b/3z^2$ using the nomenclature of Fig. 1. Therefore, by energy conservation, neglecting crack tip strains which are assumed to remain constant

$$\frac{d}{dz}\left(zRx + \frac{\pi^2Exd^3b}{3z^2}\right) = 0 \qquad (1)$$

$$z = \left(\frac{2\pi^2Ed^3b}{3R}\right)^{1/3} \qquad (2)$$

This equation, giving the size of the hole in a Volterra dislocation, bears comparison with that due to Frank[10] who suggested that such holes should be small. Peierls[11] also suggested that

Fig. 1 *a*, Rubber laminate with a single reversible adhesive interface; *b*, Volterra edge dislocation in the rubber laminate.



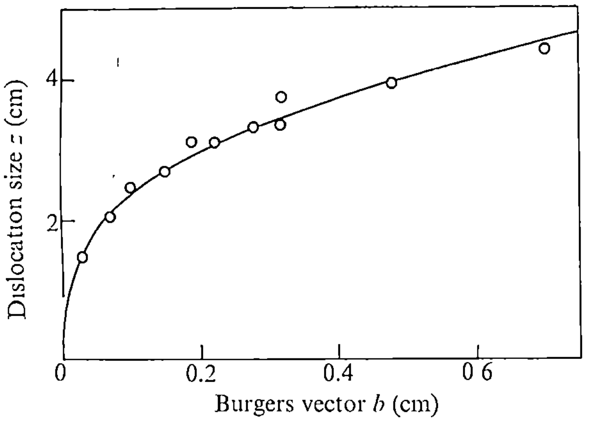


Fig. 2 The size of a rubber dislocation.——, Equation (2) with $R = 0.57\ \mathrm{J\,m^{-2}}$.

dislocations should be small using the enigmatic argument, "... we were not actually justified in our fundamental assumptions, which took the extension of the dislocation to be large. But the dislocation cannot, in any case, be much larger than we have found, since the equations ought to be correct if it were."

The dislocations of my experiments had big holes, as shown by the results of Fig. 2. To obtain these results, a dislocation of desired Burgers vector was partially closed by applying pressure at the cracks. These cracks opened up spontaneously on releasing the pressure however, and the dimension z was measured after 10 min. Equation (2) describes the results reasonably well if the interface energy R is taken to be 0.57 $\mathrm{J\,m^{-2}}$, about that measured in peeling tests at similar crack speeds.

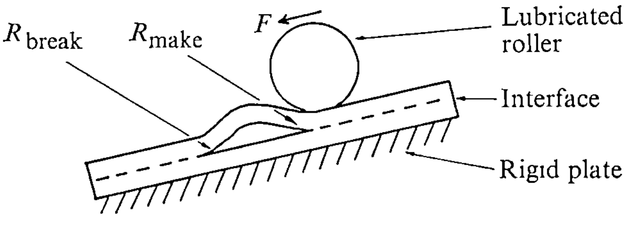
The Volterra dislocation could also be moved along the interface using a talc-lubricated roller (Fig. 3). The crack at the front of the dislocation then opened continuously and that at the rear closed. A propagation criterion was derived by considering the work done by the applied force F against the surface forces at the crack tips. If the energy expended in cracking is R_{break} per unit area, and the energy gained in reforming the interface is R_{make}, then

$$F = x(R_{\mathrm{break}} - R_{\mathrm{make}}) \qquad (3)$$

This equation, supported by experiment, shows that resistance to dislocation motion arises by interfacial hysteresis[12], akin to contact angle hysteresis, where energy is dissipated in breaking and remaking an interfacial bond. A similar equation describes the rolling friction of a cylinder on a smooth surface[13,14].

A stimulating phenomenon observed in these experiments was dislocation disappearance. The dislocation became shorter as it travelled, finally disappearing altogether. This was seen to be a result of the shedding of strain energy. Rubber deposited behind the moving dislocation was not unstrained, but was under slight compression. Thus the moving dislocation left some of its strain energy behind, gradually disappearing in the process. Another way of making the dislocation disappear was to deform the laminate so as to bring the sheets of rubber together across the dislocation. Stretching or bending the laminate did this; the dislocation healed completely and was reluctant to reappear.

Fig. 3 Dislocation movement



Equations (2) and (3) gave a rather oversimplified view of the behaviour of the dislocation. The surface energy of the rubber was not a constant but varied over several orders of magnitude with crack speed (both making and breaking)[12], with temperature, and with time of interfacial contact. Equilibrium could not, in fact, be achieved because of adhesive hysteresis[13].

Such non-equilibrium effects have not been taken into account in previous dislocation theories, yet they produce some amusing demonstrations. For example, the dislocation travelled at constant speed under steady load but increased in speed and became shorter as the driving force was raised; the dislocation moved faster as the temperature was increased; a second dislocation moved faster than the first; two similar dislocations repelled each other and resisted merging. If sufficient force was applied however, the dislocations joined to form a large dislocation.

These observations may be of value in explaining the deformation of materials, both crystalline and amorphous. In addition, some curious properties of composites[15] and frictional contacts[16–18] might be clarified.

Creeping-film phenomenon of potassium chloride solution

A PECULIAR creeping film that is similar to the superfilm of liquid helium II, but which occurs at room temperatures and has a much lower transfer rate, takes place in saturated potassium chloride aqueous solution. In an electrolytic experiment using saturated KCl solution as the salt bridge, we noticed that without any disturbance the solution could not be kept in the beaker all the time. A thin surface film creeps up the beaker wall very slowly, about several centimetres a day, flows out over the brim and then down the outside surface of the beaker. Creeping can also be observed up the surface of the electrode and the salt bridge tube (Fig.. 1). On surfaces over which the film has crept, potassium chloride crystals form as the water in which KCl is dissolved evaporates. Within a few days the solution in the beaker drains out completely and the entire surface of the beaker becomes covered with a thin layer of potassium chloride crystals, about 10^{-2} cm thick.

Another anomaly is the leakage of the same liquid solution from a supposedly 'seamless' glass tube connector used for the connection of the salt bridge. The solution flows out through the 'seamless slit', and then spreads all over the outside surface (Fig. 2). The creeping film then evaporates, and crystals form. The creep rate is lower than the previous case. The phenomenon occurs when the connector is

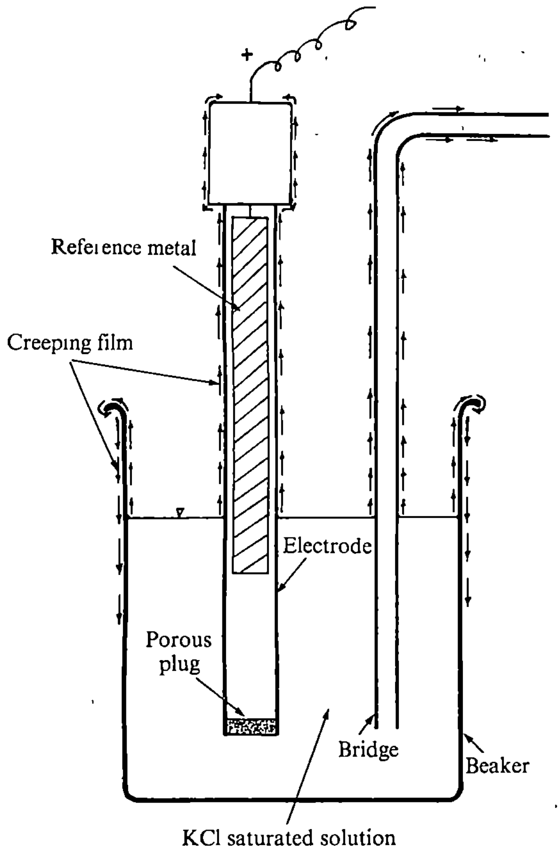

Fig. 1 Surface creep in a set-up including an electrode and a salt bridge.

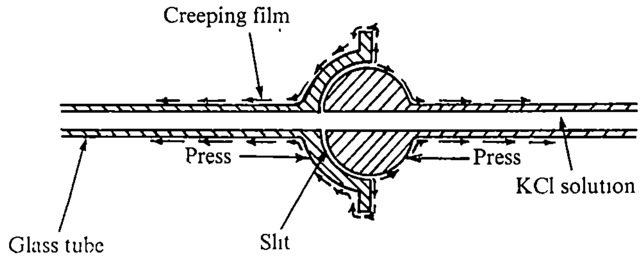
pressed with a clamp so tightly that water or air, even at very high pressures, cannot pass through.

An experiment was carried out to investigate whether this creeping thin film resulted from the electrical effect of the electrode. Experiments similar to the surface film experiment for liquid helium II were carried out. Instead of the electrode and the salt bridge, two small glass tubes, 1.8 cm in diameter and 11 cm long, were filled with 4 cm and 7 cm, respectively, of saturated KCl aqueous solution and immersed in two 400-cm^3 beakers containing 300 cm^3 of same KCl solution. The glass tubes were immersed in such a way as to provide a difference in level of 3 cm between the liquid in the tube and that in the beaker. To investigate the possible effect of the difference in level, experiment A was performed with the liquid in the tube higher than that in the beaker (Fig. 3). In experiment B the level was lower in the tube. The experiments were carried out with the surface as clean as possible so as to avoid contamination. No observable disturbance was allowed during the experiments. Flow of the creeping film along the surface of the beaker and along the inner and outer surfaces of the tube was observed, with a transfer rate of several centimetres a day.

Fig. 2 Flow through a 'seamless slit' connector.



The film thickness was estimated to be 10^{-2} cm from observation of crystal thickness.

The creeping rate of the liquid inside the tube in experiment A was, however, higher than that observed in experiment B. About two weeks later, the flow spread all over the inner and outer surfaces of the beaker, and started to extend across the bench until the solution had completely drained out. The solution also ascended the tube surface and crept along the supporting string. It is interesting that dried crystals accumulated at the entrance to the tube.

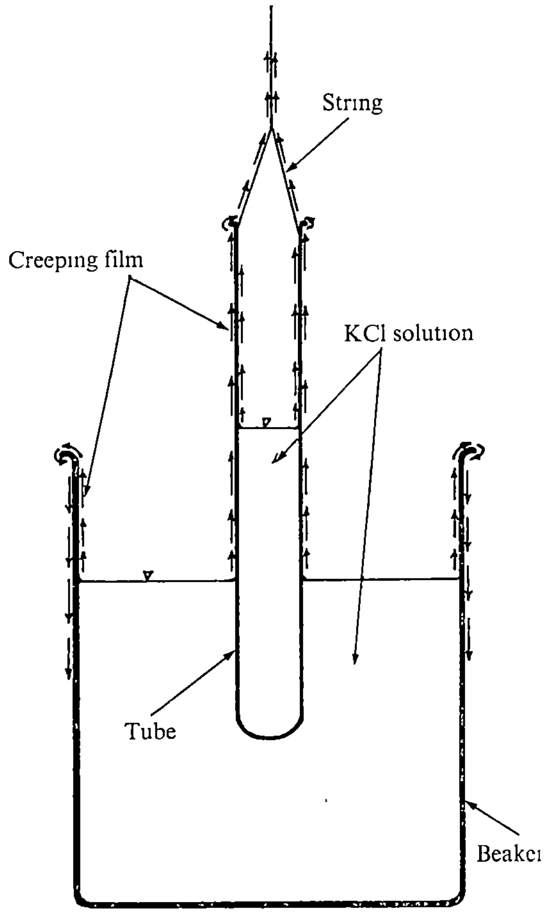


Fig. 3 Experimental set-up without electrode.

After all of the solution in the beaker had drained out, we observed that the heavily accumulated crystal formed a helical shape on the outer wall of the tube and the inner wall of the beaker.

The temperature was maintained at about 22 °C, though slight fluctuations were inevitable. Humidity was not controlled during the experiments. It seems that humidity as well as surface conditions were responsible for the creeping rate of the film. We repeated the experiments using a 'wet' surface, and the transfer rate increased by a factor of about three. But we could not reproduce the experiment from run to run even by using very clean surfaces. It seems that the creep is unlikely to occur if the solution is not saturated (this can happen if the temperature rises so that the solution becomes unsaturated).

This surface film phenomenon cannot be explained in terms of the evaporation of the solution from the bulk liquid level with subsequent condensation on to the surface, because the film creeps over the brim of the beaker. The experiments showed that the phenomenon is not attributable to any electrical effect although that may play a rôle if an electrode is present. No satisfactory interpretations based on present knowledge of either surface chemistry or transport theory can be given. The superfilm phenomenon of liquid helium II seems similar to the phenomenon described here; however, potassium chloride solution has entirely different physical and chemical properties from helium II.

We attribute this phenomenon to the interactions of the ions with the surface of the beaker or tube and the surrounding gaseous molecules; the major driving force is not clear. The leakage through a tightened glass connector is also inexplicable.

Radiometric age of early *Hipparion* fauna in North-west Africa

A TUFF for which a $^{40}Ar/^{39}Ar$ date of 12.18±1.03 Myr has been obtained is located in the lower level of the Bou Hanifia continental formation (= Oued el Hammam), several metres below the famous *Hipparion primigenium* locality[1–3]. The tuff forms a continuous layer in the lower part of the continental formation and can be observed on either side of the Oued el Hammam Dam. The *Hipparion* fossiliferous horizon (Bou Hanifia I) lies in a second deposit of greatly weathered tuffs and has yielded a few micromammal remains. About 15 m above Bou Hanifia I, a second micromammal locality has been discovered (Bou Hanifia II)[4].

The faunal lists are as shown in Table 1.

Table 1 Faunal lists for Bou Hanifia I and II

Bou Hanifia I	Bou Hanifia II
Hipparion primigenium (Von Meyer) *Dicerorhinus primaevus* Aramb. *Orycteropus mauritanicus* Aramb. *Palaeotragus germaini* Aramb. *Samotherium* sp. *Damalavus boroccoi* Aramb. *Gazella praegaudryi* Aramb. *Percrocuta algeriensis* (Aramb.) *Propotamochoerus devauxi* Aramb. The Bou Hanifia Formation, about 400 m thick, lies unconformably on a lower Miocene (Cartennian) formation[1,2], and is overlain by a marine formation assigned to the N17 Zone of Blow[5]. The transition from continental to marine horizons can be observed 6 km to the south of the dam along the N7 road from Sfisef to Ain Fekan, beyond the 'three rivers' bridge. A third micromammal deposit (Sidi Salem) has been discovered there directly below some intermediate brackish deposits with *Potamides* and oysters[4]. Its fauna closely resembles that of the Oued Zra which is 9.7 Myr old, but it contains more highly evolved species. The Sidi Salem deposit is more recent than 9.7 Myr, and is most probably between 9 and 8 Myr old. Thus, the Bou Hanifia Formation covers a time span of around 12–9.7 Myr BP.

Table 2 Relationships of Middle and Upper Miocene micromammal faunas from northern Africa to marine chronology, radiometric dates and continental chronology

			N 7							

The period covered by the formation, its relationships with the marine formation, its mammal fauna and the radiometric dates obtained, enhance its importance in the study of the Middle and Upper Miocene of Africa.

Several conclusions can be drawn from the date obtained for the Bou Hanifia tuff.

- The immigration of *Hipparion primigenium* is contemporary in northern Africa and western Europe[6]. The oldest *Hipparion* (*H. primigenium*) known in tropical Africa[7] is slightly more recent than those of northern Africa and Europe. (The meaning of this heterochronism is not yet understood.)
- The immigration of the primitive Murid, *Progonomys cathalai* Schaub, is synchronous with that of *H. primigenium* in the Mediterranean Basin; this has been postulated already[8], but no radiometric date has been obtained before for a fauna including an association of the two species.
- The pre-Vallesian age of the Beni-Mellal fauna is confirmed[4] establishing that it is more or less contemporaneous with that of Fort Ternan in Kenya[9]. On that basis the association observed in Tunisia of Upper Langhian foraminifers[10] with micromammals similar to those of Beni-Mellal[11] seems explicable[10].
- The dates complete the biochronological sequence calibrated with rodents of the micromammal localities of the Middle and Upper Maghrebian Miocene (ref. 4, and Table 2).

Table 2 requires further comment:

- *Hipparion primigenium* persists in northern Africa through the Turolian (Melg el Ouidane Deposit). The species is known from around 4 Myr BP in eastern Africa[12].
- *Hipparion sitifense* Pomel from the Sétif[13] and Mascara[14] lacustrine limestones has been found from the Upper Miocene of Algeria (Amama 2 deposit) and Kenya[16]. So an Upper Pliocene age for the Mascara and Sétif limestones cannot be considered as definitively established.
- An initial conventional K/Ar date of 7.84 Myr was first obtained for the Bou Hanifia tuff. This date contradicted the age indicated by the presence of the Bou Hanifia rodents which are less evolved than those of the Oued Zra deposit (9.7 ± 0.5 Myr) and did not tie in with the more primitive character of the Bou Hanifia large mammals comparable to those of the oldest Samos localities (Samos 1–4), for which a date of 9.3 Myr years has been obtained[17]. Here again, the evolution of rodents provides a particularly dependable tool for the elaboration of continental biostratigraphic scales. The interpretation of the full ^{40}Ar/^{39}Ar age spectrum analysis of biotite from the Bou Hanifia tuff is that it was altered during early cementation/diagenesis around 12.18 ± 1.03 Myr BP; the age of sedimentation must have been a little earlier.

Orientation specific colour adaptation at a binocular site

MCCOLLOUGH[1] found that after alternate viewing of vertically oriented red gratings and horizontally oriented blue gratings, achromatic gratings appear tinted blue when oriented vertically and pink when oriented horizontally. This indicates the existence of colour specific edge detectors in the visual system. Further, since interocular transfer of the effect was not possible, McCollough concluded that no binocular cells are involved in this type of adaptation. This view has been supported by many investigators[2–5] who used different paradigms. But their failure to illustrate orientation-contingent colour adaptation at a binocular locus may be attributable to the fact that most of their experimental situations, like McCollough's, did not provide the ideal stimulus for binocular neurones, which respond best, showing "binocular synergy", only when the stimulus is simultaneously presented to both eyes[6–9]. I have attempted optimal excitation of the binocular cells by alternately presenting red vertical and blue horizontal gratings to both eyes and isolating adaptation of binocular neurones by cancelling monocular adaptation with presentation of a pair of complementary gratings (blue vertical and red horizontal) to each eye separately for an equal length of time. The results of this procedure show that adaptation does involve binocular neurones.

If only the monocular channels are colour coded, no aftereffect should be obtainable on viewing an achromatic test pattern, since the group of monocular neurones specific to any of the two orientations have been presented with both the complementary colours for equal periods of time. On the other hand, if any of the binocular orientation detectors are colour contingent, an aftereffect complementary to the binocular presentation, namely, an achromatic test grating appearing bluish when vertical and pinkish when horizontal, should be seen on viewing the test stimulus with both eyes. I am aware of MacKay and MacKay's argument[10] against selective adaptation of single units sensitive to colour and orientation, but since it is not contradictory to my central theme I shall talk of "selective adaptation of cells", and leave discussion of their hypothesis for the final interpretation.

Coloured rectangular gratings (dark : light = 1 : 2) of 2.5 cycles per degree, subtending a visual angle of 15° at a distance of 8 feet were presented to five naive observers with normal form and colour vision in the following sequence (colour filters used were Wratten Nos 25 and 44): red vertical, binocular; blue vertical, right eye; red horizontal, right eye; blue horizontal, binocular; red horizontal, left eye; blue vertical, left eye. Each of the above presentations was for 8.5 s with a dark interval of 1.5 s between successive presentations, and the whole cycle was repeated for a total duration of 30 min. When these observers were later shown a test pattern containing achromatic gratings of both vertical and horizontal orientations, all of them reported seeing bluish vertical and pinkish horizontal gratings when both the eyes were open; with either eye occluded they all reported seeing pinkish vertical and bluish horizontal gratings. No leading questions were put to them and their choice of colour tints on viewing the test stimulus was always spontaneous. The aftereffects could be easily obtained up to 24 h after the adaptation, comparable to the time-course of the classical McCollough phenomenon.

These observations point to the colour specificity of two types of binocular cells: (1) cells which respond much more strongly for a binocular stimulus than for a monocular one. Electrophysiologically, most binocular units have been shown to be of this type[6-9], though their colour specificity has not been clearly demonstrated. (2) Neurones which receive a facilitatory input from one eye and an inhibitory signal from the other. The simple cells in area 17 reported by Hubel and Wiesel to be monocularly driven[6,11] have been shown[12] to receive a binocular input in the cat. Though these cells are excited only through the "dominant" eye, an "incorrectly" placed stimulus in the non-dominant eye has a strong inhibitory effect. A typical receptive field in the non-dominant eye has a large inhibitory surround and a "non-inhibitory" centre. The gratings that we used in our experiment, when binocularly presented, are bound to excite the inhibitory surround in the non-dominant eye's receptive field, and consequently suppress the response of the cortical cell, even though the dominant eye may be receiving the right stimulus. Thus these units would respond to the lines of a grating, when they are presented to the dominant eye alone, but not for a binocular presentation. If neurones such as these could be involved in a colour-specific adaptation, it would explain our observers reporting pinkish vertical and bluish horizontal aftereffects when one of the two eyes was occluded.

MacKay and MacKay, after measuring the time-course of the McCollough effect, questioned[10] the concept[1] of selective adaptation of single units sensitive to colour and orientation, and suggested, alternatively, cooperative synaptic and subsynaptic changes among an associative network of neurones. I suggest that these changes could occur at a binocular site too. The binocular units may not themselves be colour coded, but they are at least actively involved in the hypothetical neuronal changes. The claims that the McCollough effect is confined to monocular channels[1-5] or that it could be just retinal[10] are not tenable. It can even be proposed that all McCollough adaptation occurs in the visual cortex, in accord with the electrophysiological findings of cells with only concentric receptive fields before the striate cortex in the visual pathway[13].

My results are consistent with the extensive neurophysiological evidence for colour coded cells in the visual cortex[14-19]. Though only a few of these cells possess both colour and spatial specificities[16], it can be suggested that all the colour sensitive neurones, whether they have orientation specificity or not, are involved in structural changes with orientation-specific binocular neurones to yield long lasting aftereffects contingent on colour and orientation. This model is basically similar to the one proposed by Leppmann[20] The relative sparsity of cells with both specificities and the hypothetical neural changes justifies the requirement of a strong cellular response (binocular synergy) to bring out an aftereffect, in contrast to the easy interocular transfer[2] of pattern adaptation.

My observations are also the first psychophysical correlates of some of the stimulus properties of the various binocular neurones described with electrophysiological techniques, namely, the facilitated binocular response[6-9] and the subtle inhibitory input from an otherwise uninfluential eye[12]. It would be interesting to apply our experimental paradigm to other phenomena, such as aftereffects contingent on colour and movement, that do not show[21] interocular transfer.

I thank D. Carden and D. A. Wooding for technical help and Drs J. J. Kulikowski, V. M. Rao and P. E. King-Smith for comments.

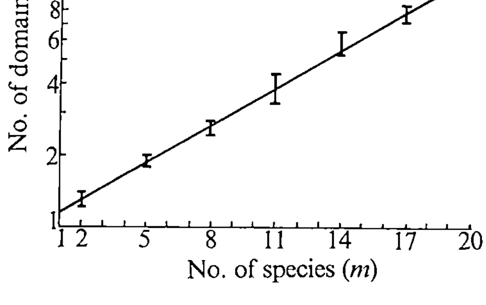
Multiple domains of attraction in competition communities

ECOLOGISTS typically explain the absence of a species in an area by searching for ultimate climatic or physical factors that limit its distribution or favour its competitors. The possibility that the system is not in equilibrium—that colonisation has not occurred—is not normally considered. Even less appreciated is that there may be a number of alternative stable equilibrium communities which may develop in a given area and that the final outcome may depend solely or partially on historical factors such as the sequence and numbers in which each species colonises. Here we investigate the theoretical possibility of this proposition for competition communities.

Examples of multiple domains of attraction are present in intertidal communities[1], microbial systems[2] between flour beetles[3] and on defaunated mangrove islands[4]. Diamond's study of competition among 400 bird species on the several hundred islands off the New Guinea archipelago offers some excellent examples[5]. He was forced to go beyond the normal competition theory and to introduce the concept of community assembly rules (forbidden and permitted subsets of species) and transition probabilities between them. We here investigate some of the dynamical underpinnings of species assembly rules.

Fig. 1 Number of domains of attraction against the initial number of species in the competition system. The mean interspecies competition ($\bar{a}$) is 1 0. Bars indicate ±1 s.e.



Unfortunately, it is impossible to analyse analytically such global stability problems as this for large numbers of interacting species. The local (or Liapunov) stability analyses of ecological communities of May[6], Gilpin[7], Roughgarden[8] and others is inappropriate here. We have opted to explore state-space landscape of interspecific competition communities by numerically integrating a normalised version of the Lotka[9] and Volterra[10] equations:

$$dN_i/dt = N_i(1 - a_{ij} N_j) \qquad (1)$$
$$i = 1 - m, \quad a_{ii} = 1, \quad a_{ij} \geq 0$$

where N_i is the population density of the *i*th species and a_{ij} is the competition of the *j*th species on the *i*th species. Each species has a low density exponential growth rate of 1 in the absence of other species and reaches a single species equilibrium of 1. For a random assignment of the a_i, we wish to know the number of domains of attraction of the system and their probability of occurrence. We could do this by testing the feasibility, stability and resistance to invasion of the 2^m different combinations of the *m* species. But this is very costly for large *m*, and, moreover, tells nothing about the probability of occurrence of the different domains of attraction. We have therefore chosen to randomly initialise the system on the hyperplane $\Sigma N_i = 1$. Thus, each initialisation corresponds to one possible combination of relative abundances of the potential colonising species pool. Equation (1) is then solved by computer iteration until a stable domain is reached. During the course of this iteration certain species will become extinct. It is theoretically possible that a limit cycle (or perhaps ergodic behaviour) would result, but in the several hundred systems we explored we did not find any such case. Perhaps this was due to the biologically realistic truncation used—any species that fell below one one hundred thousandth of its single species equilibrium went extinct.

We initially used colonising pools species (*m*) of size 2, 5, 8, 11, and 14. Values of *a* were drawn from a rectangular distribution with a mean interspecies competition coefficient ($\bar{a}$) of 0.35, 0.5, 0.65, 0.8 and 1.0. In one series the *a* matrix was symmetrical; in another all the terms of the *a* matrix were random; in a third series the *a* matrix was half a symmetrical matrix plus half a random matrix. For each *m* and $\bar{a}$ combination, 10 matrices were generated each of which was solved with 20 different initialisations. A multivariate analysis of the resulting data—that is, the number of domains of attraction compared with community size and mean strength of interspecies competition—produced a single parameter model that explained almost 90% of the experimental variance

$$D = \exp[p(m-1)\bar{a}] \qquad (2)$$

where *D* is the number of domains of attraction and *p* is an empirical parameter. For the symmetrical, mixed and random matrices, respectively, *p* has the values (±s.e.) 0.182±0.025, 0.084±0.014, and 0.062±0.011. Thus competition matrices which are symmetric, as might be the case for resource competition between species with equal niche breadths and single species equilibria, give more domains of attraction than nonsymmetric competition. The latter might occur where there is interference competition or where there is much dimensionality in niche packing.

To test empirical relation (2) for the functional relationship between *D* and *m*, we ran a more exhaustive series of tests in which each competition matrix was initialised 200 times; the *a* matrices were half symmetrical and half random and $\bar{a}$ was 1.0; *m* was varied between 2 and 20 in steps of 3. The results are shown in Fig. 1. The logarithmic relationship between *D* and *m* is confirmed, although the regression line misses the point ($D = 1$, $m = 1$), passage through which is logically necessary, by a few per cent. This could be corrected by adding a small constant to the right hand side of equation (2).

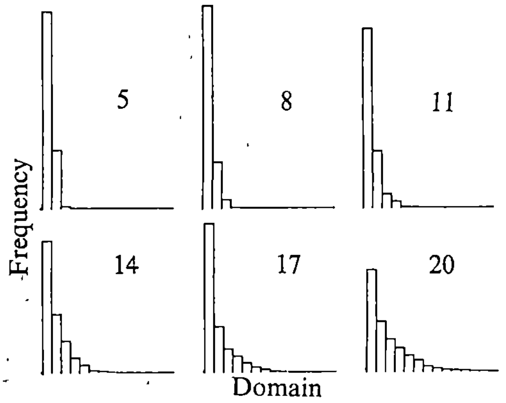


Fig. 2 Relative frequency of the domains of attraction for different initial community sizes. The domains are ordered by decreasing the frequency.

It is clear that relation (2) cannot hold for arbitrarily large values of $\bar{a}$, since for any *m* there exists an upper bound on the possible number of alternative equilibria. In the range of $\bar{a}$ that we investigated, however, the exponential dependence of *D* on $\bar{a}$ was a better fit than a linear dependence.

The relative 'volumes' of the domains of attraction were determined by counting the number of times a particular competitive assemblage occurred over the 200 times each *a* matrix was initialised. In Fig. 2 these are plotted with histograms. The bar on the far left represents the average frequency of the most common domain for the 10 different competition matrices, the next bar is the next most frequent domain and so on. As *m* increases the distribution spreads out but the relative volume of the largest domain of attraction decreases only slightly.

In Fig. 3 we have plotted both the mean number of species in a domain (weighted average over all domains, *a* matrices, and initialisations) and the mean total density of species in the domains as a function of the number of possible colonising species (*m*), for an average *a* of 1.0. These asymptote at ordinate of 2.5 species and 1.4 times the single-species equilibrium density, respectively, at an *m* of about 10.

A particular solution with a small domain of attraction may be easily perturbed by species increases or random perturbations to a solution with a broad basin of attraction, from which only larger perturbations will knock the system into other potential domains. It is interesting in this context that there is no regularity with the number of species present in a particular solution and the size of the domain of that solution for a particular *a* matrix. For example, stable domains containing both very few (for example, one) and large number of species, may be relatively unstable to global perturbations. Neither have we been able to discern any obvious heuristic rules in our trials which enable us to predict the attributes of the largest domains of attraction based on either species number,

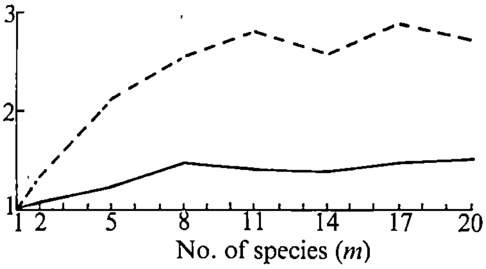

Fig. 3 Mean number of species present in a domain of attraction against initial number of species in the community (dashed line) and the mean total density ΣN_i of the species in a domain of attraction against the initial number of species in the community (solid line).

total density of all species, or combinations of these variables.

Since these results come from equations that are no more than a caricature of ecological reality, our results must be taken as provisional. Nonetheless, some interesting and practical conclusions may be drawn. Pest eradication programmes or the introduction of biological control agents may be viewed in some situations as global perturbations of community equilibria, or as attempts to go from one stable domain of attraction to another which is economically or aesthetically more desirable. The likelihood of success will depend on the relative size of the domain of the existing community compared with the size of the desired community, and the size and direction of the manipulated perturbation (for example, the number of individuals introduced). In some situations there may only be a few starting configurations of colonisation sequences leading to the formation of an economically desirable community. The lack of initial success in a species introduction plan does not necessarily mean that success will not be reached using another stocking rate or at a different time when resident species numbers are different.

Seasonal effects on carbon isotope composition of cactus in a desert environment

IN plants with crassulacean acid metabolism (CAM), CO_2 is fixed in the light by ribulose-1,5-bisphosphate carboxylase[1,2] and in the dark by phosphoenol pyruvate (PEP) carboxylase[2,3]. Because these two enzymes fractionate the stable isotopes of carbon (^{12}C and ^{13}C) in the atmosphere and discriminate against ^{13}C to different extents[4], the wide range of values of carbon isotope discrimination ratios ($\delta^{13}C$) found in these plants[5] has been attributed to different contributions of dark and light fixation to carbon gain[6]. The proportion of total carbon fixed at night can be altered by environmental variables such as temperature[7], water status[8] and photoperiod[5]. Predictable changes in $\delta^{13}C$ values have been observed when these environmental conditions have been varied. With one exception, all such studies have been performed in artificial conditions. Because the $\delta^{13}C$ ratio of CAM plants has been used as an indicator of environment in palaeoecological investigations[9], we have examined the sensitivity of these $\delta^{13}C$ ratios to seasonal environmental influences in a natural system. Using *Opuntia acanthocarpa, O. basilaris* and *O. bigelovii*, we found that the carbon isotope composition of the plants did not change during the experiment, indicating the insensitivity of this measurement to short term seasonal influences in this environment.

The experimental site was at an altitude of 289 m in the Phillip L. Boyd Desert Research Centre at Palm Desert, California, and had a climate characterised by the temperature and rainfall pattern shown in Fig. 1. Tissue for each analysis was sampled by taking cork-borer cores transversely through the cactus cladodes. Each determination[10] was based on at least three cores and for *O. basilaris* and *O. bigelovii*, they were sectioned into cortex and pith, using the vascular strands as a guide for the division. Total titratable acidity and malic acid content[3] were determined in addition to the $\delta^{13}C$ ratio. Figure 1 shows that the extent of the diurnal change in titratable acidity responded to rainfall, particularly in the autumn. These results agree with those obtained previously with *O. basilaris* on the same site[11,12]. In the previous study, nocturnal stomatal opening occurred briefly after rain, facilitating dark CO_2

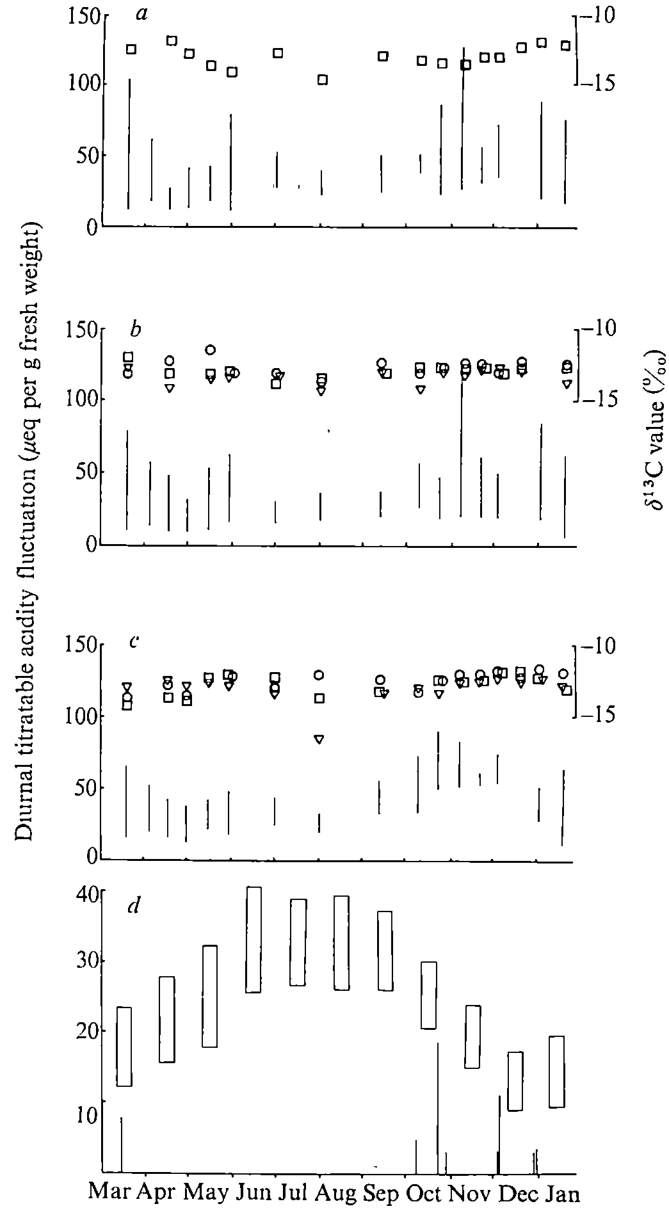

Fig. 1 Diurnal titratable acidity fluctuations (bars) and $\delta^{13}C$ values in natural populations of *O. acanthocarpa* (*a*) *O. basilaris* (*b*) and *O. bigelovii* (*c*) sampled in an environment with (*d*) the indicated mean monthly temperature ranges (blocks) and rainfall (bars). □, Bulk tissues; ▽, cortex; ○, pith. Titratable acidity was determined by titration of boiled aqueous tissue extracts to *p*H 7.0 with 0.01 N KOH. Correlation coefficients between $\delta^{13}C$ ratios and diurnal acidity changes: *a*, −0.0503; *b*, −0.3155; *c*, 0.1308; and time: *a*, −0.035; *b*, −0.209; *c*, −0.290. Mean annual $\delta^{13}C$ value and s.e.m.: *a*, −13.1±0.193; *b*, −13.0±0.085; *c*, −12.8±0.121.

fixation which resulted in increased diurnal fluctuations in acidity. At other times, stomata remained closed throughout the day and the small diurnal changes in acidity observed in these conditions were assumed to correspond to nightly fixation of respiratory CO_2 only. In no conditions did stomata open in the light This pattern of CO_2 uptake would involve only PEP carboxylase in the assimilation of atmospheric CO_2, and from this a stable $\delta^{13}C$ ratio of the magnitude observed in C_4 species would be predicted. Such a ratio was observed in this experiment (Fig. 1). Statistical analysis of the results indicated that the $\delta^{13}C$ ratios of *O. acanthocarpa* and *O. bigelovii* were correlated with neither the time of year nor the diurnal change in titratable acidity. The correlation between $\delta^{13}C$ value and diurnal fluctuation in titratable acidity for *O basilaris* was significant ($P=0\ 05$). But, the range of $\delta^{13}C$ values observed for all species was within the limits of observation and C_4 species[5]. In *O. basilaris* and *O. bigelovii* the $\delta^{13}C$ ratios measured in pith and cortex samples were not significantly different from the bulk value for the tissue. In other experiments (our unpublished data), although carbon fixed at night was initially found localised in the cortex, radial equilibration with the pith occurred in a few days.

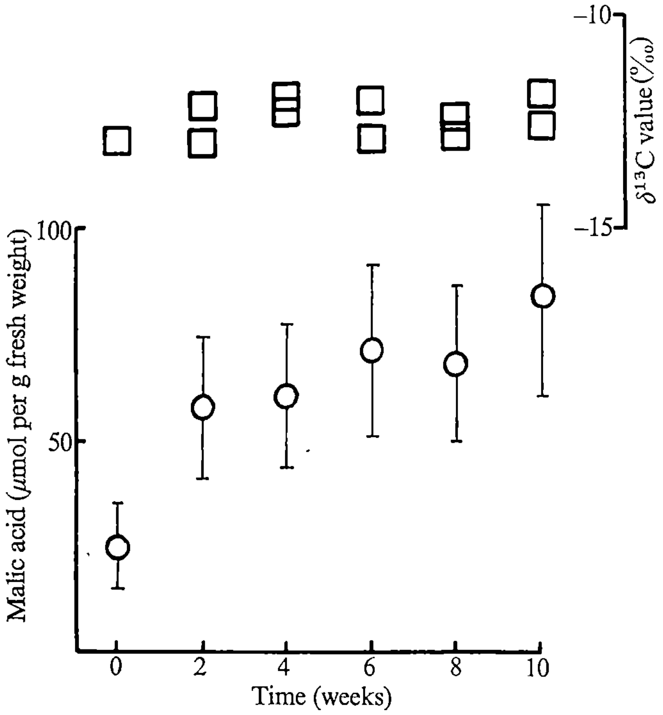

Fig. 2 Response of morning *O. bigelovii* malic acid levels and $\delta^{13}C$ values to irrigation in autumn A natural clone of plants was irrigated with 6–10 mm of water every 2 weeks. Correlation coefficient between $\delta^{13}C$ values and time was 0.412. Mean and standard error of the $\delta^{13}C$ values was $-12\ 6 \pm 0.137$. Vertical bars indicate 95% confidence limits for the malic acid estimation.

The sensitivity of the $\delta^{13}C$ ratio to environmental change was further examined in a clone of *O. bigelovii* which was subject to regular irrigation in autumn, when the cooler days and improved water status of the plants was expected to promote daytime CO_2 fixation[8], and therefore a decline in the $\delta^{13}C$ ratio. The results, presented in Fig. 2, indicate that although the production of malic acid at night increased markedly, the $\delta^{13}C$ ratio remained stable at a high value. The data presented here therefore indicate that the $\delta^{13}C$ ratio of the plants studied is relatively insensitive to short term seasonal changes in natural desert conditions. The data also confirm that no exogenous CO_2 is fixed in the light in this environment. These experiments imply then, that the varying $\delta^{13}C$ ratios observed in wild populations of cactus[1,9] are a result of long term environmental differences rather than seasonal effects. This result gives credence to the use of such ratios for the reconstruction of past climates[9].

This research was conducted while B.G.S. was a CSIRO postdoctoral student. We thank Mrs K. A. Card for $\delta^{13}C$ analysis and Mr J. Zabriskie for assistance in the field.

Real-time delayed tracking in flies

A DARK target on a bright background is fixated[1] and tracked[2,3] by a flying fly. The delay (dead time) in the fly's behavioural response to a change in the retinal image of the target is very small (about 20 ms)[3–5]. An artificial increase of this delay may give useful insight into the kind of control systems used by the tracking fly. Comparable psychophysical tracking experiments have been performed. For instance, when a televised display of a person's own behaviour in (closed-loop) pursuit tracking is delayed, his performance, as measured by time on target, is seriously impaired[6]. It is possible to delay the fly's response in artificial closed-loop conditions, and we have therefore used the effects of delayed visual feedback on tracking performance to test quantitatively a theoretical description of the visual orientation behaviour of flies[1,7,8].

A female fly (head fixed to the thorax) was attached to a fast torque meter, in the centre of a cylindrical panorama, as described before[1]. The torque signal is transduced into angular displacement of the 'panorama' through an analog simulation of the flight dynamics. In this way it is possible to simulate a free flight situation, in so far as the fly can track a target moving in the horizontal plane. In our experiments the moving target consisted of a black vertical stripe. The angular speed of the target was determined by a zero-mean Gaussian noise added to the torque signal of the fly. The torque, F, of the fly was delayed in steps of 78 ms by means of a standard tape recorder. The experimental situation is described by the following equation

$$[\theta\psi(t)+k\psi(t)]+k\omega(t) = -F(t-\varepsilon) \qquad (1)$$

where the angular error $\psi(t)$, represents the actual position of the target on the fly's retina. The terms in brackets on the left give the analog approximation of the flight dynamics (θ is the moment of inertia of the fly, k represents a rotational

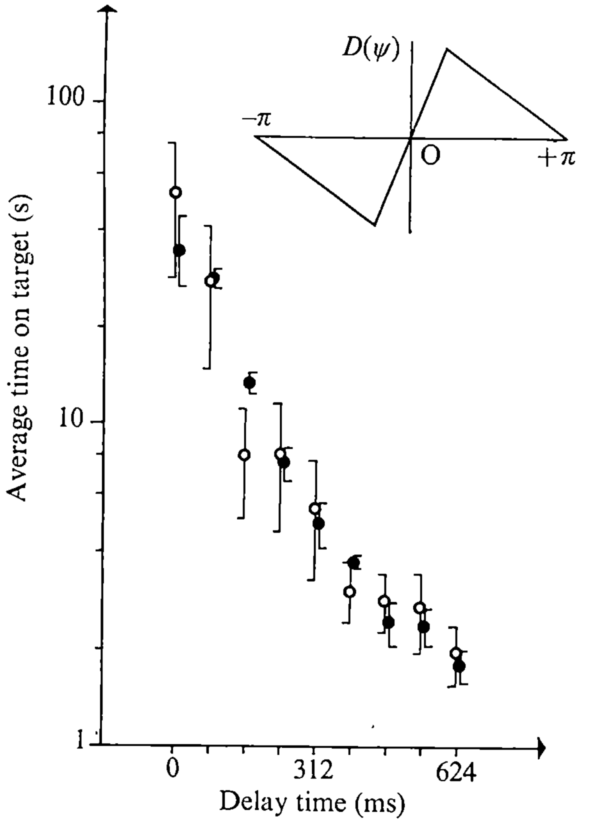

Fig. 1 Tracking performance under delayed response. The data points represent the mean time on target for six female flies, *Musca domestica* L. (○) and for four analog simulations of equation (1) (●). The vertical bars indicate the standard deviation of the mean. The inset shows the response function $D(\psi)$ which gives the ψ-dependent 'attractiveness' of a black stripe for the fly. $D(\psi)$ and the other parameter values used in the simulation are the same as those measured by Reichardt[1]. With these values, equation (2) without the terms $N(t)$ and $k\omega(t)$ shows oscillatory solutions for $\varepsilon \geqslant 156$ ms. Correspondingly, the associated linearised equation becomes unstable $\omega(t)$, the target angular velocity, is a Gaussian zero-mean process in all experiments, with a flat spectrum up to 15 Hz and an r.m.s. amplitude of about 50° s^{-1}. The width of the stripe was 2°, and its vertical length about 60°.

friction constant). $\omega(t)$ is the zero-mean Gaussian process representing the angular speed imposed on the target in our experiment. The average time on target T was measured as a function of the artificial delay ε. The object was considered to be lost by the fly when the angular error $\psi(t)$ between the direction of flight of the fly and the object reached ±170°.

In tracking behaviour, an increasing delay impairs performance: the greater the delay, the smaller is T (Fig. 1). The relationship between delay and time on target does not seem to fit a simple function. Psychophysical experiments, on the other hand, seem to show a simple inverse linear relationship between T (on a logarithmic scale) and magnitude of delay[6]. The orientation behaviour of flies and various tracking situations can be described quantitatively by a phenomenological theory[2–4,7–14], which leads to the equation

$$\theta\ddot{\psi}(t)+k\dot{\psi}(t)+k\omega(t) = -D[\psi(t)]-r\psi(t)+N(t) \qquad (2)$$

where the right hand side describes the instantaneous torque of the fly. $N(t)$ is a zero-mean Gaussian, band-limited random process, independent of visual input; $r\dot{\psi}$ represents a velocity-dependent, direction-sensitive optomotor response; $D(\psi)$ is a nonlinear anti-symmetrical function describing the fly's response to the stripe position (inset Fig. 1 and legend). All these terms have been characterised quantitatively[1,3,4,7].

If the right hand side is delayed by ε, equation (2) should represent our experimental situation. An approximate analytical solution in T has been obtained[9] in the case $\varepsilon = 0$ but seems otherwise extremely difficult. Therefore, to check the validity of the model, we carried out an analog simulation of equation (2), using the parameter values measured by Reichardt[1]. T was measured in the same conditions and with the same experimental arrangement as was used for the fly (Fig. 1). In the simulation we neglected the internal delay time of the fly (20 ms), and our results are consistent with previous evidence[3,7] that it can indeed be neglected.

The satisfactory agreement between the two sets of data of Fig. 1 supports the validity of the hypothesis underlying the phenomenological theory. Not only do the quantitative values of T as a function of ε agree within the limits of experimental error, but also the autocorrelations of the process $\psi(t)$ for the various values of ε are similar. In summary, equation (2), in addition to explaining various orientation situations quantitatively, also accounts for the delayed tracking described here. An important consequence is that the range of validity of the terms $D(\psi)$ and $r\psi$, representing the fly's visual induced response, extends through the rather extreme tracking conditions of our experiment. In particular, the function $D(\psi)$, which to a great extent determines the tracking performance, seems to be an almost invariant property of the visual control system of the fly.

Determination of polarity in the amphibian limb

ACCORDING to the classical work of Harrison and his followers[1–6], the anteroposterior polarity of amphibian limbs consists of a 'molecular polarisation' of the cells which has been acquired by the late gastrula stage of development. I here present evidence that the polarity of the anteroposterior pattern is caused at a later stage of

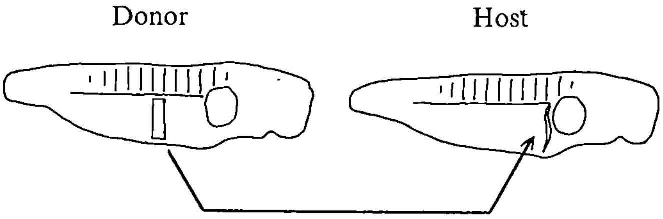

Fig. 1 Diagram of the reduplication-inducing graft described in the text. Operations were performed with electrolytically sharpened tungsten needles. The embryos were in half-strength Holtfreter solution containing 1/3,000 MS222 (Sandoz). The grafts were kept in place for 1–2 h with glass bridges. Embryos were kept in half-strength Holtfreter until the wounds had healed (usually overnight) and then transferred to 1/10 × Holtfreter containing 1/10,000 Nystatin (Squibb) and 1/2,000 Sulphadiazine (May and Baker). After hatching, larvae were kept in tap water which had been left to stand for 24 h. They were fed on brine shrimps (California Brine Shrimps Inc.) until all of the limb cartilages had developed, which takes about 4 weeks at 18 °C.

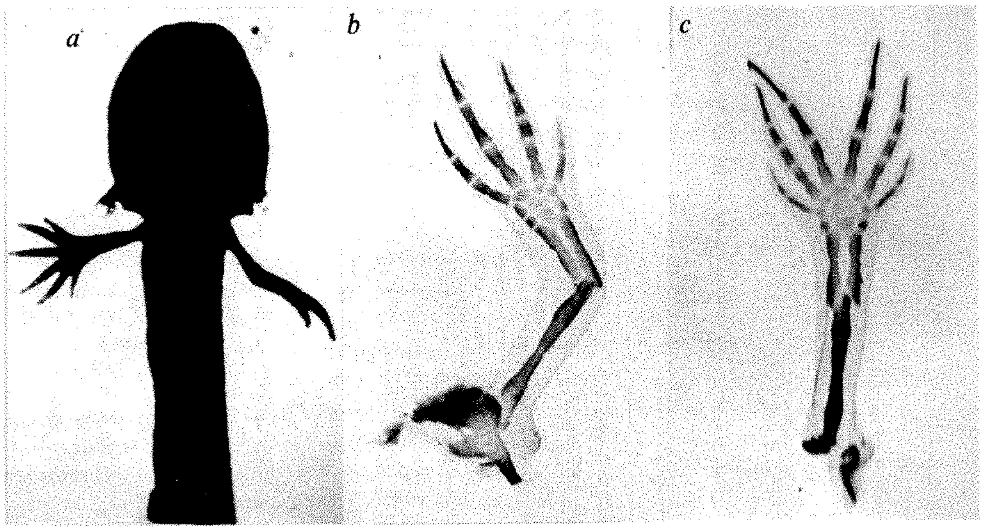

Fig 2 *a*, A reduplicated limb *in situ* showing its unusual posture; *b*, normal axolotl limb; *c*, reduplicated axolotl limb. For (*b*) and (*c*) the limbs were fixed in 5% trichloroacetic acid for 3 h, bleached overnight in Mayer's bleach, stained for 30 min with 0.1% Alcian green in acid acohol, differentiated overnight in acid alcohol, dehydrated and cleared in oil of wintergreen.

development by a signal emitted from a region posterior to the limb rudiment. In so far as this signal can travel in both directions it is not necessary to postulate any polarity at the cellular level.

The basic experiment which demonstrates the existence of the polarising region is shown in Fig. 1. It was performed on stage-34 embryos of the axolotl (*Ambystoma mexicanum*)[7]. A strip of tissue consisting of ectoderm and lateral plate mesoderm was grafted from a position ventral to the 6th somite into a slit made ventral to the junction of somites 2 and 3, that is, from the posterior to the anterior margin of the limb rudiment. In 15 out of 25 cases the host forelimb developed into a mirror symmetrical reduplication. These reduplications consist of two posterior halves arranged symmetrically around the mid-axis. Typically, they have five to seven digits and a corresponding number of more proximal elements (Fig. 2*b* and *c*). The pattern of outgrowth of the buds is also symmetrical. The direction of growth is lateral, rather than dorsoposterior, so that the reduplicated limbs stick straight out from the body when they are fully developed (Fig. 2*a*).

When the grafts were taken from an anterior position (ventral to the 3rd somite), the host limbs developed normally (6 of 6 cases), suggesting that the phenomenon is not a nonspecific wounding or grafting effect. When such anterior strips were grafted posterior to the limb rudiment (ventral to the 6th somite) the host limbs also developed normally (6 of 6 cases). So the cause of the reduplications cannot simply be a disharmonic combination of anterior and posterior tissues.

The main reason for thinking that the grafts of posterior origin emit some form of signal is that the reduplications are formed entirely from host tissues. There are several lines of evidence for this, but the most clear cut is that the effect can be produced by an interspecific graft from embryos of the Spanish salamander (*Pleurodeles waltlii*) to the axolotl, and the resulting reduplications consist entirely of axolotl-type elements (Fig. 3). The same may be shown by the use of vitally stained grafts. It therefore seems that the signal from the polarising region is not instructive. What it does in this experiment is to evoke the formation of normal host elements in an abnormal position.

The approximate extents of the polarising and competent tissues were determined by further grafting. Pieces of tissue from the flank were assayed for polarising activity by studying whether or not they produced reduplications when grafted anterior to the limb rudiment. Other strips of tissue were assayed for 'limb competence' by being grafted to the flank between the fore and hind limb rudiments. Because of the extensive regulative ability of this system such fragments can develop into complete supernumerary limbs if they are competent (Fig. 4). It is clear that the zone of limb competence lies ventral to somites 3–5 as described by Harrison[1]. But the polarising region extends well beyond this, the greatest activity lying in the dorsal lateral plate ventral to somites 5–8. Thus, although it is not possible to prove the existence of a sharp boundary by grafting experiments, there is certainly a considerable geographical separation between the two types of tissue.

It is now possible to explain the occurrence of redupli-

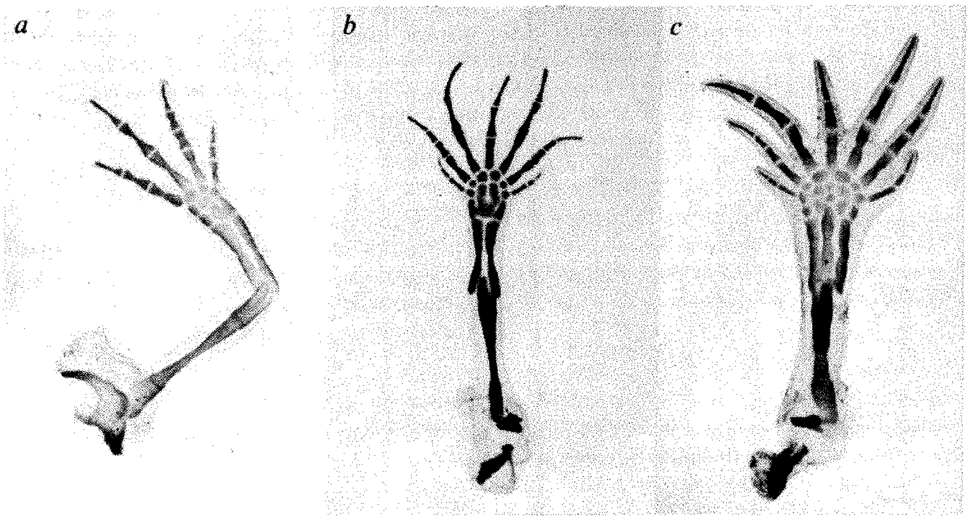

Fig. 3 *a*, Normal limb of *Pleurodeles waltlii*; note the spindle-shaped phalanges and the fusion of intermediale and ulnare in the proximal row of carpals. *b*, Reduplication produced by a pleurodele–pleurodele graft; all cartilage elements are of pleurodele character. *c*, Reduplication produced by a pleurodele–axolotl graft; all cartilage elements are of axolotl character.

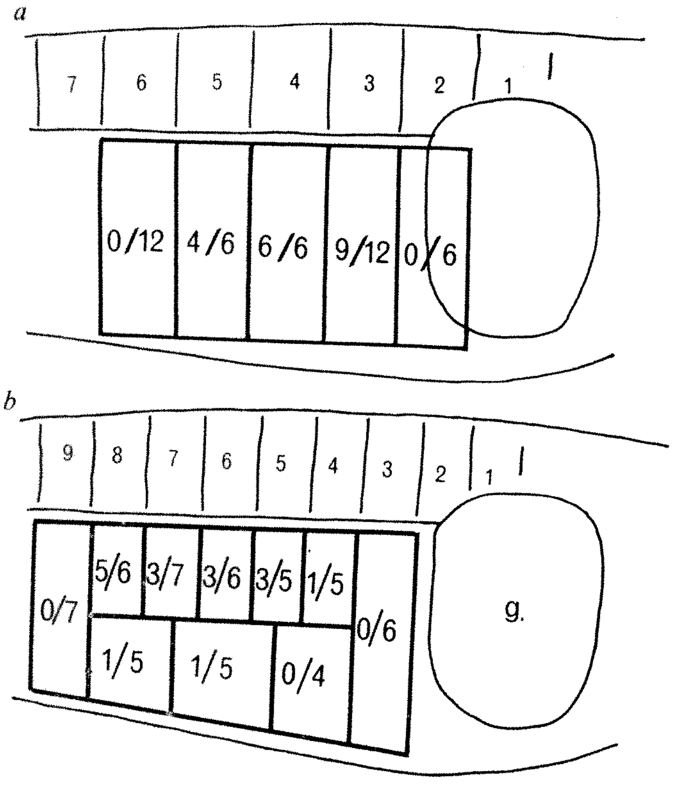

Fig. 4 *a*, Distribution of limb competence in stage-34 axolotl embryos, as assayed by the ability of fragments to form limb buds when grafted to the flank. *b*, Distribution of polarising ability at the same stage, as assayed by the ability of fragments to produce reduplication of the host forelimb when grafted ventral to the junction of somites 2 and 3. g, Gill rudiment. For both (*a*) and (*b*) the numbers in each box represent the number of positive cases over the total number of grafts for this particular fragment of tissue.

cations in the earlier, classical experiments. Most of that work involved rotations and transplantations of the so-called 'limb disks'. These consisted of lateral plate tissue extending from the level of the 6th somite to the anterior edge of the 3rd and therefore must have contained both polarising and competent tissue.

When such a limb disk was grafted to the normal site in normal orientation it gave a normal limb. When it was grafted to the normal site in reversed anteroposterior orientation it gave a reduplicated limb[2]. This is presumably because in the former case the polarising tissue remained in its usual posterior position, but in the latter case it was present on both sides of the competent tissue, as in the experiments described above. When a limb disk was grafted to the flank with reversed anteroposterior orientation, it gave a normal limb of reversed polarity. When the graft was normally orientated on the flank it often gave a reduplication[2]. This result was particularly mystifying to Harrison because the reduplications arose from the graft which was 'harmonic' with respect to the body axis. It is no longer surprising, however, because it can now be seen that it was the normally orientated grafts which had polarising tissue on both sides.

In addition, it is probably the polarising region that is responsible for the polarity of inducted limbs. Balinsky[8] and Takaya[5] showed that supernumerary limbs could be induced from the flanks of newts by implantation of fragments of nasal placode tissue. Nearly all these supernumeraries were single and of reversed anteroposterior polarity with respect to the body. This is just what would be expected if the placode induces a new zone of competent tissue posterior to the host polarising region.

Considering more recent work, it is clear that the existence of a posterior polarising region makes amphibian limb development seem much more like that of other vertebrates than previously thought. A polarising region has been described in the limb buds of the chick and mouse with very similar properties[9-12]. There remain two important differences, however: first, the interaction in *Ambystoma* and *Pleurodeles* seems to occur several days before the formation of a visible limb bud, whereas that of the chick is active during bud outgrowth; and second, the urodele limb rudiment is highly regulative in the anteroposterior axis whereas that of the chick is not.

I thank Lewis Wolpert, Julian Lewis and Cheryll Tickle for discussions, Julia Hunt for the axolotl eggs, and the MRC for a fellowship.

Langerhans cells form a reticuloepithelial trap for external contact antigens

THE outermost covering of the body, the epidermis, is a thin epithelial sheath comprising three distinct cell types, keratinocytes, melanocytes and Langerhans cells. The physicochemical and photo-protective role of the first two is well known, but the function of the third is still unknown, over a hundred years since its discovery[1]. The Langerhans cell was reported earlier as having a sensory role, or as being an effete form of the dendritic malanocyte below it[2], but it occurs in the dermis[3] and is mesenchymal, rather than neuroectodermal, in origin. Its fine structure reveals no melanin, but distinctive racquet-shaped granules. It has also been proposed that it is a macrophage[4] or that it may be involved in keratinisation, but recent evidence has suggested an immune function for the Langerhans cell in the development of contact dermatitis[5,6]. To investigate this possibility, we have exposed separated epidermal sheets to metals, aldehydes and amines known to act as contact antigens, and have observed their distribution histologically. We report here the selective uptake of antigens causing allergic contact dermatitis by Langerhans cells of the epidermis in guinea pigs and man.

Adult male white Hartley guinea pigs (300 g) were killed by cervical dislocation. After electric clipper removal of hair, ears were excised and inner and outer skin layers removed from cartilage by forceps. Human specimens were superficial horizontal skin slices removed by razor blade, with or without local lidocaine anaesthesia from male and female white adults with normal skin. The epidermis was finely dissected free after incubation in buffered EDTA solution for 2 h 37 °C (ref. 7), or in 1 M sodium bromide (pH 6.8, 0.1 M phosphate buffer) for 30 min. To brace metal antigens, the epidermal sheets were kept in mercuric chloride (7 mM), nickel chloride hexahydrate (12 mM), cobaltous chloride hexahydrate (12 mM), or chromic chloride hexahydrate (12 mM) in Tris-maleate buffer, pH

7.4 with 5% glucose for 60 min at 37 °C. The sheets were developed by immersion in 175 mM ammonium sulphide for 20 min at room temperature (22 °C), and then fixed in cold cacodylate formaldehyde (4 °C) for 20 min. This was followed by a 4-min exposure to Timm silver nitrate developer. Control staining of the Langerhans cells used lead nitrate (6 mM) in adenosine-5-triphosphate (ATP), glucose, Tris-maleate buffer with $MgSO_4$ added. The specimens were mounted in glycerine jelly.

The uptake of formaldehyde and glutaraldehyde was studied by exposing the separated epidermis to formaldehyde or glutaraldehyde (4%) solution for 20 min at 4 °C followed by paraphenylenediamine (PPD) (46 mM) in sodium borate–carbonate buffer (*p*H 10.8) for 60 min. Subsequent exposure to 3% hydrogen peroxide for 10 min at room temperature (22 °C) preceded mounting in glycerine jelly.

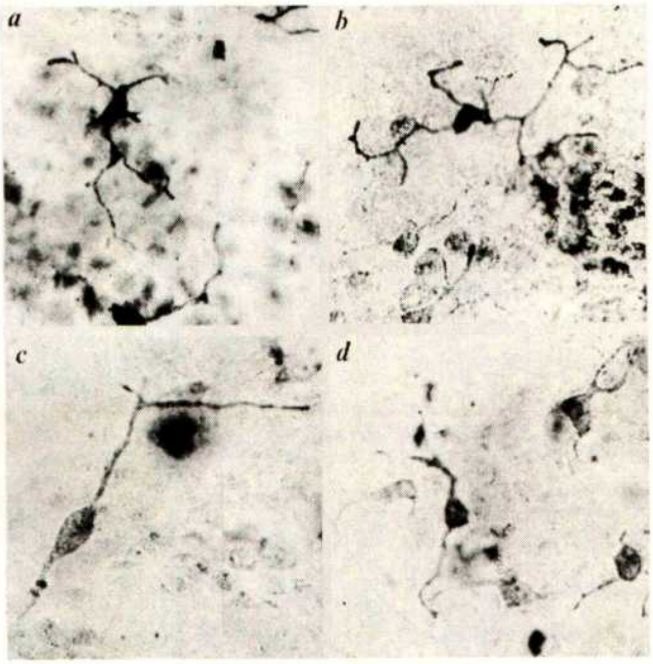

Fig. 1 Demonstration of selective uptake of various antigens by Langerhans cells in human epidermis. *a*, Mercuric chloride (ammonium sulphide developer, formaldehyde fix, Timm intensifier); *b*, nickel chloride (as in *a*); *c*, chromic chloride (as in *a*); *d*, formaldehyde (paraphenylenediamine developer, hydrogen peroxide intensifier). (×352.)

Amine uptake was studied by exposing fresh, unfixed epidermal razor biopsy specimens to PPD (46 mM) in borate buffer (*p*H 10.8), or to ethylenediamine dihydrochloride (8 mM) in 5% glucose in water for 20 min at 37 °C. The PPD-treated epidermis was then exposed to 5% *o*-phthaldialdehyde in absolute ethanol for 10 min at room temperature and mounted in xylene. The ethylenediamine-treated epidermis was exposed to 5% *o*-phthaldialdehyde in xylene for 10 min at room temperature and mounted in xylene.

All the antigens listed were selectively taken up by high level dendritic cells which could be identified in controls as Langerhans cells by the standard ATPase stain[7]. The metallic antigens, mercury, nickel and chromium (Fig. 1*a–c*) produced particularly clear outlines of the cell body with long dendrites coursing between the adjacent keratinocytes. Cobalt deposition was equally specific, although the dendrites here appeared shorter and less filamentous.

The uptake of formaldehyde clearly delineated the high level dendritic cell (Fig 1*d*), as did glutaraldehyde. The uptake of PPD and ethylenediamine by the Langerhans cells could be seen clearly only when fresh epidermal shavings were used, and it was difficult to achieve uniform staining. All the results were essentially the same in guinea pigs as in man.

This study reveals a hitherto unknown affinity of the Langerhans cell network for the most commonly known external contact sensitisers and indicates that haptens or antigens which penetrate the stratum corneum into the living avascular epidermis are trapped by a specialised protective reticulum of dendritic cells. We call this network of Langerhans cells a reticuloepithelial system, indicating its close relationship to the reticuloendothelial system which clears the body of antigens which have entered the general circulation. Thus, the epidermis has a trap for external contact antigens which parallels that of the lymph node and spleen for circulating antigenic material. The cells which remove foreign antigens from the epidermis are metallophilic, as are the specialised non-phagocytic reticuloendothelial cells of the spleen[8]. The Langerhans cells are further characterised by a high level of ATPase activity typical of reticuloendothelial cells[9]. Even more striking is the dendritic nature of the Langerhans cell, which duplicates that of the antigen-retaining cells of the lymph nodes and spleen[10]. These dendrites help the cell in its protective and clearing functions and in well stained specimens they form a virtually impassable intercellular system high in the epidermis.

The anatomy of the epidermis does not require classical phagocytes, since it is molecular, rather than particulate, matter which enters this syncytium. The Langerhans cell is thus a specialised mesenchymal scavenger which engulfs and processes chemicals entering the epidermal intercellular spaces from above or below. It must metabolise many compounds by its highly active intracellular enzyme system[4], but other compounds such as we have studied persist as sensitising antigens localised to the Langerhans cell. This cell seems to be the target cell for cytolysis and immunopathology in contact dermatitis and could be a new model for observations on the nature of delayed hypersensitivity. Our investigation was limited to antigens which could be identified by direct histological techniques, but it should be possible to trace other antigens to this reticuloepithelial system by appropriate radioactive and immunofluorescent techniques. In any event, the monoplanar topography of the Langerhans cell system within the upper epidermis may make it a more attractive test model for study than the analogous antigen-trapping cell system hidden within the spleen, lymph node and blood vessels.

Ability of activated complement components to induce lysosomal enzyme release from macrophages

THE mechanism underlying chronic inflammation is of considerable medical importance both in temperate countries—where diseases such as rheumatoid arthritis are common—and in tropical countries—where various chronic inflammatory conditions cause much disease and disability. It is generally accepted that the macrophage is the central cell in chronic inflammation. We have drawn attention to the parallelism between the capacity of various agents to induce chronic inflammation *in vivo* and selective lysosomal enzyme secretion from cultures of macrophages[1,2]. The mechanism by which macrophage enzyme secretion is induced is unknown: we now report a mechanism mediated by cleavage products of the complement component C3.

Mononuclear phagocytic cells interact with complement in several ways. Human monocytes, mouse peritoneal macrophages and rabbit alveolar macrophages have receptors for C3b (refs 3 and 4). The experiments reported here show that attachment of C3b to mouse macrophages in culture results in a dose-dependent and time-dependent release of lysosomal enzymes into the medium. Figures 1 and 2 show data for *β*-galactosidase and *β*-glucuronidase, and similar observations have been made with *N*-acetyl-*β*-D-glucosaminidase. The selectivity of the release, which occurs without cell killing, is shown morphologically and by the failure of lactate dehydrogenase to appear in the medium; the levels of this enzyme increase in cells to which C3b is attached. The C3a fragment induces release of histamine from cells that store this substance[5]. We have observed that addition of C3a to macrophage cultures also results in release of acid hydrolases. But when the time course was studied, lysosomal enzyme release in the presence of C3a was always accompanied by loss of cellular lactate dehydrogenase (Figs 2 and 3), showing that the cells had been killed. The distinct effects of C3b and C3a on mononuclear phagocytes *in vitro* are interesting in view of the possible differences in the ways by which they interact with membranes.

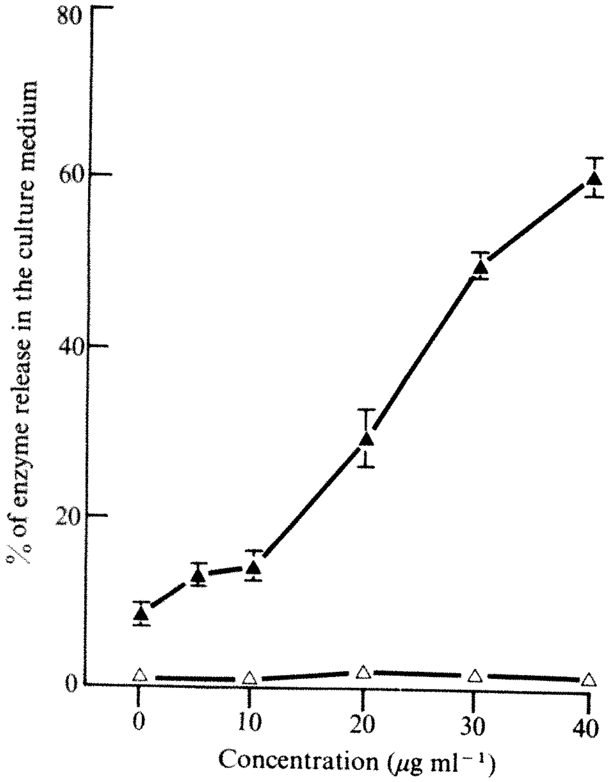

Fig. 1 The release of β-galactosidase (▲) and lactate dehydrogenase (△) from macrophages exposed to increasing concentrations of C3b. Mouse peritoneal macrophage cultures were prepared as before[12]. C3b was generated and purified as before[13]. Cells were exposed to increasing amounts of C3b for 72 h. At this time the culture medium was removed and the adherent cells were washed once with phosphate-buffered saline and then released by adding saline containing 0.1% (w/v) Triton X-100 (BDH). All fractions were assayed for β-galactosidase activity by the method of Conchie *et al.*[14]. Lactate dehydrogenase was assayed by determining the rate of oxidation of reduced nicotinamide adenine dinucleotide at 340 μm. Each value represents the mean ± s.d. of four separate plates.

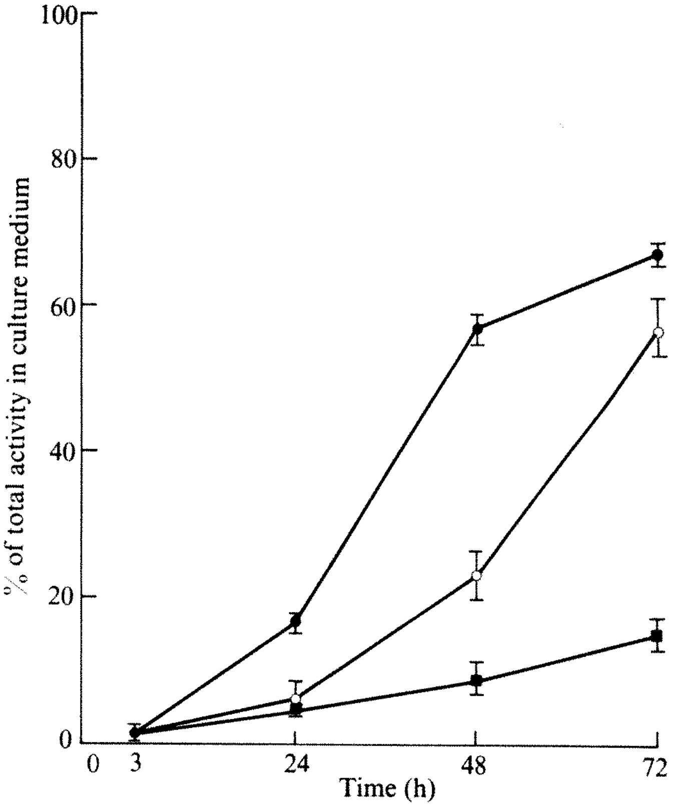

Fig. 2 The time dependence of macrophage β-glucuronidase release induced by the purified complement components C3 (■), C3b (○) and C3a (●). Highly purified guinea pig C3 was prepared as before[15]. For generation and purification of C3a, purified C3 was incubated with the C3-cleaving complex which is formed when cobra venom factor interacts with factor B, factor D and Mg^{2+} (ref. 16). This reaction mixture was put over a column of Sephadex G-100 (Pharmacia). The fractions which mediated contraction of isolated terminal guinea pig ileum were pooled and concentrated. Purified C3, C3b and C3a were provided by Dr D. Bitter-Suermann, Institut für Medizinisch Mikrobiologie, Mainz. The experimental conditions were identical to those described in Fig. 1. Each point represents the mean ± s.d. of four separate plates.

It is now clear that both granulocytes[6,7] and macrophages, phagocytic cells associated with acute and chronic inflammation respectively, can selectively release lysosomal hydrolases through the mediation of complement cleavage products, with no detectable loss of viability. This phenomenon may explain the ability of macrophages to cause tissue damage and degradation at sites of chronic inflammation while retaining their viability over long periods. This interpretation is supported by evidence that other agents inducing chronic inflammation, such as group A streptococcal cell walls[8], dental plaque[9], carrageenan[1,2] and mouldy hay dust (our unpublished results with J. Edwards), also cause selective release of lysosomal hydrolases from viable macrophages *in vitro*. All these agents

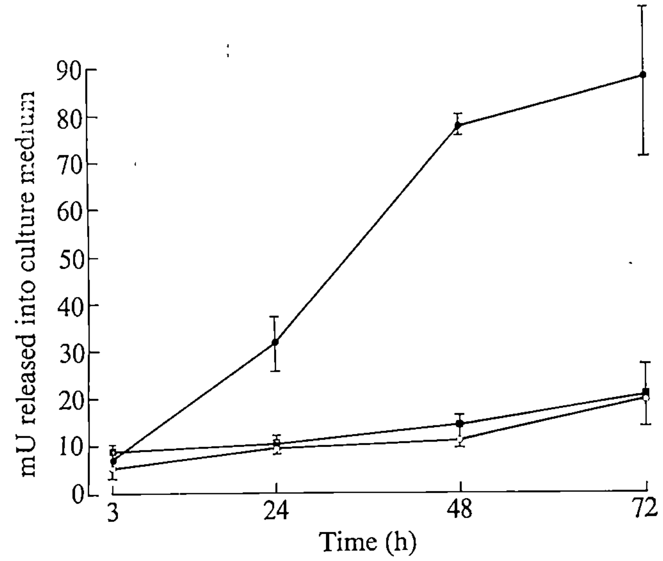

Fig. 3 Time-dependent release of lactate dehydrogenase from macrophages exposed to the purified complement components C3 (○), C3b (■) and C3a (●). The experimental conditions were identical to those described for Figs 1 and 2. Each point represents the mean ± s d. of four separate plates.

have been shown to activate complement by the alternative pathway[10,11], so generating C3b, which may be the common factor mediating enzyme release from macrophages. This system is amplified because we have found that enzymes released from stimulated macrophages can cleave C3, generating more C3b, which would, in turn, induce further enzyme release. The role of this amplification system in chronic inflammation clearly merits detailed study.

Isologous IgG-induced tolerance to benzyl penicilloyl

INDUCTION of tolerance by haptens linked to non-immunogenic carriers[1–5] is used widely, not only to investigate the cellular mechanism of tolerance[6] but also as a new approach to the treatment of experimental immune disease[7]. A potentially therapeutic application of carrier-induced tolerance is the treatment of allergic diseases. In this respect, systemic hypersensitivity reactions to penicillin constitute a major cause of death due to anaphylaxis, and penicilloyl determinant is involved in approximately half of the cases[8–10]. We report here the suppression of reaginic antibody to the benzyl penicilloyl (BPO) determinant in unprimed as well as primed mice.

Benzyl penicilloyl was bound covalently in the penicilloyl configuration to several protein carriers, and residual unbound hapten was removed by gel filtration[11]. IgG1 (MOPC245) mouse gamma globulin (MGG1) was prepared as before[12]. The following hapten carrier conjugates were used: BPO_{17}–ovalbumin (OVA) as immunising antigen, BPO_{23}–MGG1 as the tolerogen and BPO_{37}–bovine gamma globulin (BGG) as challenge antigen in the 4-h passive cutaneous anaphylaxis assay in Sprague–Dawley rats for mouse IgE antibody[13].

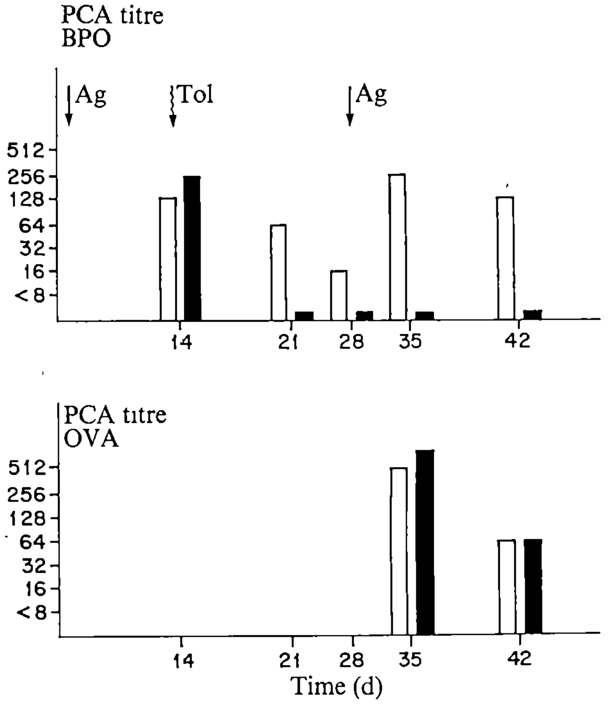

Fig. 1 Suppression of BPO IgE antibody in BDF_1 mice with BPO–MGG1 during an ongoing primary immune response. Each column represents the BPO and OVA PCA titre of pooled sera from either 10 control mice or 10 mice treated with tolerogen (Tol). The small arrows indicate the time of tolerogen or antigen administration. Open columns, control; black columns, treated with tolerogen.

The immunising regimen of Levine and Vas[14] was used to raise reaginic anti-hapten antibody in (C57BL/6×DBA/2)F_1 (BDF_1) mice. To determine whether the primary immune response to BPO could be suppressed by a single dose of tolerogen, a group of 10 (6–8-week-old) male BDF_1 mice were given 1 mg of BPO_{23}–MGG1 intravenously. Immediately thereafter these mice, as well as a group of 10 control BDF_1 mice, were injected intraperitoneally with 1 μg of BPO_{17}-OVA and 1 mg of $Al(OH)_3$ in 0.5 ml of phosphate-buffered saline (*p*H 7.4). The mice were bled on day 14 (which was shown in preliminary studies to correspond to the peak of the primary IgE antibody) and on days 21 and 28. After the third bleeding, both groups were again injected with BPO_{17}–OVA and alum and were bled 4 and 8 d later. The serum from individual mice was pooled to obtain sufficient for passive cutaneous anaphylaxis (PCA) titration. The titre of IgE anti-BPO antibody for the control group on day 14 was 1/128, 1/32 on day 21 and not detectable in serum diluted 1:8 on day 28. In contrast, in the group treated with tolerogen, no IgE antibody to BPO was detectable in serum obtained on days 14, 21 and 28 at a dilution of 1:8. The secondary response to BPO was also suppressed in the animals made tolerant to BPO–MGG1. The BPO PCA titre was 1/128 on day 4 and 1/2,048 on day 8 for the controls after the second immunogen injection. On both days, no BPO IgE antibody was detectable in serum diluted 1:8 in animals previously rendered tolerant.

To determine whether pre-existing IgE antibody response to BPO could be suppressed, two groups of 10 BDF$_1$ mice were immunised as described above. After 14 d both groups had IgE anti-BPO antibody in their serum (Fig. 1). At this time, one group of mice received 2.5 mg of BPO$_{23}$–MGG1 intravenously. All mice were bled 21 and 28 d after the initial immunisation. Both groups were subsequently injected with 1 μg of BPO$_{17}$–OVA in Al(OH)$_3$, and bled 1 and 2 weeks later. Figure 1 shows that the reaginic antibody to BPO was suppressed during both the primary and secondary response. In the secondary response, the suppression to BPO was hapten specific, since the response to the carrier OVA was unaffected.

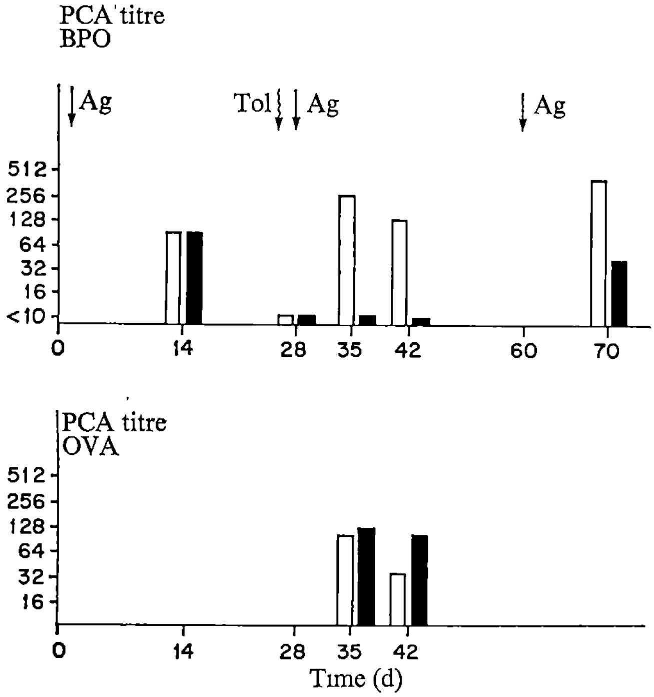

Fig. 2 Suppression of BPO IgE antibody in BDF$_1$ mice with BPO–MGG1 in the secondary immune response of primed mice. Each column represents the BPO and OVA PCA titre of pooled sera from either six control mice or six mice treated with tolerogen. The small arrows indicate the time of tolerogen and antigen administration. Columns as in Fig. 1

Finally, tolerance induction was studied in mice which had been primed with antigen after the IgE response had subsided. Immunised animals, given 1 mg of tolerogen before secondary immunisation with BPO$_{17}$–OVA, did not have detectable IgE anti-BPO antibody in their serum during the secondary response. In contrast, the IgE antibody response to the carrier OVA was the same in both groups (Fig. 2). After the third immunisation with antigen, the response to BPO was also diminished in animals treated with tolerogen before the second immunisation We believe we were dealing primarily with IgE Ab because the method of immunisation favours the production of IgE[14]. Mouse IgE but not IgG1 primed rat mast cells for PCA reaction[13] and finally the antibody involved in our experiment was susceptible to heating at 56 °C for 4 h (ref. 13).

The results suggest that the formation of reaginic antibody to the major determinant of penicillin can be suppressed in mice by injection of BPO isologous IgG before primary immunisation, during a continuing primary immune response, and before a secondary injection of hapten conjugate into primed animals. Suppression of the response was specific for the hapten, since IgE antibody to the carrier OVA was unaffected. The lack of fatal reactions in sensitised mice given 2.5 mg of BPO$_{23}$–MGG1 intravenously is interesting. The dose administered may constitute antigen excess in this system, and/or the presentation of the hapten on isologous Ig may have a protective effect. Katz and Benacerraf, using DNP–D–GL as a tolerogen[15,16], and Lee and Sehon, using DNP–MGG as a tolerogen[17,18], have shown that IgE antibody to DNP can be suppressed in either primed or unprimed rodents. Our studies extend these observations to an antigenic determinant which is prominently involved in human hypersensitivity reactions. The potential use of autologous human IgG as a carrier for induction of tolerance to antigenic determinants responsible for allergic diseases may have interesting implications

These studies were supported in part by a National Cancer Institute contract and a grant from the National Institutes of Health.

Retransformation of a thermosensitive BALB/c–3T3 transformant by murine sarcoma virus at the non-permissive temperature

CERTAIN fibroblast cell lines exhibit some of the properties of transformed cells at one temperature while retaining normal properties at a higher temperature. For example, the spontaneous transformants of BALB/c–3T3 cells isolated by W Eckhart (unpublished results) can grow in soft agar at 32 °C (the permissive temperature) but not at 39 °C (the non-permissive temperature). They show transformed morphology at 32 °C but normal morphology at 39 °C (ref. 1). They have certain temperature-sensitive surface properties such as ability to grow in Agarose, loss of a transformation-sensitive iodinatable glycoprotein (LETS)[2,3], increase in total cell proteolytic activity[4] and loss of the growth promoting activity of fibroblast growth factor[5]. But they behave normally with respect to the regulation of intracellular events. Unlike transformed fibroblasts, both at permissive and non-permissive temperatures, BALB/c–3T3 cells exhibit density-dependent growth inhibition[5]. They cease growing as a result of serum limitation and express the typical increases in protein synthesis, ribosomal RNA synthesis and DNA synthesis when growth is initiated[1,6] The evidence therefore suggests that the transformants have lost their potential to express a transformed phenotype at the non-permissive temperature. I now show that this is not an irreversible loss by demonstrating that murine sarcoma virus (MSV) can transform the cells at the non-permissive temperature.

Table 1 Transformation assay of tsCl 1 and BALB/c–3T3 Cells with MSV at 39 °C

Virus dilution	No. of transformed foci per plate tsCl 1	No. of transformed foci per plate BALB/c–3T3	No. of labelled foci per plate tsCl 1	No. of labelled foci per plate BALB/c–3T3
10^{-2}	⩽500	⩾500	⩾500	⩾500
10^{-3}	150±20	87±12	185±24	105±15
10^{-4}	17±5	10±3	25±8	13±4
Mock infected	0	0	0	0

tsCl 1 or BALB/c–3T3 cells (10^6) were plated per 90-mm dish in Dulbecco's modified Eagle's medium containing 10% foetal calf serum (Flow). A day later, the cells were treated in 1 ml of medium containing polybrene (25 µg ml^{-1}) and Kirsten MSV (10^6 FFU) at the appropriate dilutions, or in mock-infected controls, for 2 h with frequent shaking. The cells were then allowed to incubate in medium containing 10% serum Transformed foci could be seen 3–4 d after exposure to virus and were scored at 7 d. Results obtained using a microscope, are expressed as the number of transformed foci per plate. Alternatively, on day 7, when the cultures became confluent, the cells were incubated in medium containing 1% serum and ^{3}H-thymidine (3 µCi ml^{-1}) at 1 µM for 24 h. Subsequent fixing and autoradiography of the dishes showed that only cell nuclei of transformed foci became labelled. Dishes were stained with Giemsa and results were expressed as the number of visible radioactively labelled colonies per dish All numbers represent averages of three separate determination ± two standard deviations.

An independent temperature-sensitive clone of BALB/c–3T3 cells (tsCl.1) was infected at 39 °C with a Kirsten strain of MSV (supplied by Dr G S. Martin). Transformed foci appeared in both tsCl.1 and the control BALB/c–3T3[7]-infected cultures. Both mutants and parent cell cultures were characterised with respect to saturation densities, regulation of DNA synthesis, growth in agar, and proteolytic activity in a casein overlay assay. The data presented here indicate that tsCl.1 can be transformed at 39 °C and that it can be rendered as fully transformed as the virally transformed cell lines Py3T3 (ref. 8) and SV3T3 (ref. 9).

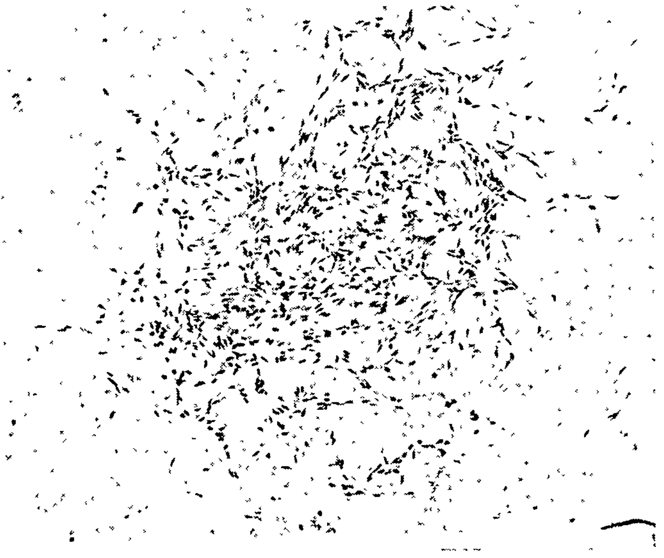

Fig. 1 Radioactively labelled focus of BALB/c–3T3 cells induced by MSV at 39 °C. Seven days after infection with MSV, the cells were exposed to ^{3}H-thymidine (3 µCi ml^{-1}) at 1 µM in Dulbecco's modified Eagle's medium containing 1% foetal calf serum for 24 h and processed as described previously. Cells were stained with Giemsa and photographed under the light microscope (×35).

Logarithmically growing cells were exposed to various dilutions of Kirsten MSV (10^6 FFU) at 39 °C. Foci were seen 3–4 d after infection but were routinely counted on day 7. As reported previously[10–12], their detection was difficult and required optimal culture conditions, such as rich medium and high inoculation densities. Transformed foci appeared as round refractile cells, adhered poorly to the plastic dish, had a tendency to float off into the medium and could not be stained easily. To screen large numbers of cultures for transformed foci rapidly, I developed a method which involves exposure of the virus-infected cultures to ^{3}H-thymidine in a medium containing low serum concentrations (0.5–1% foetal calf serum). In confluent cultures, transformed foci showed incorporation of ^{3}H-thymidine into labelled nuclei, whereas the uninfected parental BALB/c–3T3 cells remained unlabelled. As Fig. 1 shows, after autoradiography[13] and subsequent staining of the dishes, transformed foci could be recognised and counted. Table 1 shows the transformation assay of tsCl.1 and the parental

Table 2 Caseinolytic activity and growth in soft agar

Cell type	Temperature (° C)	Degree of casein hydrolysis (scale 0 to +4) MSV infected	Degree of casein hydrolysis (scale 0 to +4) Uninfected	Colony formation (%) MSV infected	Colony formation (%) Uninfected
tsCl.1	32	+4	+3	34	22
	39	+4	0	39	0.7
BALB/c–3T3	32	+3	0	20	0.3
	39	+3	0	28	0.5

Ten transformed foci were selected independently from each of the MSV-infected tsCl.1 and BALB/c–3T3 cells at various dilutions. While the uninfected parental cultures contained no detectable virus, all focus-derived lines showed evidence of virus production as determined by an XC plaque assay[11], thus excluding spontaneously transformed foci For the measurement of caseinolytic activity, untransformed BALB/c–3T3, mutant tsCl.1, and cloned MSV-transformed BALB/c–3T3 and tsCl 1 cells grown at their respective temperatures were each plated at 10^5 cells per 5-cm Petri dish in Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum. After 5 h the monolayers were washed twice in serum-free medium and overlayered with 1 ml of medium at 45 °C, containing 0.6% Agarose (Difco), 2% powdered milk (Marvel), and 0.5% green African monkey serum (Gibco) The Agarose was allowed to harden at room temperature and the plates were then returned to incubate at 32 °C and 39 °C. The extent of plasmin-mediated caseinolysis was estimated after 40–50 h at 39 °C and after 80–120 h at 32 °C, based on a scale of 0 (no clearing) to +4 (complete clearing), according to the proportion of casein removed The ability of the cells described above to grow in soft agar was determined by plating 10^5 cells in medium containing 10% foetal calf serum in 5-cm Petri dishes. A day later cells were overlayered with 5 ml of a suspension of 0.33% agar (Difco) and 10% foetal calf serum in medium at 45 °C Cells were incubated at 32 °C or 39 °C and the number of colonies per dish determined 2 and 3 weeks later. The percentage of cells which grew in agar is shown Results represent averages of the focus-derived lines as determined in three separate experiments

BALB/c–3T3 cells at 39 °C. Transformed foci in the unstained dishes were scored, with the aid of a microscope, 7 d after infection. They were then compared with the numbers of labelled foci in the autoradiographed and stained dishes. The use of labelled nuclei makes possible detection of small colonies so that the numbers of labelled foci were slightly higher. The results showed essentially a one-hit response curve[12].

Fibroblasts transformed by DNA or RNA tumour viruses show markedly higher levels of proteolytic activity than do their normal untransformed counterparts[14,15]. This arginine-specific protease converts serum plasminogen to its enzymatically active form, plasmin. The plasmin in turn can be detected by its ability to hydrolyse milk protein in a casein overlay assay[16]. MSV-transformed tsCl.1 and BALB/c–3T3 foci were selected independently and grown at their respective temperatures. Monolayers of the cloned cultures and their normal counterparts were overlayered with Agarose containing casein in the presence of 0.5% monkey serum, and the extent of caseinolysis was measured at 32 °C and 39 °C. Thus, the transformed tsCl.1 and BALB/c–3T3 cells showed a marked caseinolytic activity over the non-transformed counterparts at 39 °C (Table 2). Similarly, when the cultures were trypsinised and tested for their ability to grow in soft agar[17], another parameter for measuring the degree of transformation in cell lines, the MSV-transformed variant and parent cells formed 39% and 28% colonies at 39 °C, respectively, compared with 0.7% and 0.5% colony formation of the uninfected cultures (Table 2).

Cloning efficiency and saturation density of the MSV transformants were higher at both temperatures compared with the uninfected cell counterpart at 32 °C. Thus, the final cell density of tsCl.1 in medium containing low serum concentration (1% foetal calf serum) was approximately twice as great at 32 °C than at 39 °C (2×10^6 and 0.9×10^6 cells per 5-cm dish at 32 °C and 39 °C, respectively), similar to untransformed 3T3 cells. In contrast, approximately a tenfold increase in saturation density of the MSV-transformed tsCl.1 and BALB/c–3T3 cells was observed over the normal phenotype. At low serum concentrations, MSV-transformed tsCl.1 cells reached saturation densities of 19×10^6 cells per 5-cm dish at 39 °C and 32 °C, respectively. Similarly, MSV-infected tsCl.1 cultures left to become confluent and exposed to ^{3}H-thymidine for 24 h at 39 °C and for 48 h at 32 °C showed incorporation of radioactivity only into nuclei of transformed foci. This was also the case for the parental BALB/c–3T3 cells (Fig. 1), which is another method of demonstrating that the MSV-transformed cells have overcome density-dependent inhibition of growth with respect to DNA synthesis.

Whether retransformation of a temperature-sensitive cell mutant at the non-permissive temperature is a general phenomenon that can be carried out with either DNA or RNA viruses remains to be determined. Renger retransformed temperature-sensitive SV3T3 cells with MSV at the non-permissive temperature[18] but the same cells could not be retransformed with high multiplicity SV40 (ref. 19). Similarly, SV3T3 revertants initially isolated by Pollack *et al.*[20], and the revertants of polyoma-transformed BHK cells[21] could not be retransformed by their respective viruses but could be rendered fully transformed by exposure to murine[18] or hamster sarcoma[21] viruses, respectively. In this study, however, tsCl.1 and another similar independent clone tsCl.10 (supplied by Dr W. Eckhart) could be retransformed both by an RNA virus (MSV) and by a DNA virus (SV40) at the non-permissive temperature. Unlike SV3T3, the SV40-transformed ts clones could grow in soft agar (not shown).

In summary, MSV-induced transformation of temperature-sensitive cell variants can be accomplished at the non-permissive temperature. Thus, I have demonstrated growth in soft agar, increase in caseinolytic activity, higher saturation densities and loss of regulation of growth and DNA synthesis after MSV transformation. My results suggest that a virus function can render these temperature-sensitive cells fully transformed with respect to certain properties of their intracellular machinery. Alternatively, the process of virus infection may induce a cell regulatory function. This possibility is being investigated, using a temperature-sensitive mutant of MSV to determine whether complementation can occur between the cellular mutation and the viral mutations which render the viral transformation temperature sensitive.

I thank Dr R. Dulbecco for support and encouragement, Drs G. S. Martin and N. Teich for murine sarcoma virus and for advice, Dr W. Eckhart for temperature-sensitive cell variants and Drs A. Shatkin, S. Kerwar and P. S. Rudland for criticism of the manuscript. This work was supported by a fellowship from the Jane Coffin Childs Memorial Fund for Medical Research.

Exceptional mutagenicity of a benzo[*a*]pyrene diol epoxide in cultured mammalian cells

BENZO[*a*]PYRENE (BP) is one of a group of chemically inert carcinogens which, in order to exert their cytotoxic, mutagenic and carcinogenic effects, require metabolic activation by mixed function oxygenases (MFO) to products capable of covalent reaction with cellular macromolecules[1–3]. More specifically, it has been shown in mouse skin[4] and various cultured mammalian cells[5], that, in the case of DNA, the extent of this reaction correlates with the carcinogenic potency of the compound. The hypothesis that DNA is the important target for this series of hydrocarbons is further supported by evidence that the most carcinogenic members are also the most mutagenic towards hamster cells *in vitro*[1]. Here we present evidence that a diol epoxide derivative of BP is a powerful mutagen when applied to mammalian cells, and suggest therefore that this compound is the ultimate carcinogenic metabolite of BP.

Although various models have been proposed regarding the nature of the BP–DNA reaction[6], convincing experimental evidence has been lacking. Recent chromatographic analysis of DNA from hamster embryo cells exposed to ^{3}H-BP, however, has established that, for this hydrocarbon, the binding species is a *trans*-7,8-dihydro-7,8-dihydroxy-9,10-epoxy derivative produced by a two-step metabolic event through the 7,8-epoxide[7]. Hulbert has predicted[8], on theoretical grounds, that two stereoisomers of this diol epoxide are possible (designated syn and anti, see Fig. 1) and that only one of these, syn, would be expected to react significantly with DNA *in vivo*. Both isomers have been synthesised and the stereochemistry of each confirmed by analysis of their integrated proton nuclear magnetic resonance (NMR) spectra[9].

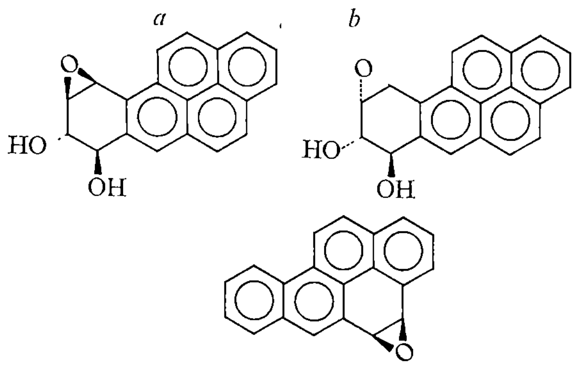

Fig. 1 Structural formulae of the three benzo[*a*]pyrene (BP) derivatives under investigation. *a*, BP diol epoxide syn configuration, *b*, BP diol epoxide anti configuration; *c*, BP-4,5-oxide (K-region epoxide). The two stereoisomers of BP diol epoxide have been designated syn and anti[9] to indicate the relationship of the epoxy group *cis* or *trans* to the 7-hydroxyl function. Hulbert[8] predicted that hydrogen bonding between these two groups, which is possible only in the case of syn, will facilitate opening of the epoxide, in effect producing an aralkyl carbonium ion on C9 or C10 of the molecule. This isomer would therefore react with appreciable S_N1 character and so show little preference *in vivo* for strong nucleophiles over relatively weak nucleophiles such as DNA. Anti and BP-4,5-oxide on the other hand, would be expected to react predominantly by an S_N2 mechanism and be much less reactive towards DNA, especially in the presence of strong competing nucleophiles such as the SH groups of glutathione and proteins.

We therefore thought it prudent to examine, in cultured mammalian cells, the cytotoxic and mutagenic properties of both diol epoxide isomers and to compare their respective activities with BP-4,5-oxide, the so-called K-region epoxide. For this purpose we used V79 cells, an established line with undetectable MFO activity[10] and, as a mutational marker, resistance to the purine analogue 8-azaguanine. This system is used widely to study mutagens which act directly and it is generally accepted that variants arise as a consequence of gene mutation. Our results indicate that all three compounds differ in their ability to induce mutations at this locus and that one diol epoxide isomer has exceptional mutagenic properties.

Figure 2 summarises the results of several experiments in which the three derivatives were compared in identical conditions. Parallel cultures of exponentially growing cells were exposed for 24 h to a range of concentrations of each compound, and replicate samples were plated for determination of induced cytotoxicity and mutagenesis (details in Fig. 2 legend). For each derivative a similar type of multitarget dose–survival curve was obtained, with a shouldered region at low doses followed by a steep exponential portion. The dose range required to achieve this response, however, varied, approximately in the ratio 1:3:6 for anti, syn and BP-4,5-oxide respectively. Similarly, the corresponding D_0 values were calculated as 0.10, 0.25, 0.85 μg cm^{-3} of culture medium. Further interpretation of the survival data in terms of the extent of the hydrocarbon–DNA reaction was precluded because labelled BP diol epoxides were not available.

The mutational response, as a measure of specific DNA modification, not only reflected the overall variations observed in the survival experiments but also revealed more subtle

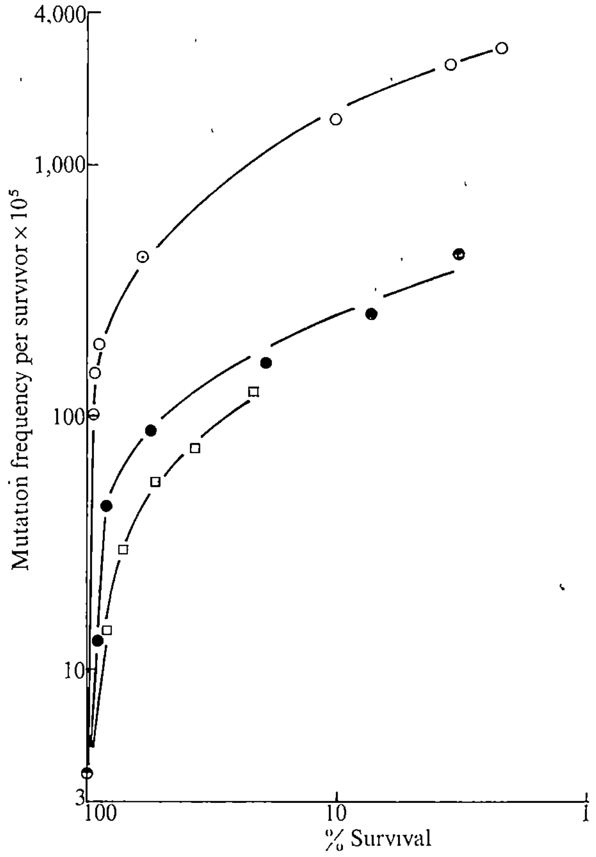

Fig. 2 Mutagenesis of V79 Chinese hamster cells as a function of percentage survival: ○, BP diol epoxide anti; ●, BP diol epoxide syn; □, BP-4,5-oxide. The results, derived from individual dose–response experiments, were expressed in this way to facilitate a direct comparison between the derivatives in terms of mutagenic efficiency. Mutation frequency was plotted on a logarithmic scale so that all three responses could be represented accurately on one graph. Linear–logarithmic plots of mutation frequency against survival respectively were linear below 85% survival. In all experiments 75-cm^2 plastic tissue culture flasks (Falcon), containing 30 cm^3 of Dulbecco's modified minimal essential medium with 10% foetal calf serum (Gibco), were each seeded with 8×10^5 cells grown from a clonal stock frozen in liquid nitrogen. After 18 h the resulting exponentially growing cultures were treated with various doses of the compounds added in 0.1 cm^3 of dimethylsulphoxide (DMSO). All hydrocarbon solutions were made up immediately before use in DMSO which had been dried over a molecular sieve. The precise concentration of each derivative in solution was established by ultraviolet spectrophotometry. After 24 h of treatment at 37 °C the cells were detached from each flask with trypsin–EDTA and the density of the resulting single-cell suspension was estimated with a haemocytometer. For the determination of induced toxicity, 2×10^2 cells, and for mutagenesis 5×10^4 cells, were plated in 5-cm and 9-cm plastic tissue culture dishes (Sterilin) respectively, and incubated at 37 °C in a humidified atmosphere of 5% CO_2:95% air. Mass selection of mutants defective in the purine salvage enzyme, hypoxanthine guanine phosphoribosyl transferase was effected by adding 8-azaguanine to the plates such that its final concentration in the medium was 30 μg cm^{-3}. To achieve maximum recovery of mutants, a complete expression time curve[11] was constructed for each dose of hydrocarbon. In practice, five to ten replicates were treated with 8-azaguanine at each of six expression time points ranging from 0 to 120 h after plating. Survival plates were stained after 7 d of incubation, mutation plates 3 d later, and colonies of more than about 50 cells were scored macroscopically. Mutation frequencies were corrected for toxicity and calculated per surviving cell. The values shown in the figure are those obtained from the peak expression times which ranged from about 48 h for shoulder doses to 96 h for the more lethal treatments. Control frequencies never exceeded 4×10^{-5} per survivor. We have already discussed the various pitfalls encountered in this type of experiment[12].

differences between the compounds. The dose response was cumulative for each compound, a characteristic observed by others who used these cells as targets for the classical mutagens EMS, MMS, X rays and ultraviolet light[13,14]. Although syn and BP-4,5-oxide proved relatively powerful mutagens, the absolute mutation frequencies obtained with anti were unexpectedly high. Wood *et al.* have tested BP-4,5-oxide in V79 cells[15] and the close agreement of our results with those for that epoxide served as a useful indication of the reproducibility of the system.

A double logarithmic plot of mutation frequency against survival is used frequently to discriminate between mutagens where the only measure of effective dose is induced toxicity. When the results discussed above are plotted in this way (Fig. 2) the true mutagenic potency of anti becomes clear, it being more than eight times as active as BP-4,5-oxide at 37% survival (e^{-1} = one lethal hit). This distinction between cytotoxic events and mutagenesis is best illustrated by applying the term "mutagenic efficiency"[16] to our data, which we define as the mean rate of increase of mutation frequency per lethal hit.

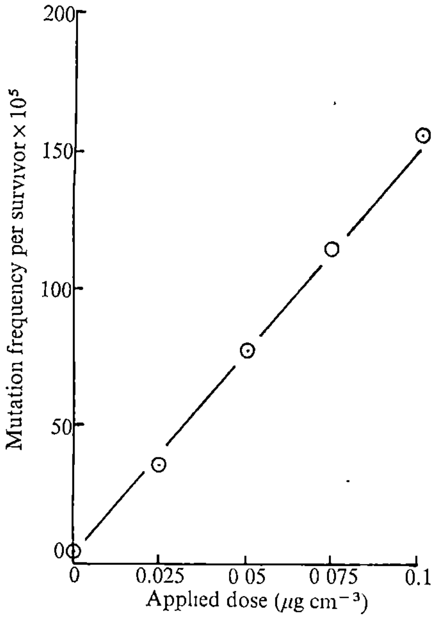

Fig. 3 The mutagenic activity of antidiol epoxide at shoulder doses. Experiments were carried out as described in legend to Fig. 2.

For all three compounds linear-logarithmic plots of induced mutation frequency against survival respectively were approximately linear when only the exponential portion of each survival curve was considered, thus reflecting a direct proportionality between the two effects. The response in each case can therefore be represented adequately by an equation of the form: $y = ax+b$, where a is the slope and thus the mutagenic efficiency, and b is the intercept on the y (mutation frequency) axis, resulting from a higher rate of mutagenesis at minimally lethal and subtoxic doses. For anti, syn and BP-4,5-oxide these equations were calculated as: $y_{\mathrm{anti}} = 10^{-4}\ (56x+20)$, $y_{\mathrm{syn}} = 10^{-4}\ (8.6x+2.3)$ and $y_{\mathrm{k}} = 10^{-4}\ (8.6x+0.1)$, respectively.

Although BP-4,5-oxide was, not unexpectedly, the least powerful of the BP derivatives tested, the observed differences between the two diol epoxide isomers are difficult to explain on the basis of Hulbert's arguments[8]. Indeed, the syn isomer was predicted to be the most active. It should be appreciated, however, that mutagenesis has been examined at only a single genetic locus so far, and this may not be representative of the whole genome or indeed those targets relevant to carcinogenesis. Also, we have not finally established which isomer binds to DNA after BP is metabolised *in vivo*. Nevertheless, we feel that the possible contribution of these findings towards the understanding of BP carcinogenesis cannot be ignored.

Further examination of the anti isomer with respect to its mutagenic potency at sublethal shoulder doses proved equally exciting. The results (Fig. 3) demonstrate that in the absence of measureable toxicity, mutagenesis increases proportionally with dose. The type of low dose experiment is likely to be much more representative of human exposure to environmental BP. Moreover, the induction of cancer through somatic mutation(s) may well require that a powerful carcinogen be an efficient mutagen, that is that it can induce the necessary mutations in the DNA of the target cell with the minimum of concomitant side effects. The anti isomer of diol epoxide discussed here certainly meets this requirement.

We thank Dr F. Beland and Professor R. G. Harvey, University of Chicago, for BP derivatives. This work was supported by a contract from the NIH and in part by grants to the Institute of Cancer Research from the Medical Research Council and the Cancer Research Campaign.

Tumorigenicity and the expression of cell-surface carbohydrates

TUMOUR cell populations are heterogeneous with respect to various biological properties[1–3]. Immunological properties that influence tumour–host relationships and metastatic properties of tumours may also differ between subpopulations of tumour cells[4,5]. In addition, conditions of growth may favour the emergence of subpopulations, and the immunogenic modification of susceptible subpopulations. We have reported that highly immunogenic tumour cells can be isolated from the parental tumour by concanavalin A (con A)–affinity chromatography[6,7], and the relative proportion of different subpopulations varied with different conditions of growth. We now report that the tumorigenicity of murine adenocarcinoma varies as a function of the tumour subpopulations present, as defined by their expression of cell-surface carbohydrates.

The transplantable mammary adenocarcinoma A-10 (syngeneic to strain A/J mice) has been maintained as an ascitic tumour in B6AF$_1$ (C57BL/6×A/J) mice, and in monolayer culture using RPMI 1640 medium, supplemented with 10% foetal calf serum and antibiotics.

The tumorigenicity of A-10 cells grown *in vivo* and *in vitro* is summarised in Table 1. An intraperitoneal inoculum of 10^2 or 10^3 cells grown *in vivo* routinely caused 100% mortality of B6AF$_1$ mice, whereas similar inocula of cells grown *in vitro* caused about 50% mortality. Inocula of up to 10^6 cultured cells were not always 100% fatal (J.J.K. and

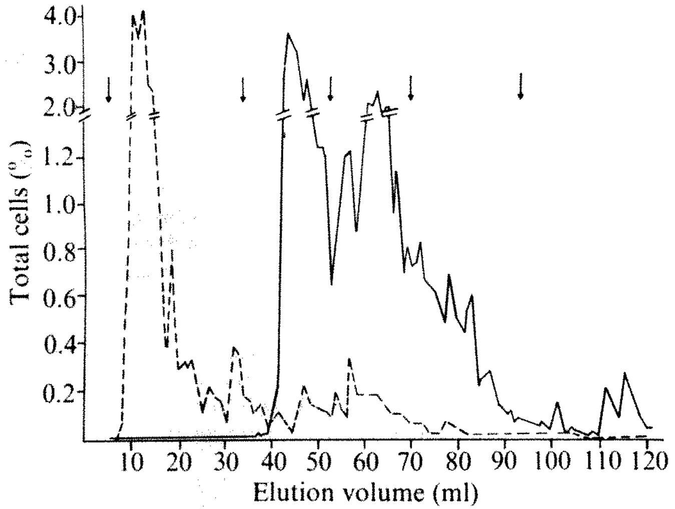

Fig. 1 The elution profile of A-10 cells from con A–affinity columns. The percentage of total cells is shown as a function of elution volume. This technique has been described in detail elsewhere[7]. Cells were prepared as described in Table 1, and eluted with the sequential addition (arrows) of PBS, α-methyl-D-mannoside, α-methyl-D-glucoside, sucrose and α-D-glucose. ---, Cells grown *in vivo*; —, cells grown *in vitro*. Ammonium oxalate wash of cultured cells did not affect the elution profile.

W.A.S., unpublished results). This difference in tumorigenicity was probably mediated by immunological mechanisms since an inoculum of 10^2 cultured cells killed 100% of immunosuppressed mice with an average survival time similar to that for mice inoculated with cells grown *in vivo*.

Cultured A-10 cells regained the tumorigenicity observed for cells grown *in vivo* when subsequently passaged as an ascitic tumour. Thus the tumorigenicity of this murine adenocarcinoma depended on conditions of tumour cell growth.

The elution profile of A-10 cells from con A–affinity columns also depended on conditions of cell growth (Fig. 1). Tumours grown *in vivo* contained a large subpopulation of cells eluted with PBS (not initially binding the column) and few cells were released by subsequent addition of sugar competitors for con A binding. In contrast, cultured A-10 tumour contained virtually no PBS-eluted subpopulation, and was characterised by subpopulations released with the different sugar solutions.

The elution profile of cultured A-10 cells was evaluated after the first and second passage in normal mice. As Fig. 2 shows, the first passage of cultured cells *in vivo* gave subpopulations characteristic of cells grown both *in vivo* and *in vitro*, that is, cells eluted with PBS, and large numbers of cells released by sugar solutions. The tumorigenicity of these cells was comparable with that observed for cultured cells (Table 1). But, after the second passage of cultured cells *in vivo*, the elution profile had reverted almost completely to that of tumour grown *in vivo*. A large subpopulation was defined by elution with PBS, and few cells were released from the column by sugar. This profile correlated with a marked increase in tumorigenicity.

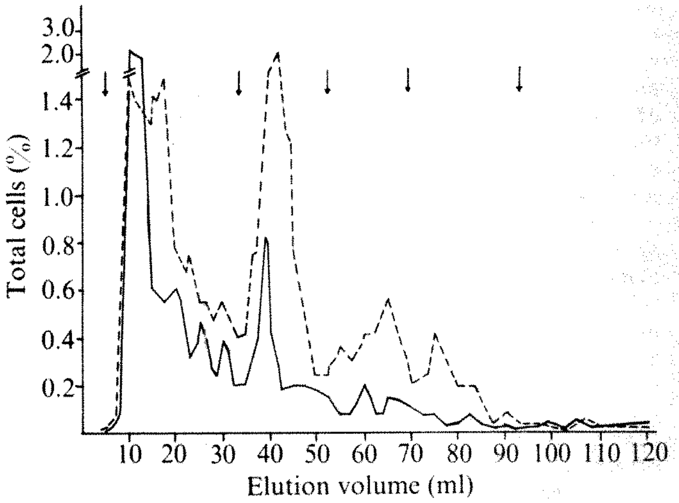

Fig. 2 The elution profile of cultured A-10 tumour after the first (- - -) and second (—) passage in B6AF$_1$ mice. The percentage of total cells is shown as a function of elution volume (see Fig. 1).

The antigenic properties of tumour cells and the expression of tumour-associated antigens have been altered by conditions of growth before[8–11], but few studies have correlated surface properties of intact cells with either progressive tumour growth or tumour rejection. Studies on the tumorigenicity and strain-specificity of another murine mammary tumour, TA3 (refs 12–15), have shown the presence of a membrane glycoprotein, epiglycan, which correlated with loss of strain-specificity of TA3–Ha cells. Epiglycan was lost reversibly after these cells were cultured, and correlated with a return of strain-specific tumorigenicity. When TA3–Ha cells were grown *in vitro* other membrane changes occurred[15], including a marked increase in the molar proportion of mannose to total hexosamine. In the light of our results, the relative increase of this con A-binding carbohydrate is particularly interesting.

We have demonstrated that tumour cell subpopulations of different immunogenicity could be isolated by a method based on their expression of cell-surface carbohydrates[6,7]. In addition, complement-dependent cytotoxicity of serum from tumour-immune animals was inhibited by α-methyl-D-mannoside, a sugar used to elute highly immunogenic cells from con A columns. It seems reasonable that the relative

Table 1 Tumorigenicity of A-10 cells in B6AF$_1$ mice after growth *in vivo* or *in vitro*

Inoculum, growth conditions, host	No. survivors/No. inoculated	Survival time
10^2 Cells, *in vivo* normal host	0/10	23.2±2.3
10^3 Cells, *in vivo* normal host	0/10	21.0±1.8
10^2 Cells, *in vitro* normal host	5/10	27.1±0.8
10^2 Cells, *in vitro* immunosuppressed host	0/10	23.0±0.6
10^2 Cells, *in vitro* to *in vivo*, 1st passage, normal host	4/5	33.0
10^3 Cells, *in vitro* to *in vivo*, 1st passage, normal host	3/5	31.0
10^2 Cells, *in vitro* to *in vivo*, 2nd passage, normal host	0/5	24.2±0.6
10^3 Cells, *in vitro* to *in vivo*, 2nd passage, normal host	0/5	18.6±1.7

Tumorigenicity of A-10 cells was determined by transplantability into B6AF$_1$ mice. Tumour cells grown *in vivo* were washed once in 1% ammonium oxalate (to lyse erythrocytes), followed by two washes in PBS. Cells grown *in vitro* were collected from logarithmic-phase cultures by a rubber policeman, followed by two washes in PBS. Cells for all experiments were >90% viable, as judged by Trypan blue exclusion. Immunosuppression of B6AF$_1$ mice was by whole body irradiation, 450 rad, 24 h before injection of tumour. Intraperitoneal injections contained the appropriate number of cells in 0.2 ml of PBS. Survival time of mice represents the arithmetic mean ± s.e.

amount of mannose-like carbohydrates on the cell surface could influence the antigenic expression of tumour cells.

On the basis of our observations, together with the evidence of heterogeneity in tumour cell populations[7,16], we can speculate on the tumorigenicity of A-10 adenocarcinoma. The subpopulation eluted with PBS comprised a substantial proportion of A-10 tumour grown *in vivo* (45%–50%) and was absent from cultured cells. But the presence of this subpopulation was not necessary for tumour growth *per se*, for cultured cells grew in immunosuppressed mice. This subpopulation may therefore be analogous to the phenotypic expression of epiglycan, and decreased expression of tumour-associated antigens; concomitant with a decreased proportion of mannose-like moieties at the cell surface.

The subpopulations of cells released by sugar, predominantly a feature of cultured cells, would be the inverse analogue of the above situation. The increased proportion of cell-surface con A-binding moieties could result in an increased expression of tumour-associated antigens and decreased tumorigenicity, except in the immunosuppressed host. We observed a 300-fold increase in the agglutinability of A-10 cells by con A after the cell line was established *in vitro*, which was consistent with increased expression of mannose-like moieties (J.J.K., unpublished results). These subpopulations would be selected against by passage of tumour *in vivo*, and the PBS-eluted phenotype would become dominant (Fig. 2). Tumorigenicity would be restored in the normal host.

Although more complex explanations are possible, the concept of tumour-cell subpopulations which depend on tumour-cell environment may have implications for the way in which tumour-cell properties ultimately influence the relationship between tumour and host.

We thank Ms Debbie Santelli and Mr Marshall Ferrell for technical assistance. The A-10 cell line was a gift from Dr Barbara Sanford, National Institutes of Health. This work was supported in part by contracts from the National Cancer Institute.

Characterisation of Aleutian disease antigens

ALEUTIAN DISEASE (AD), which affects certain *Mustelidae*, is a persistent viral infection with development of non-neutralising antibody and gammapathy[1–3]. Some of the antigens developed in the course of AD are detectable by counter-immunoelectrophoresis (CEP) using sera from chronically infected mink. We have obtained evidence of two antigenic forms, Ag-1 and Ag-2, which have been characterised by molecular size, primary protein subunit components and by electron microscopy. Hollow ring-like structures, similar to those described with such viruses as φX174[4], rat virus, Haden, adeno-associated virus and others[5], were found associated with the AD virus (ADV) and seem to be the predominant antigenic component of Ag-1.

The CEP antigens, Ag-1 and Ag-2, were prepared from liver homogenates of ADV-infected mink by repeated Freon extraction and pelleting as described by Cho and Ingram[6]. These extracts were analysed by CEP at each step during the re-extraction procedure. Subsequently, samples rich in Ag-1 and Ag-2 were analysed by velocity sedimentation, molecular filtration and equilibrium density sedimentation. Further analyses consisted of electron microscopy and SDS–polyacrylamide gel electrophoresis of purified antigens.

Electrophoresis of antigens Ag-1 and Ag-2 by CEP revealed that they had different electrophoretic mobilities (Fig. 1). When Ag-1 and Ag-2 were mixed in varying proportions (threefold serial dilutions of Ag-2 and a constant amount of Ag-1), they consistently showed two precipitin bands when resolved by CEP against pooled AD antisera. CEP patterns revealed that Ag-2 was gradually lost during preparative steps consisting of repeated Freon extraction and pelleting; whereas Ag-1 persisted in these conditions. This formed the basis for the partial fractionation of Ag-2 and Ag-1 since Ag-2 was the predominant component in

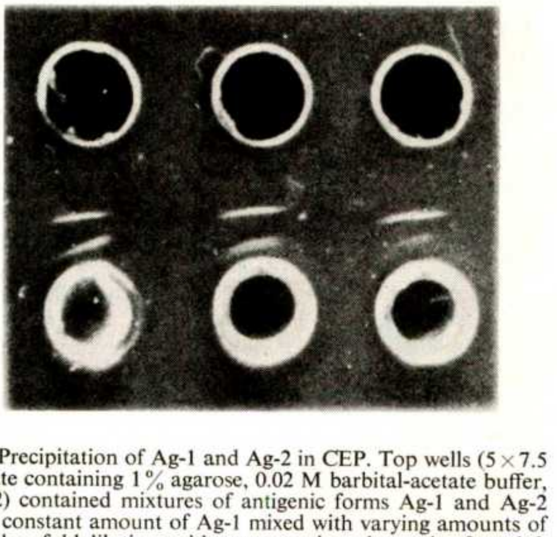

Fig. 1 Precipitation of Ag-1 and Ag-2 in CEP. Top wells (5×7.5 cm plate containing 1% agarose, 0.02 M barbital-acetate buffer, *p*H 8.2) contained mixtures of antigenic forms Ag-1 and Ag-2 with a constant amount of Ag-1 mixed with varying amounts of Ag-2 (threefold dilutions with concentrations decreasing from left to right). The bottom wells contained AD antisera. Ag-1 and Ag-2 were prepared from livers of pastel mink infected 8 d previously with 1 ml 10% w/v liver suspension, Connecticut strain ADV. The method of Cho and Ingram[6] was used which consisted of homogenisation, low speed centrifugation, and three repeated extractions of supernatants with Freon (Du Pont, trichlorotrifluoroethane). The antigens were pelleted from the aqueous phase by high speed centrifugation (180,000*g* for 90 min) to yield Ag-2. Further repeated Freon extraction (1 part Freon, 3 parts antigen solution) followed by high speed centrifugation yielded only Ag-1 activity. The Ag-1 was further purified by equilibrium density centrifugation (CsCl); fractions containing peak Ag-1 activity (1.33–1.35 g cm^{-3}) were dialysed and used in the above precipitations.

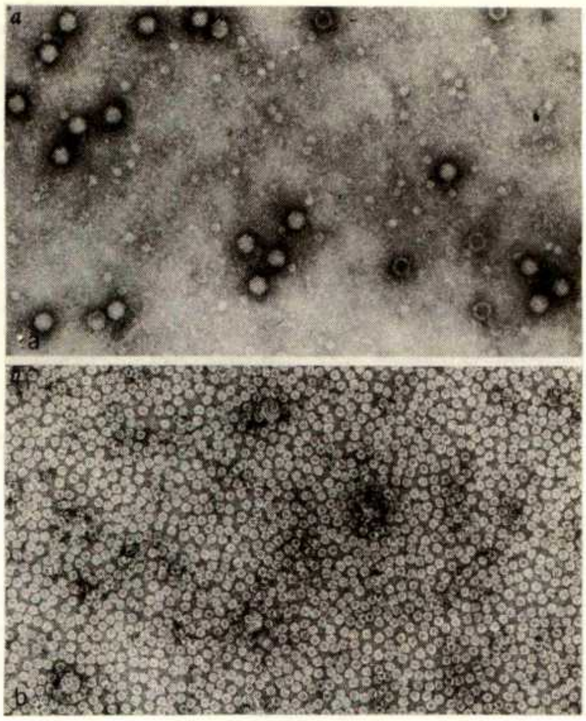

Fig. 2 *a* and *b*, Electron micrographs of Ag-1 component (pooled CsCl fraction 1.33–1.35). *a*, Icosahedral virus particles as well as ring-like structures (stained with sodium phosphotungstic acid, *p*H 7.0). *b*, Similar material stained with uranyl acetate, *p*H 4.2. Magnification: *a*, 100,000; *b*, 117,500.

intermediate (three times) Freon extracted preparations. The relative titre of Ag-2 in these preparations was about 100-fold greater than Ag-1 when estimated by endpoint titrations. On the other hand, after five extractions with Freon, Ag-1 was the only detectable antigenic structure which formed a precipitin band. Although the antigenic forms, Ag-1 and Ag-2, differed in mobility in CEP, they seemed to have similar molecular weights of 2.5×10^6 (gel filtration through Biogel A-15m) and similar sedimentation coefficients (80S).

Ag-1 was further purified by density gradient centrifugation in CsCR as described in Fig. 1. Fractions containing peak antigenic activity (1.33–1.35 g cm^{-3}) were pooled and used for electron microscopy (Fig. 2) and for polyacrylamide gel electrophoretic analyses (Fig. 3).

Electron micrographs of the CsCl fractions containing the CEP antigen showed some intact particles of 27 nm and a large population of ring structures of 13 nm (Fig. 2). Cho and Ingram[7] have also described both ring structures and intact ADV particles. The intact particles cannot be the predominant CEP antigen, Ag-1, because of the low sedimentation coefficient (80S) of Ag-1. Since there were practically no empty particles in the preparation which otherwise could have accounted for this 80S antigen, it seems that the ring structures comprised the CEP antigen, Ag-1. We cannot say whether these structures are generated from intact or defective virus particles as a result of isolation procedures or whether they have accumulated as the result of defective assembly.

The subunit components of Ag-1 as determined by SDS–polyacrylamide gel analysis had molecular weights of 30,000, 25,000 and 15,000 (Fig. 2), which, if they are viral coded, are typical of a picornavirus polypeptide configuration[8] rather than a parvovirus polypeptide pattern, since parvoviruses usually have subunits of molecular weight >50,000 (ref. 9). Since there is always a possibility of cleavage occurring in the primary protein subunits of Ag-1, by the procedures used here for iodination of Ag-1, classification of the Ag-1 as a derivative of a parvovirus or picornavirus would have to be attempted by independent methods. Ag-1 purified from mink infected with the Canadian ADV isolate (F. J. Depauli Ontario Veterinary College, Guelph) showed a polypeptide composition of similar molecular weights. We are pursuing comparative structural and serological characterisation of the subunit proteins of Ag-1 from different strains of ADV. It is conceivable that different strains of ADV may be distinguished on the basis of their subunit compositions.

Ag-2 is a fragile structure which does not produce a discrete band in CsCl density gradients (1.2–1.5 g cm^{-3}) and has not yet been characterised by electron microscopy. The acrylamide gel analyses of Ag-2 (Fig. 2) showed the presence of only one protein subunit of molecular weight 15,000.

Antigenic activity of Ag-2 was not detectable after RNase treatment but was after DNase; whereas Ag-1 was resistant to both. Incubation of Ag-2 with 10 $\mu\text{g ml}^{-1}$ RNase at 37 °C for 30 min completely destroyed the Ag-2 CEP antigenic activity. It has been suggested that the δ peptide of picornavirus is associated with virion RNA. It is conceivable that Ag-2 represents such a viral substructure; however, it could also represent an association of viral protein with host RNA. The only antigenic form that could be isolated from

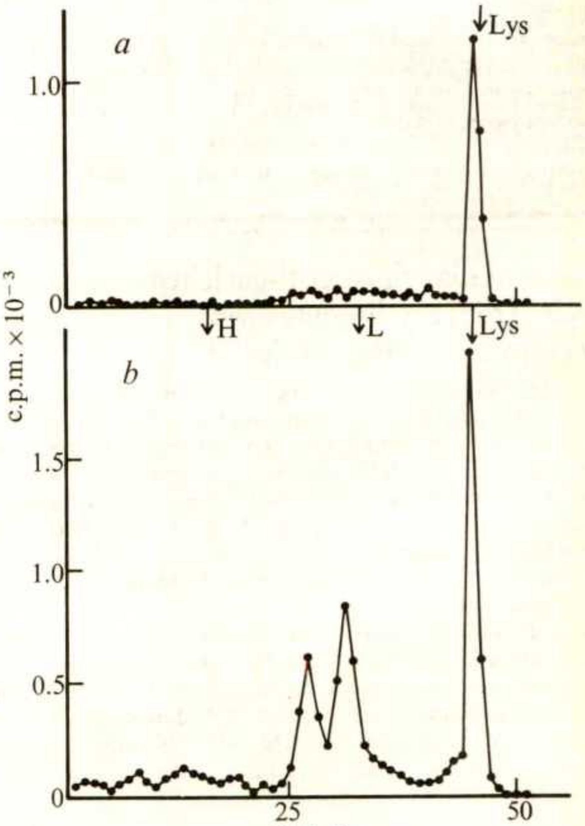

Fig. 3 Electrophoresis of dissociated ^{125}I-labelled Ag-2(*a*) and Ag-1(*b*) on 10% SDS–polyacrylamide gels. Aliquots of Ag-1 and Ag-2 (shown in Fig. 1) were labelled with Na^{125}I using the method of Greenwood *et al.*[10] and dialysed against 0.02 M barbital-acetate buffer, *p*H 8.2, and precipitated in CEP by antibody. The CEP plates were then extensively washed with PBS until free of unreacted components (established by autoradiographs). The precipitin bands were cut out, heated sufficiently in a water bath to melt the agarose and diluted in dissociation buffer (8 M urea–3% SDS at *p*H 8.0) before analysis on SDS–polyacrylamide gel electrophoresis. These precipitin bands were reduced and alkylated[11] in the dissociating buffer and dialysed for 12 h in Tris-HCl buffer, *p*H 6.8, before SDS–polyacrylamide gel electrophoresis[12]. The total gel was cut into 51 slices and counted in a Nuclear Chicago counter. Gels containing samples were compared with standards of human IgG heavy (H) and light (L) chains and lysozyme (Lys) run separately for molecular weight computation.

mink naturally infected in ranch conditions was Ag-2. Further studies on biological and immunological activities of Ag-2 would help in determining whether its accumulation has a role in the pathogenesis of chronic AD.

In these studies we have described properties of two CEP antigens; one is associated with ring structures and the other, which seems to be a nucleoprotein, is present in large amounts especially in mink with chronic AD. Protein subunits of these antigens can be obtained in sufficient purity for primary structural characterisations. Characterisation of these proteins would enable us to determine the relationship of AD virus to other viruses and to establish a basis for the unique biological properties[2] of different ADV strains.

Release of diacylglycerol-enriched vesicles from erythrocytes with increased intracellular [Ca^{2+}]

WHEN the intracellular Ca^{2+} concentration of human red cells was increased by treatment of the cells with A23187, a divalent cation ionophore, they changed shape from discocyte to echinocyte[1–3] and the 1,2-diacylglycerol content of their membranes was increased[2–4]. In these experiments it seemed that microvesicles budded off from the microvillus-like projections on the echinocytes[2,3]. We have now isolated the microvesicles and examined their composition and structure.

Packed washed human red cells (100 ml), isolated from blood approximately 1 week after collection into acid citrate–dextrose were incubated for 90 min at 37 °C with 10 ml of a medium containing A23187 (2 μg ml^{-1}), 0.154 M NaCl, 2 mM $CaCl_2$ and 10 mM HEPES–NaOH buffer, *p*H 7.4. Cells were sedimented and washed with 90 ml of the same medium. They were then stored at 2 °C for 16 h and were again sedimented and washed. During these procedures cell lysis was about 3%. The two supernatants were centrifuged separately at 20,000*g* for 30 min and each yielded a bright red pellet overlaid by a pink fluffy layer (probably the membranes from lysed cells). The fluffy layer was removed carefully by aspiration and discarded; the red pellets were retained. No additional material was sedimented by centrifugation at $10^5 g$ for 60 min. Cells subjected to the same treatment in the absence of A23187 showed slightly more lysis, but centrifugation of their incubation medium yielded only traces of red pellet. Subsequent analysis showed no significant differences between the red pellets obtained from A23187-treated cells after 90 min and 16 h, and we concluded that these were successive collections of the same type of material and they could be pooled.

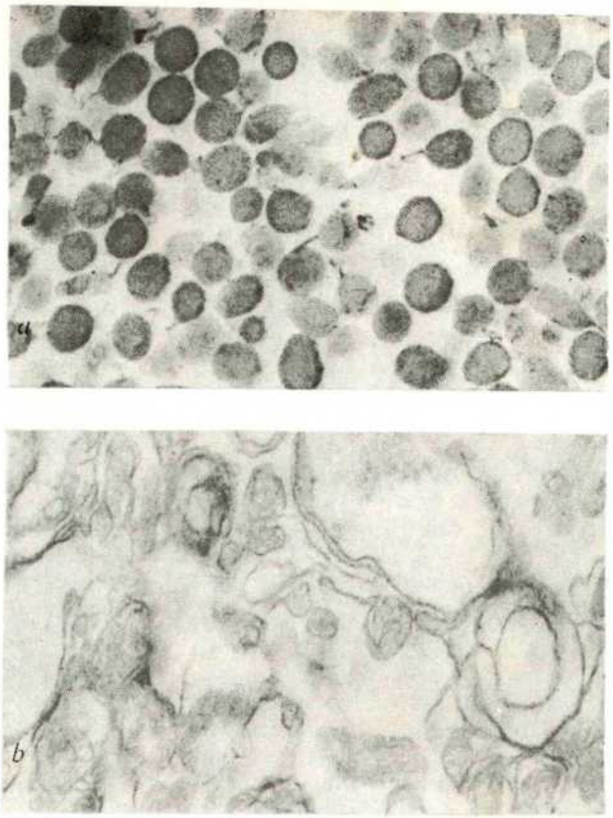

Fig. 1 Electron micrographs of intact microvesicles (*a*), and membranes isolated from glycol-lysed microvesicles from human erythrocytes treated with Ca^{2+} and ionophore A23187 (*b*). Samples were fixed with 4% glutaraldehyde followed by 1% OsO_4. Thin sections of material embedded in Epon were stained with uranyl acetate and lead citrate before examination in a Philips EM301 electron microscope. (×57,000).

*Figures in parentheses refer to the number of samples.
†Values are given as mol % of total lipids excluding glycolipids ± s.d.
‡Values are given as mol % of total phospholipids ± s.d.
§The difference between these values is statistically significant ($0.05 > P > 0.02$).
Lipids were extracted and analysed as described previously[4]. Cholesterol was determined by the method of Brown *et al.*[18].

Electron microscopy showed that the pellets consisted mainly of small spherical bodies about 100 nm in diameter with an internal electron density similar to that of erythrocytes (Fig. 1*a*); these are the characteristics expected of microvesicles budded off from the microvilli of A23187-treated cells[3]. When the pellet was frozen and thawed and then subjected to glycol-induced lysis[5], more than 90% of its haemoglobin was released, and the remaining particulate material was sedimented, by centrifugation at 70,000*g* for 30 min, as a pale pink pellet consisting of membrane fragments, some of which seemed to be larger than the profiles of the original vesicles (Fig. 1*b*).

The ratio of total lipid (phospholipid plus cholesterol) to protein for the microvesicle membrane fraction was approximately 1.4 mg lipid per mg protein but, since haemoglobin accounted for about half of the remaining protein, the ratio of lipid to non-haemoglobin protein was about 2.8. The equivalent value for haemoglobin-free erythrocyte ghosts is about 0.7 mg lipid per mg protein[5]; the microvesicle membranes were therefore markedly depleted in protein during their formation and separation from erythrocytes.

Lipid and polypeptide analyses were made on the original cells, on the A23187-treated cells remaining after the liberation of the microvesicles, and on the microvesicle fraction. The latter fraction contained 15–20% of the total cholesterol and phospholipid of the original cells, but less than 1% of their cytoplasm, as defined by haemoglobin content: this is the result expected from the much higher surface to volume ratio of vesicles compared with erythrocytes. As reported previously[2-4], there was a marked increase in 1,2-diacylglycerol content in cells with an increased intracellular Ca^{2+} concentration. The change was even more pronounced in the microvesicles: this fraction contained only a fifth of the cell lipids but almost half of the newly formed diacylglycerol (Table 1). In addition, the microvesicle fraction was depleted in phosphatidylcholine by about 12% compared with the starting material, consistent with the suggestion that phosphatidylcholine is the substrate for Ca^{2+}-stimulated diacylglycerol production[2-4].

As expected from its low protein to lipid ratio, the microvesicle fraction was deficient in polypeptide material compared with the normal membranes (Fig. 2*a* and *b*). This deficiency was due mainly to the almost complete loss of certain components which are prominent in normal membranes, particulaly bands 1 and 2 (spectrin) and band 5 (actin)[6,14]. Periodate–Schiff staining of gels revealed that the major glycoprotein component of the erythrocyte (glycophorin) was also missing from the microvesicles. In contrast, band 3 was prominent both in normal membranes and in the microvesicles (Fig. 2*a* and *b*). Acetylcholinesterase, an enzyme which occupies a superficial site on the surface of normal red cells, was also retained in the microvesicles. Some polypeptides of the microvesicle fraction were cytoplasmic components which had passed into the budding microvesicles; comparison of Fig. 2*b* and Fig. 2*c* suggested that, in addition to haemoglobin, these may have included bands 7 and 8, and possibly band 4.3. In some experiments in which cells were isolated and treated with A23187 within 1 d of collection of the blood, the microvesicles were markedly depleted even of band 3: it is not known why the membrane protein complement of the microvesicles was sensitive to the period of storage of the blood before its exposure to ionophore.

The microvesiculation which occurs in response to increased intracellular Ca^{2+} seems likely to be caused by the increase in diacylglycerol content in the erythrocyte membrane, particularly since the microvesicles themselves have the highest content of this lipid. Outward vesiculation involves membrane fusion through interactions at the cytoplasmic surface of the microvillus-like projections formed initially. Diacylglycerol, which is a fusogenic lipid[7,8], is probably produced in the inner surface of the membrane bilayer where it could mediate the fusion of cytoplasmic surfaces. Neither cell–cell fusion nor internal vesiculation, both of which involve fusion of outer membrane faces, was seen with ionophore treatment. This contrasts with the situation where diacylglycerol is formed in the outer lipid leaflet of erythrocyte membranes using exogenous phospholipase C, when inward vesiculation occurs[9]. These observation emphasise the asymmetrical nature of diacylglycerol-associated membrane budding processes. The asymmetry of the budding reaction probably arises because of the curvature induced by insertion of diacylglycerol into one leaflet of the lipid bilayer; the contraction in area of this leaflet may be a direct consequence of the formation of diacylglycerol[10]. The asymmetry is probably preserved only for as long as a gradient of the fusogenic molecule is maintained between the two lipid leaflets of the membrane. For diacyl-

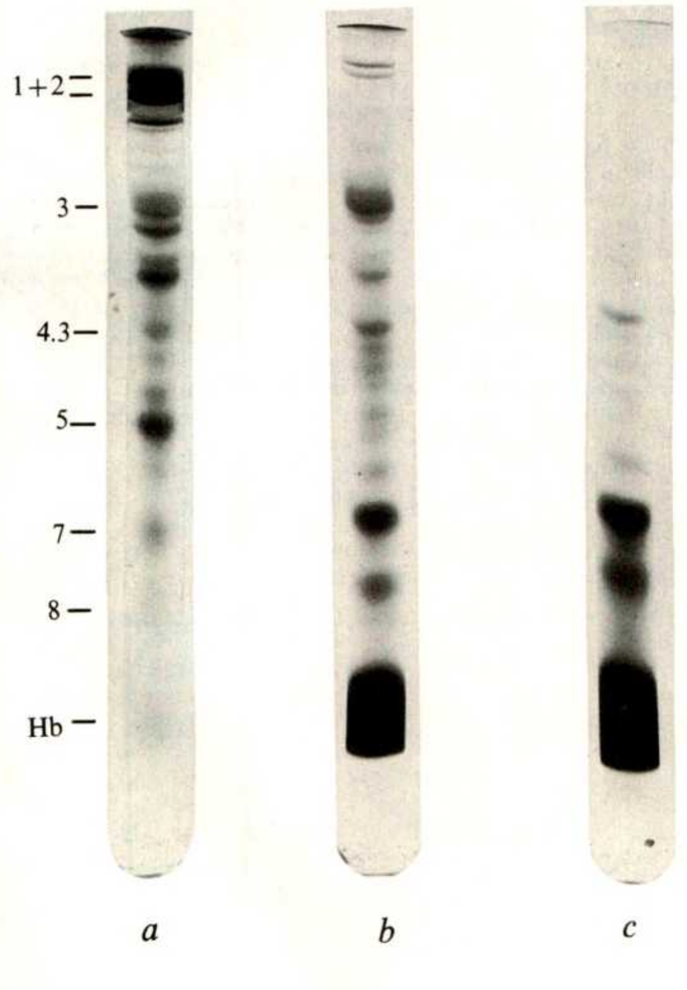

Fig. 2 Sodium dodecyl sulphate (SDS)–polyacrylamide gels of: *a*, human erythrocyte ghosts prepared by glycol lysis[5]; *b*, microvesicles released from human erythrocytes treated with Ca^{2+} and ionophore A23187; *c*, cytosol fraction prepared by centrifugation of osmotically lysed erythrocytes at 15,000*g* for 15 min. *a* and *b* contained 35 nmol of phospholipid and *c* contained about 300 µg of haemoglobin. Samples were dissolved in 10% sucrose, 4% SDS, 1% β-mercaptoethanol, 10 mM phosphate buffer, *p*H 7.0, and heated at 95 °C for 1 min before application to 6% polyacrylamide gels. Electrophoresis was carried out at 4 mA per gel, using a buffer consisting of 100 mM sodium phosphate, *p*H 7.0, containing 0.1% SDS. Gels were stained with Coomassie blue.

glycerol it seems likely that equilibration between the two leaflets is fairly rapid[9]. Heating or prolonged incubation would assist equilibration between the two leaflets and this may explain why A23187-treated cells, which do not fuse immediately at 37 °C, can be made to fuse at 47 °C or on prolonged storage[11].

The microvesicle membranes were markedly deficient in protein relative to the original erythrocyte membrane, suggesting that membrane fusion leading to outward vesiculation is more likely to occur in protein-depleted areas. This finding is consistent with a general model of membrane fusion proposed by Lucy *et al.*[12]. This model, however, envisaged the removal of all intrinsic proteins from the area of the membrane involved in fusion, whereas our data demonstrate that at least one major intrinsic protein (band 3)[13] is still present in the microvesicle membrane. Furthermore, the proteins most notably absent from microvesicles are spectrin and actin, extrinsic proteins which form a meshwork covering the inner surface of the membrane[14] where they might prevent fusion of lipid regions. It may be necessary for such extrinsic proteins to be removed from membranes before they become able to fuse.

Perhaps by virtue of their modified composition, particularly their decreased protein and increased diacylglycerol content, the microvesicle membranes may be prone to fuse with one another; this would contribute to the formation of extended membrane systems from microvesicles subjected to freeze–thawing, lysis and ultracentrifugation (Fig. 2*b*).

It has been suggested[12,15] that production of fusogenic lipids *in situ* might play a part in physiological membrane fusion events such as exocytosis or virus-induced cell fusion. The physiological role of diacylglycerol production at the inner surface of the erythrocyte membrane by an endogenous Ca^{2+}-stimulated phospholipase C is not understood, but is clearly associated with echinocytosis and outward vesiculation. Such vesiculation, possibly as a result of declining or defective Ca^{2+} homoeostasis, could explain the loss of membrane components which occurs gradually in ageing cells[16] and more rapidly in hereditary spherocytic erythrocytes[17].

We thank the MRC for financing this work.

Calcium ions regulate cyclic AMP and beating in cultured heart cells

ALTHOUGH the transport of Ca^{2+} is known to be involved in the control of beating by cultured heart cells, little is known about the regulation of this process. There is evidence that catecholamines affect heart cells through their influence on cyclic AMP[1-4]. In this way they might affect Ca^{2+} transport and, as a result, contractility. Our experiments with beating heart cells now suggest that both noradrenaline and Ca^{2+} control the concentration of cyclic AMP in the cells which, in turn, regulates the utilisation of Ca^{2+}. Addition of noradrenaline or depletion of Ca^{2+} in the external medium results in cells which beat in a lower concentration of external Ca^{2+} compared with controls.

Our experiments were carried out with rat heart cells prepared and cultured as before[5-6]. In a preliminary experiment noradrenaline (10^{-5} M) increased the cellular concentration of cyclic AMP (as determined by the method of Gilman[7]) from 3 to 8 pmol per mg protein within 2 min. It seemed therefore that since cyclic AMP has been reported to increase Ca^{2+} uptake, noradrenaline should also increase the utilisation of Ca^{2+} by beating heart cells. To test this, the beating of heart cells was measured in the presence of different concentrations of Ca^{2+}, decreasing from 8×10^{-3} M, in the presence and absence of noradrenaline (Fig. 1). The rate of beating decreased with the decreasing concentration of Ca^{2+}, and beating stopped at 10^{-4} M Ca^{2+}. In the presence of noradrenaline, however, beating was sustained down to 3×10^{-5} M Ca^{2+}. Thus, noradrenaline increased the ability of the heart cells to utilise Ca^{2+} for beating.

We also studied the effect of Ca^{2+} on the sensitivity of the cells to Ca^{2+} and on the level of cyclic AMP. We measured the concentration of external Ca^{2+} needed to reinitiate beating in heart cells partially depleted of Ca^{2+} by incubation in low Ca^{2+} medium for 2 h. (During this time, membrane-bound Ca^{2+} and most of the easily exchangeable Ca^{2+} is lost[8,9].) Cells ceased beating at a concentration of Ca^{2+} below 2.5×10^{-4} M. In cultures preincubated in 3×10^{-6} M Ca^{2+} medium for 2 h, beating was restored by 4.5×10^{-5} M Ca^{2+}. This is six times less than the concentration of Ca^{2+} needed to maintain the beating of cells preincubated in 'normal' medium, which contains 10^{-3} M Ca^{2+}. In another experiment cells incubated in 4.5×10^{-5} M Ca^{2+} stopped beating as expected, but within 2 h beating resumed spontaneously (Fig. 2). Thus the cells in low Ca^{2+} developed a sensitivity to Ca^{2+} and gained an ability to beat at the lower level. The requirement for external Ca^{2+} was

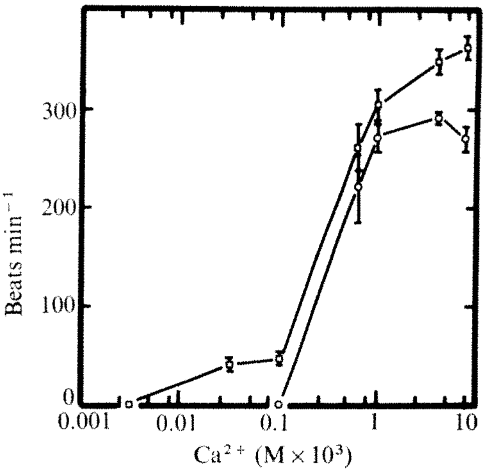

Fig. 1 Effect of noradrenaline (10^{-5} M) and Ca^{2+} on beating of heart cells. Rat heart cells were prepared as before[5,6] and incubated for 2 d in CMRL (1415AM) culture medium[14] supplemented with 5% foetal calf and 5% horse serum. Fresh medium was added 2 h before the experiment. Experimental medium was made with serum previously dialysed with Ca-free Tyrode solution; $CaCl_2$ was added to yield the indicated final Ca^{2+} concentrations, taking into account the basal level of Ca^{2+} measured by atomic absorption spectrophotometry. The rate of beating was determined visually after 20 min of incubation. The temperature was maintained at 37 °C. Data points represent the average of three or four plates; the vertical bars represent standard error of the mean. □, plus noradrenaline; ○, minus noradrenaline.

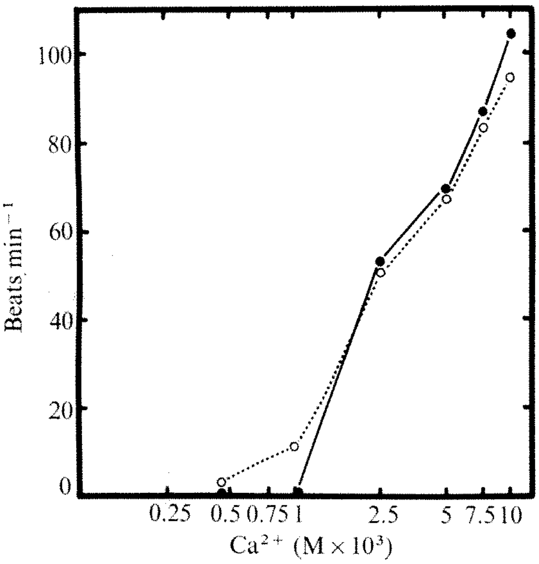

Fig. 2 Beating of heart cells conditioned in high or low Ca^{2+} medium. Two-day-old cultures were incubated in fresh medium for 2 h before the addition of experimental medium (●). Beating rates in duplicate were measured 10 min after treatment. ○, Beating rates of heart cells treated as above but with an additional incubation in 4.5×10^{-5} M Ca^{2+} for 2 h before the addition of experimental medium. The solid symbol at 4.5×10^{-5} M Ca^{2+} indicates the beating rate 10 min after the cells were placed on this medium. The open symbol at 4.5×10^{-5} M Ca^{2+} indicates the beating rate 2 h after the cells were placed on this medium.

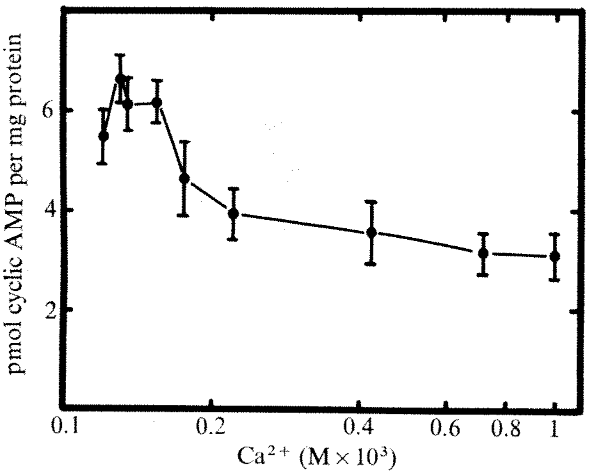
quantitatively dependent on previous exposure of the cells to Ca^{2+}. Cells incubated in a medium with high Ca^{2+} had a greater minimum external Ca^{2+} requirement to maintain beating than did cells incubated in a low Ca^{2+} medium. This indicated that the external Ca^{2+} concentration is involved in controlling the effect of Ca^{2+} on beating, and perhaps in controlling the intracellular level of Ca^{2+}.

If cyclic AMP influences Ca^{2+} transport, and in turn the external Ca^{2+} concentration also influences Ca^{2+} transport, it is possible that Ca^{2+} influences the concentration of cyclic AMP. To test this, we measured the direct effect of Ca^{2+} on cyclic AMP. In a preliminary experiment 10^{-5} M noradrenaline increased the concentration of cyclic AMP in cells incubated in 10^{-3} M Ca^{2+} from 3 to 8 pmol per mg protein. Cells in low Ca^{2+} medium responded by an increase of cyclic AMP from 3 to 12 pmol per mg protein. After 1 h the cyclic AMP in cells incubated with noradrenaline in 10^{-3} M Ca^{2+} had decreased to 5 pmol per mg protein, and with noradrenaline in low Ca^{2+} medium it had fallen only to 9 pmol per mg protein. Thus, in cells incubated in a medium containing noradrenaline and a low Ca^{2+} concentration, cyclic AMP reached a greater concentration for a longer time than in cells in medium containing more Ca^{2+}. Similar effects of noradrenaline on cyclic AMP have been reported for renal tubules in the presence of different concentrations of Ca^{2+} (ref. 10).

Fig. 3 Effect of external Ca^{2+} on cellular concentration of cyclic AMP. Two-day-old cultures were incubated for 2 h in growth medium with different Ca^{2+} concentrations, and cyclic AMP was determined. Each point represents an average of four plates. The vertical bars represent standard error of the mean. A t test was performed on grouped cyclic AMP values between 10^{-4} M and 2×10^{-4} M and between 2×10^{-4} M and 10^{-3} M. The level of significance was <0.001.



If cyclic AMP is related to the sensitivity of heart cells to Ca^{2+} then its concentration should respond directly to changes in external Ca^{2+}. When cells were incubated for 2 h in various concentrations of Ca^{2+}, their content of cyclic AMP increased from 3 to 6 pmol per mg protein as the concentration of Ca^{2+} decreased from 10^{-3} M to 10^{-4} M (Fig. 3). Thus a decrease in cellular Ca^{2+} increased the cyclic AMP and decreased the external Ca^{2+} requirement for beating, perhaps through the concomitant increase in cyclic AMP. In this way Ca^{2+} may regulate its own effect on contractility.

Ca^{2+} may affect the concentration of cyclic AMP by an effect on cyclic AMP phosphodiesterase. This enzyme is stimulated by a modulator protein which is activated by Ca^{2+} (ref. 11). It has been suggested that Ca^{2+} is the limiting factor in the normal physiological state. Thus, a decrease in Ca^{2+} would cause a decrease in cyclic AMP phosphodiesterase activity and a resultant increase in cyclic AMP. Brooker[12] has reported that the level of cyclic AMP varies cyclically in relation to the beating cycle. This could be caused by the oscillation in the cytosol Ca^{2+} level which results from increased uptake of Ca^{2+} by the sarcotubular vesicles during the diastolic part of the beating cycle. It is also interesting that we have evidence that the Ca^{2+} protein activator of cyclic AMP phosphodiesterase is located on the sarcoplasmic reticulum[13]. Ca^{2+} has multiple roles in cardiac contractility, and we suggest that it has a role in regulating its own utilisation, perhaps through its control of cyclic AMP.

Alteration of electrical activity in molluscan neurones by cyclic nucleotides and peptide factors

ELECTRICAL activity in certain molluscan neurones is subject to long lasting synaptic and hormonal modulation[1-5]. Evidence from several systems suggests that cyclic nucleotides mediate alterations in membrane properties in nerve and muscle cells[6-8]. We report here that, in certain neurones from the marine snail *Aplysia californica* and the land snail *Helix pomatia*, an increase in the intracellular concentration of cyclic nucleotides is accompanied by long lasting changes in electrical activity, and that physiological agents known to modify the electrical rhythms of these nerve cells, increase adenosine 3′,5′-cyclic monophosphate (cyclic AMP) in *Helix* and *Aplysia* nervous tissue.

Table 1 Effect of phosphodiesterase inhibitors on cyclic AMP in *Aplysia* abdominal ganglion

Treatment	Cyclic AMP (pmol per mg protein)
Control	14±2 (9)
Papaverine, 10^{-5} M	22±2* (4)
Papaverine, 3×10^{-4} M	29±4† (5)
IBMX, 10^{-5} M	38±6† (4)

Aplysia abdominal ganglia were preincubated for 30 min at 20±1 °C in control medium, then incubated for an additional 30 min in either control medium or medium containing the indicated concentration of inhibitor, before assay of cyclic AMP. After incubation, abdominal ganglia were frozen in liquid N_2, and homogenised immediately in acidified ethanol[21]. Homogenates were centrifuged to precipitate protein, and the ethanol supernatants were dried under reduced pressure. Cyclic AMP was measured by a binding assay[22]. Values are means ± s.e.m. for the number of ganglia shown in parentheses.

*Significantly different from control, $P < 0.05$.

†Significantly different from control, $P < 0.01$.

Identified neurones R15 (ref. 9) in *Aplysia* abdominal ganglion and F–1 (ref. 5) in *Helix* circumoesophageal ganglia exhibit similar patterns of endogenous electrical activity, in which an oscillating membrane potential underlies alternating periods of action potential bursts and interburst hyperpolarisations[10]. We have found that the phosphodiesterase inhibitor isobutylmethylxanthine (IBMX), added to the bath at concentrations between 10^{-5} M and 3×10^{-4} M, has profound effects on the bursting rhythm of these cells (Fig. 1*a*). After a lag of 20–45 min there was a marked increase in both the duration and amplitude of the interburst hyperpolarisation, as well as in the frequency and number of action potentials per burst. Simply shifting basal membrane potential (by intracellular injection of hyperpolarising or depolarising current) did not produce this effect. Similar concentrations of the alkaloid papaverine, another potent phosphodiesterase inhibitor, altered bursting rhythm in the same way as IBMX. These results suggested that an increase in concentrations of cyclic nucleotide might be involved in the change in electrical pattern; we found (Table 1) that cyclic AMP did accumulate in the *Aplysia* abdominal ganglion after treatment with IBMX or papaverine.

The action of IBMX and papaverine on bursting rhythm in neurones R15 and F–1 was not mimicked by externally perfused cyclic AMP or cyclic GMP in concentrations as high as 2.5×10^{-3} M. This might have been due to their failure to penetrate the cell membrane, or to their rapid destruction by intracellular phosphodiesterases before they reach the site of action. To circumvent the problem of membrane permeability, we injected solutions of cyclic AMP or cyclic GMP (2.5×10^{-3} M in water, adjusted to *p*H 7.4) into R15 and F–1 through intracellular micropipettes[11]. Approximately 1 nl of solution was injected, and intracellular dilutions of 10–20-fold can be assumed. No change in bursting rhythm was observed in three preparations injected with cyclic AMP and two injected with cyclic GMP, indicating that low permeability is not sufficient to explain

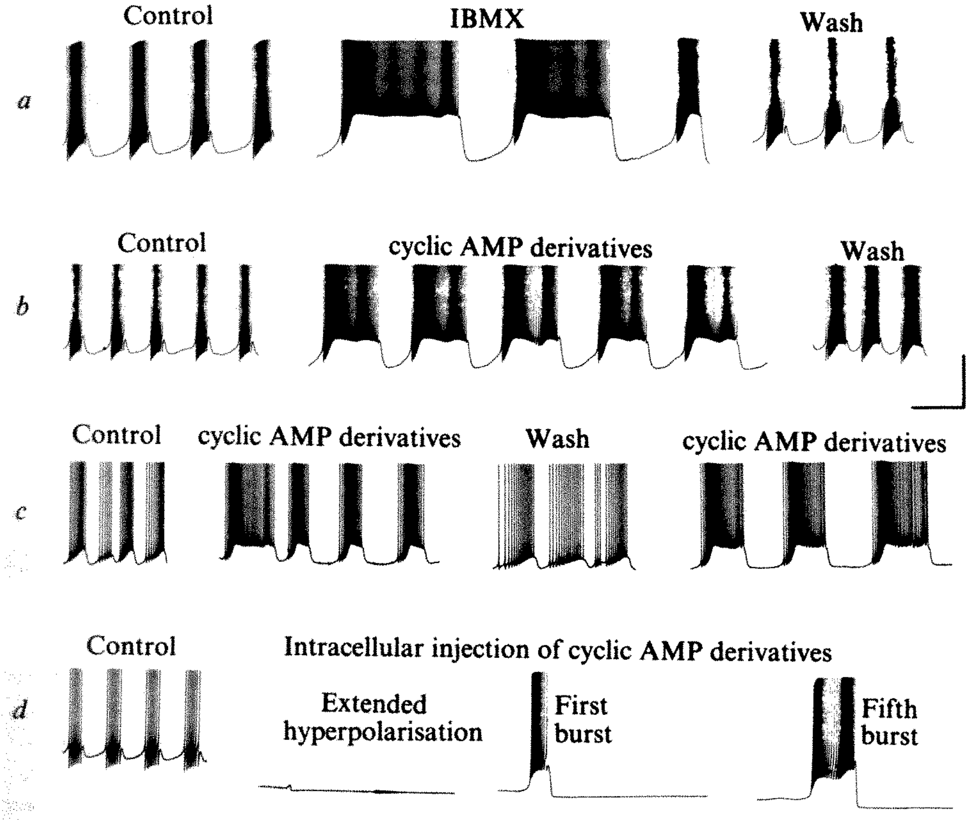

Fig. 1 Effects of IBMX and cyclic AMP derivatives on electrical activity in neurones R15 and F–1. Intracellular recording micropipettes were filled with either 3 M KCl or 0.6 M K_2SO_4. All experiments were performed at 20±1 °C, between 0800 and 2100. *a*, Electrical activity was measured in cell R15 in an *Aplysia* abdominal ganglion during perfusion with normal *Aplysia* medium[21] (control), then 45 min after addition of *Aplysia* medium containing 3×10^{-4} M IBMX, and finally normal medium again (wash). *b*, Same as (*a*) except that a mixture of 8-benzylthio cyclic AMP and 8-(4-aminobutylamino) cyclic AMP (10^{-3} M each, obtained from ICN, Cleveland) was used in place of IBMX. *c*, Electrical activity measured in cell F–1 in *Helix* nervous system perfused with normal *Helix* medium (control), then *Helix* medium containing a mixture of cyclic AMP derivatives as in (*b*). After a 90-min wash with normal medium the derivatives were reintroduced. *d*, Effects of injection into R15 of the mixture of cyclic AMP derivatives (10^{-3} M each dissolved in water adjusted to *p*H 7.4). Within 6 min the cell hyperpolarised to a level 23 mV below that of the pre-injection interburst hyperpolarisation level, and remained silent for 30 min. When bursting returned, the pattern was similar to that observed after application of phosphodiesterase inhibitors and cyclic AMP derivatives to the bath. Shown are the first and fifth (18 min after first) bursts after the extended hyperpolarisation. Calibration: 40 mV, 20 s.

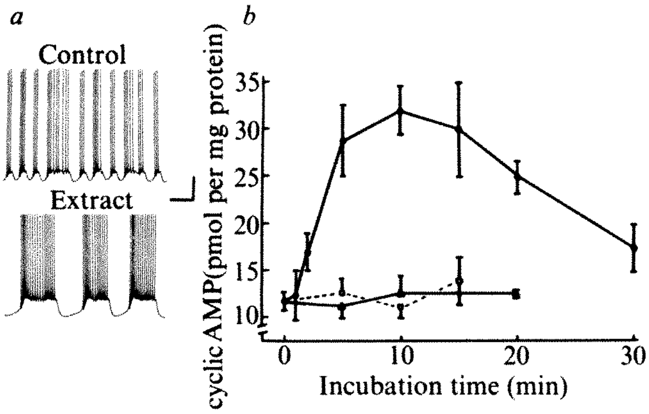

Fig. 2 Effects of *Helix* circumoesophageal ganglia extract on neuronal membrane properties and concentrations of cyclic AMP in *Helix* nervous system. Ganglia were removed from active[25] *Helix*, placed in 5-ml beakers containing 1 ml of *Helix* medium (modified from that described previously[2] by addition of amino acids and vitamins[21]), and preincubated at 20±1 °C for 30 min before the start of the experiment. Acetic acid extract from 2.5 *Helix* circumoesophageal ganglia (total tissue wet weight 59 mg, total tissue protein content 1.6 mg), prepared as before[2] and lyophilised, was resuspended in 1 ml of *Helix* medium as test substance. Ganglia were incubated in medium either with or without extract, were frozen in liquid N_2 and homogenised immediately in acidified ethanol. Homogenates were treated as for Table 1. Concentrations of cyclic AMP were measured by a binding assay[21]. The same resuspended extract was used for both (*a*) and (*b*). *a*, Membrane potential traces of cell F–1 before (top) or 20 min after (bottom) replacement of control bathing medium with extract-containing medium. The change in bursting rhythm induced by the extract could be reversed by prolonged washing in extract-free medium. Calibration: 20 mV, 10 s. *b*, Concentrations of cyclic AMP in circumoesophageal ganglia incubated in control medium (▲) or medium containing extract (●) for various times. Other circumoesophageal ganglia were incubated in 1 ml of medium, containing acetic acid extract of *Helix* foot muscle (total tissue wet weight 263 mg, total tissue protein content 9.4 mg), for various times (□). Data are mean ± s.e.m. for 5–12 samples.

their lack of effect during application to the bath. Accordingly, we examined the effects of the 8-benzylthio, 8-parachlorophenylthio, and 8-(4-aminobutylamino) derivatives of cyclic AMP, all of which inhibit, and are highly resistant to breakdown by, phosphodiesterases[12]. These compounds are also potent activators of mammalian[12] protein kinases, and are more effective than cyclic AMP in altering electricial activity in cerebellar Purkinje cells[13]. All the derivatives, perfused at concentrations ranging from 10^{-5} M to 10^{-3} M, modified the bursting rhythm in cells R15 and F–1 after a 20–45-min lag (Fig. 1*b* and *c*). The effect was observed in all ten cells tested, and was transitory (although lasting at least 20 min) in six of them, even though the drug remained in the bathing medium. Reintroduction of the appropriate derivative, after a 1-h wash, caused a long-lasting (20 min or longer) reappearance of the modified bursting rhythm, again after a 20–45-min lag. Application of 10^{-3} M $N^6,O^{2'}$-dibutyryl cyclic AMP to the bath had no effect, in agreement with a previous report[14].

The 8-parachlorophenylthio derivative of cyclic GMP, perfused at 10^{-3} M, did not affect the interburst hyperpolarisation in any of four R15 cells tested. Occasionally we noted an increased burst amplitude during treatment with this compound; this occurred preferentially after the long lasting, spontaneous i.p.s.p.s., already documented in R15 (ref. 15). In all four cells, treatment with 8-parachlorophenylthio cyclic GMP was followed by perfusion with the same concentration of 8-parachlorophenylthio cyclic AMP, either with or without an intervening wash. In all cases the cyclic AMP derivative potentiated the interburst hyperpolarisation, previously unaffected by the cyclic GMP derivative.

It is unlikely that the altered bursting rhythm reflects changes in neurones presynaptic to R15 and F–1. All three cyclic AMP derivatives which were effective when applied to the bath were also effective when injected into the cell bodies of R15 and F–1 (Fig. 1*d*). Again, a time lag was observed, suggesting that the lag after external application did not reflect a slow intracellular buildup of the derivatives, but rather was due to some slowly occurring metabolic process, or to diffusion of the derivatives to a site where they can act. Presumably, the membrane of the cell body, the site of action potential generation in bursting molluscan neurones[16], is available to the compounds soon after their injection. In addition, tetrodotoxin-treated *Aplysia* ganglia, in which action potentials are suppressed, but slow oscillatory waves in R15 continue[17], showed a lengthening of both hyperpolarising and depolarising phases of the cycle, when 3×10^{-4} M IBMX was added (our unpublished results). This indicates that the IBMX-induced change in R15 firing pattern (Fig. 1*a*) did not result from an alteration in firing pattern of some presynaptic neurone; it also demonstrates that the modified electrical rhythm did not require action potentials in R15.

Peptides from various sources can markedly alter membrane properties of certain molluscan neurones in a manner similar to that which we observed after exposure to cyclic nucleotides. Active factors include the vertebrate neurohypophysial hormones vasopressin and oxytocin[1,18], as well as peptide-containing extracts from the nervous system of the terrestrial snail *Otala lactea*[2] and *A. californica*[2,3]. This suggests that cyclic AMP is an intermediary in the action of these agents, and we observed the accumulation of cyclic AMP in molluscan nervous system exposed to peptide hormones and peptide-containing extracts, at concentrations similar to those which alter neuronal membrane properties.

The effects of a *Helix* circumoesophageal ganglia extract on neuronal membrane properties and on cyclic nucleotide levels in *Helix* nervous system are shown in Fig. 2. As previously reported for cell 11 of *Otala*[2], the extract markedly increased the depth and duration of the interburst hyperpolarisation, as well as the number and frequency of action potentials per burst, in cell F–1 of *Helix* (Fig. 2*a*), a result similar to that observed after addition of cyclic nucleotides to the medium bathing the nervous system. The same concentration of extract caused a large increase in cyclic AMP in *Helix* circumoesophageal ganglia (Fig. 2*b*). Concentrations of cyclic AMP were increased after as little as 2 min of incubation, reached a maximum at about 10 min, and

Table 2 Effect of *Aplysia* bag-cell extract on cyclic AMP in *Aplysia* nervous system

Tissue fraction	Cyclic AMP (pmol per mg protein) Control	Bag-cell extract
Neurone R2 soma	23±1 (9)	20±3 (8)
Neurone R15 soma	16±6 (9)	19±6 (9)
Left upper quadrant of AG	14±3 (8)	38±8* (9)
Remainder of AG	12±1 (8)	30±5* (8)
Connective nerves	15±3 (5)	13±4 (5)

Acetic acid extracts of clusters of neurosecretory neurones (bag cells) from abdominal ganglia (AG) of *Aplysia* were prepared as described by Ifshin *et al.*[2]. The extracts were lyophilised and resuspended in appropriate volumes of *Aplysia* medium. AG were preincubated in *Aplysia* medium for 30 min at 20±1 °C, then incubated in control medium or 1 ml of medium containing extract from four bag-cell clusters per ml, for 10 min before dissection. AG were then frozen in ethylene glycol-dry ice[23], and identified neuronal cell bodies and segments of the AG were dissected and homogenised in acidified ethanol. Homogenates were treated as described for Table 1. R15 somata were assayed by radioimmunoassay[24], other fractions by binding assay[21]. Values are means ± s.e.m. for the number of samples shown in parentheses.

*Significantly different from control, $P < 0.01$.

returned to near basal levels by 30 min. The factor in the extract responsible for the increase in cyclic AMP was stable at 100 °C or in 50% acetic acid, eluted in the exclusion volume of a Sephadex G-10 column and was destroyed by Pronase. In all these respects it is identical to the factor, tentatively identified as a peptide, which alters bursting rhythm in *Otala* cell 11 (ref. 2). An acetic acid extract of snail foot muscle affected neither bursting rhythm[2] nor concentrations of cyclic AMP (Fig. 2*b*).

The demonstration that an *Aplysia* bag-cell extract alters bursting rhythm in cell R15 of the abdominal ganglion[3], and that cyclic nucleotides can mimic this effect, led us to investigate the influence of such an extract on cyclic AMP in different regions of the abdominal ganglion. No change in concentrations of cyclic AMP was observed in the cell bodies of the silent neurone R2 or the bursting neurone R15 after incubation of the abdominal ganglion with extract (Table 2). There was, however, a large increase in cyclic AMP in the left upper quadrant of the abdominal ganglion (which is rich in bursting neurones[19]), as well as in that portion of the ganglion remaining after removal of the R2 and R15 cell bodies and the left upper quadrant. The lack of any accumulation of cyclic AMP in the somata of R2 and R15 suggests that the response is confined to the neuropil, which contains both neuronal processes and glia[20]. Since connective nerves which are rich in stellate glial cells[20] did not accumulate cyclic AMP in the presence of bag-cell extract (Table 2), it is unlikely that this class of glia is involved.

Our findings are all consistent with the possibility that cyclic AMP mediates the effects of peptides on bursting rhythm, and may play a role in modulating the membrane properties of certain nerve cells.

We thank Miss Eva Bergström for technical assistance.

N-demethylation of morphine in rat brain is localised in sites with high opiate receptor content

N-DEMETHYLATION of morphine, a principal biotransformation of this opiate alkaloid, has been demonstrated in several species including man[1–4]. The primary site of the reaction is the liver[5,6] but its existence in the central nervous system (CNS) has been inferred from experiments both *in vitro* with rat brain slices[7], and *in vivo* with hepatectomised rats[8]. The enzymatic *N*-demethylation of morphine and other biologically active tertiary amines has been studied extensively and both Axelrod[5,6] and Beckett *et al.*[9] have proposed that *N*-demethylation of narcotics is intimately involved in the mechanism of analgesia and the development of tolerance to and dependence on these agents. Subsequently, other investigators have questioned the validity of these hypotheses[10,11] and critical reviews of the experimental support of these theories have been published[12,13]. Belleau and Morgan[14] have revived interest in the biological significance of the *N*-demethylation of narcotics by proposing a provocative concept of clastic binding to opiate receptors in which the process of *N*-demethylation participates in conjunction with the opiate receptor in the mechanism of opiate action. This concept requires that the location of the sites of *N*-demethylation within the CNS is proximal to or coincident with that of the opiate receptors. Previous reports[7,8,15] have described the *N*-demethylation of morphine by the whole brain, and our study was initiated to locate the reaction at specific sites. To do this *in vivo,* we used a new, highly sensitive assay. A mixture of 6-^{3}H-morphine[16], and *N*–^{14}CH$_3$-morphine (Amersham/Searle), of known isotope ratio, was injected into each rat and, after killing, the isotope ratio of selected tissues was determined accurately by combustion in a tissue oxidiser. *N*-demethylation of this mixture generates ^{14}C-containing fragments originating from the *N*-methyl group, but the *N*-demethylated products of the reaction contain only ^{3}H. The former are dissipated from the site of reaction much more rapidly than the latter, so that an increase in the ratio of ^{3}H to ^{14}C in a specific tissue would serve to indicate the presence, and also the extent, of any *in situ* *N*-demethylation.

The results of a series of experiments are listed in Table 1. The liver is a known site of *N*-demethylation[5,6] and in every study this tissue contains a ratio of ^{3}H to ^{14}C significantly greater than that of the blood and can therefore be considered as a positive control. The only other tissues showing a similar increase in the isotopic ratio were in the CNS and consisted of the hypothalamus, the medial thalamus and the corpus striatum. The ratio of ^{3}H to ^{14}C in these tissues was significantly greater than that in the blood, indicating that the peripherally administered morphine was *N*-demethylated at these sites. In contrast, none of the other tissues examined had a ratio of ^{3}H to ^{14}C greater than that of the blood, suggesting that they were not sites of *N*-demethylation. This evidence, however, need not be exclusive since further dissection of the other brain areas could provide fraction(s) with disproportionate isotope ratios which were obscured by the isotope contents of the larger section in our work.

These results were obtained in experiment 1 in which a pharmacological dose of morphine ($\sim 10\ \mathrm{mg\ kg^{-1}}$) was injected. In experiments 2 and 3, in which tracer or subpharmacological doses of morphine were injected, there were no comparable changes in isotope ratio, in spite of continued clear and undiminished evidence of the *N*-demethylation in the liver. This failure to observe isotope ratio differences in the central tissues in these experiments cannot be due to insensitivity of detection for although the tissues contained less material, the amount of radioactivity present in the CNS regions was comparable with that in experiment 1. This suggests that *N*-demethylation in the brain proceeds only when pharmacological concentrations of the substrate are present, which tends to confirm the biological significance of the reaction. Alternatively, it is possible that morphine is demethylated in the CNS when low doses are present, but that the smaller amounts of *N*-demethylated products formed are lost from the site of the reaction within 30 min, and the loss of both isotopes results in failure to observe changes in ratio. In experiment 4, in which a pharmacological dose of morphine was used but the animals were killed after 60 min, there is significantly

The recorded isotope ratios are the average for six male Sprague–Dawley rats (~ 250 g) used in each study. Significance (to blood) was calculated by Student's *t* test[24]. Animals were killed by cervical fracture, and the CNS was dissected as before[25]. Tissues were combusted in an Oxymat tissue oxidiser (Intertechnique). The tritiated water and $^{14}CO_2$ released by each sample was trapped and counted in a Packard scintillation counter. In experiments 1, 2, 3 and 5, animals were killed 30 min after injection; in experiment 4, after 60 min. Doses were: experiment 1, 2.5 mg morphine per rat; 2, 0.2 mg morphine per rat; 3, 0.02 mg morphine per rat; 4, 2.5 mg morphine per rat; 5, 2.5 mg morphine + 0.1 mg naloxone per rat.

less evidence for *N*-demethylation in the hypothalamus, corpus striatum and medial thalamus, presumably due to the greater loss of the tritium-containing *N*-demethylated products from the site of the reaction during the longer time. The isotope ratios in the liver were not affected by the increase in time, suggesting either a continuing reaction or a greater retention time of the *N*-demethylated products in this organ.

The observed isotope ratio changes in specific central tissues could be interpreted to arise not from *in situ* *N*-demethylation of the 6-^{3}H-morphine–N-$^{14}CH_3$-morphine mixture, but as a product of preferential uptake of *N*-demethylated compounds originating from the liver. Several lines of evidence argue against this interpretation. Demethylated (nor-)morphine and presumably other *N*-demethylated products cross the blood–brain barrier less effectively than the corresponding *N*-methyl derivatives[17,18] and this would lead to isotope ratio changes, which would be the reverse of those observed. Furthermore, in unpublished studies in which liver *N*-demethylation was abolished, changes were observed in the isotope ratio in the CNS. Finally, in experiment 4, in spite of continuing liver *N*-demethylation, the changes in isotope ratio in the CNS were reduced substantially with time.

Our work demonstrates that the *N*-demethylation of morphine in the brain of the rat is limited to specific sites which include the hypothalamus, medial thalamus and corpus striatum. These tissues have been reported to contain relatively high concentrations of opiate receptors[19–22], whereas sites described as deficient in opiate receptors, such as the cerebral cortex, cerebellum and the medulla, showed no evidence of *N*-demethylation. Therefore there is coincidence between the sites of this biotransformation and the presence of opiate receptors, which supports the hypothesis that the receptor-mediated mechanism of opiate action involves *N*-demethylation. Further support for this concept was sought in experiment 5, in which the presence of the narcotic antagonist naloxone was expected to affect the demethylation of morphine in the CNS. But neither in the CNS nor in the liver were there any clear changes in morphine *N*-demethylation. These negative results suggest that either the reaction is not pharmacologically significant, or that the antagonist interferes with the chain of events subsequent to *N*-demethylation of the agonist. Alternatively, the antagonist may affect either the time scale or quantitative aspects of *N*-demethylation in a manner which does not become evident in the conditions we used.

We have previously utilised a double isotope procedure with *N*-$^{14}CH_3$-morphine and ^{3}H-naloxone in an effort to demonstrate displacement of the agonist by the antagonist in specific central sites[23]. We knew that *N*-demethylation might distort the results and performed a reverse isotope experiment in which 6-^{3}H-morphine and ^{14}C-naloxone were used. There was no evidence of any change in isotope ratio, and we assumed that *N*-demethylation of morphine does not proceed to a sufficient degree in the CNS to be detectable by these methods. These experiments, however, were carried out with sub-pharmacological doses of morphine. In subsequent experiments using pharmacological doses of *N*-$^{14}CH_3$-morphine and ^{3}H-naloxone we observed greater ratios of ^{3}H to ^{14}C in the medial thalamus and hypothalamus and interpreted these changes as indicative of displacement of morphine by the antagonist in these tissues. In view of these results, these interpretations must be revised since they were due to *N*-demethylation of the morphine and loss of the ^{14}C fragment from the tissue. The extent of this biotransformation is comparable with the 'displacement' observed. Displacement of agonist by antagonist from receptors *in vivo* is still presumed to occur, but in amounts not detectable by our procedures.

Immunocytochemical evidence for the presence of arginine vasotocin in the rat pineal gland

THE discovery that the pineal gland contained melatonin[1] provided the stimulus for a multidisciplinary approach to the study of this organ. Considerable evidence suggests that this gland affects reproductive physiology. For example, it contains biologically active polypeptides. One of the first of these to be identified was arginine vasotocin (AVT), initially isolated from extracts of bovine pineal gland[2], and later identified chemically and found to have antigonadotropic properties[3,4]. There is physiological and radioimmunoassay evidence for the origin of AVT in the pineal gland. We now present immunocytochemical evidence for the presence of this polypeptide in the pineal gland.

AVT was conjugated to bovine serum albumin, and antiserum to the complex was prepared in adult male guinea pigs. The antiserum was absorbed with 1 mg of bovine serum albumin per ml of undiluted serum before use. Pineal glands and hypothalami from ten adult male rats were fixed in Bouin's solution and embedded in paraffin. Immunochemical staining was carried out with undiluted antiserum to AVT according to the procedure of Nakane and Pierce[7]. Controls similar to those described by Petrusz[8] were carried out to assure specificity of staining.

Because of the marked structural similarity of AVT, arginine vasopressin (AVP) and oxytocin, and because other investigators have claimed that the pineal gland contains AVP[6] and luteinising hormone releasing hormone (LHRH)[9], establishment of the specificity of the antiserum to AVT was important. The findings summarised in Table 1 strongly suggest that the antiserum to AVT was specific for AVT. Moreover, the supraoptic nucleus, the paraventricular nucleus and the median eminence (regions reputedly rich in AVP, oxytocin, and LHRH, respectively) did not stain with antiserum to AVT, substantiating the immunocytochemical specificity of the antiserum to AVT.

Antiserum to AVT immunochemically stained a distinct population of cells in the rat pineal gland (Fig. 1). These cells were distributed diffusely throughout the gland. They were very irregular in form with extensive perivascular and intercellular processes. Cytoplasmic processes were frequently cupped around neighbouring cells. Most parenchymal cells were regular in outline and were identified as cells clasically described as pinealocytes or chief cells. Their characteristic pale nuclei with infolded nuclear membranes and many nucleoli were in marked contrast to the intensely staining, elongate nuclei of the immunochemically stained cells. The pronounced staining of the nuclei of the presumptive AVT cells was interesting because this was not normally observed after immunocytochemical staining of cells containing polypeptides.

Fig. 1 Light micrograph of a section from a rat pineal gland immunochemically stained with antiserum to AVT. The darkly staining reaction product of the Nakane–Pierce technique defines the presumptive AVT cells.

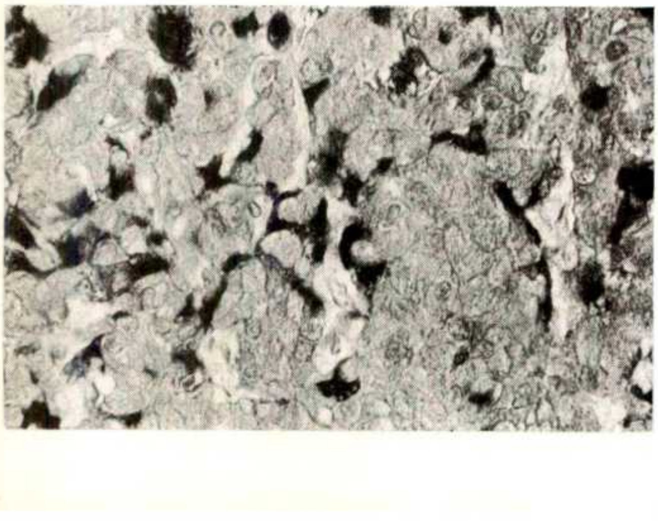

Table 1 Immunological specificity of antiserum to AVT

	Anti-AVT	Anti-AVT + AVT	Anti-AVT + AVP	Anti-AVT + OT	Anti-AVT + LHRH
Pineal gland	+	−	+	+	+

Immunological specificity was tested by absorbing undiluted antiserum to AVT with 0.2 mg of AVT, AVP, OT, or LHRH, before immunochemical staining of rat pineal sections.

These findings add further evidence for the presence of AVT in the pineal gland. Whether the immunocytochemically stained cells of this study represent a second line of pinealocytes or are glial in origin, and whether they synthesise or store AVT has yet to be determined.

We thank Dr E. G. Rennels for helpful criticism and Dr M. K. Vaughan for encouragement.

Functional roles of luminal sodium and potassium in water transport across desert scorpion ileum

IN terrestrial insects the rectum is a major site of fluid absorption and is, therefore, important in the physiological control of water balance. Water absorption in the insect rectum occurs against osmotic gradients greater than 300 mosmol l^{-1} and apparently in the absence of net ion movements from lumen to haemolymph[1,2]. Evidence suggests that net water flow from the rectal lumen to haemolymph results from increases in intercellular space osmotic pressure due to the transport across lateral cell membranes of recyclable intracellular solutes[3,4]. Little is known about the mechanism of water transport in the insect gut anterior to the rectum nor about gastrointestinal processes involved in water regulation in other terrestrial arthropods. Scorpions are ideal organisms for measurements of arthropod ileal transport because this part of the gut extends nearly the entire length of the tail and can be isolated for *in vitro* perfusion. We present here preliminary information on a sodium-dependent, potassium-inhibited water transport mechanism in the ileum of the desert scorpion *Hadrurus arizonensis*.

Scorpions were anaesthetised lightly with chloroform, and the entire ileum (2 cm) was removed and placed in a saline medium. The ionic composition and osmotic pressure of the medium were based on data obtained from flame photometry, chloride titration and osmometry of haemolymph samples, as well as on values reported from other scorpion species in the literature[5-7]. This scorpion saline had an osmotic pressure

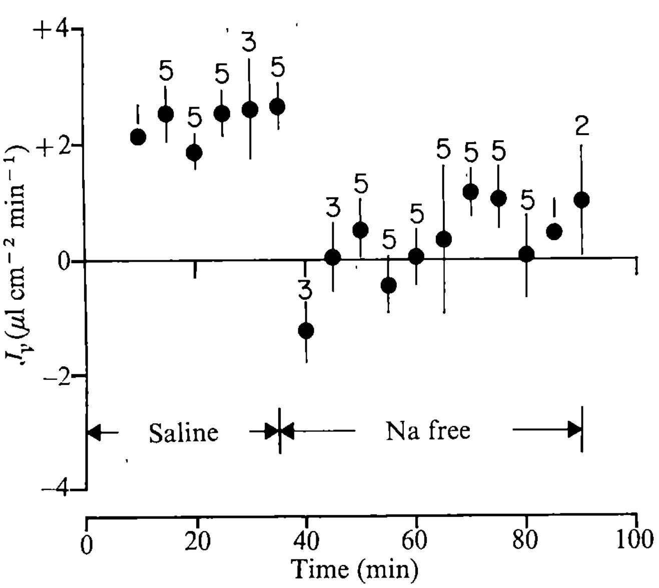

Fig. 1 Effect of sodium-free perfusate on net water flux across scorpion ileum. Ilea were first exposed to normal saline on the luminal surface for 35 min and were subsequently perfused for 55 min with medium lacking sodium. Normal saline was present in the serosal bath at all times. A positive net water flux indicates movement from mucosa to serosa. Circles represent mean flux values, vertical lines are ±1 s.e.m. and numbers signify sample size.

of 550 mosmol l^{-1}, a *p*H of 7.4, and consisted of the following ion concentrations in mM: Na, 281.5; K, 8.0; Ca, 10.0; Mg, 20.0; Cl, 260.0; HCO_3, 1.5; SO_4, 44. When incubation media of altered ionic composition were used, choline chloride was substituted for NaCl and KCl, and $KHCO_3$ for $NaHCO_3$; KCl concentrations were increased at the expense of those of NaCl (Na_2SO_4 replacing the altered NaCl), and raffinose was added to maintain approximately equal osmotic pressures on both sides of the epithelium. Ionic concentrations of normal ileal fluid were also measured by flame photometry after collection and centrifugation in haematocrit capillary tubes.

Each end of the isolated ileum was mounted on epoxy-coated 18-gauge stainless steel needles with surgical thread, immersed in 3 ml of scorpion medium in a lucite chamber, and perfused with saline by means of a polystaltic pump at a flow rate of about 125 µl min^{-1}. Net water transport (J_v) was measured by the procedures developed for perfused kidney nephrons[8] where the change in perfusate ^{131}I-albumen concentration (Squibb), after passage through the tubular preparation, provides information about the extent and direction of water flow. The perfusion rate (V_0, µl min^{-1}) was calculated as

$$V_0 = {}^{131}I_{tot}/[{}^{131}I_0]t$$

where [$^{131}I_0$] is the specific activity in the perfusion fluid (d.p.m. µl^{-1}); $^{131}I_{tot}$ the total amount of radioactivity in a sample of ileal fluid collected after passage through the gut (d.p.m.), and t the duration of the collection period (min). The rate of collection (V_f, µl min^{-1}) was estimated directly from the volume, determined gravimetrically to the nearest 0.1 mg, and duration of each collection. The net water transport rate J_v (µl cm^{-2} min^{-1}) was calculated as

$$J_v = (V_0 - V_f)/A$$

where A represents the estimated mucosal area (cm^2) determined by considering the ileum as a cylinder. A positive value of J_v reflects net movement of water from mucosa to serosa. Ilea were typically perfused with ^{131}I-albumen-labelled medium for the first 35 min (control interval), followed by perfusion for 45–55 min with medium of altered ionic composition containing the radioactive marker. Collections were made every 5 min. The serosal bath was periodically sampled for radioactivity to test for leaks. ^{131}I-albumen samples were counted in a Beckman LS-230 liquid scintillation spectrometer using a Triton X-100/toluene/Omniflour (New England Nuclear) scintillation cocktail.

Figure 1 shows that when the transmural osmotic gradient was zero (determined by measuring directly the osmotic pressures of mucosal and serosal solutions), J_v in scorpion medium was $+2.40 \pm 0.18$ µl cm^{-2} min^{-1} (mean ± s.e.m.; n = 24). That this net movement of water was energy dependent was shown in another experiment where the saline bathing both ileal surfaces contained 1 mM NaCN and 1 mM iodoacetate. Net flow in these conditions was reduced to +0.14±

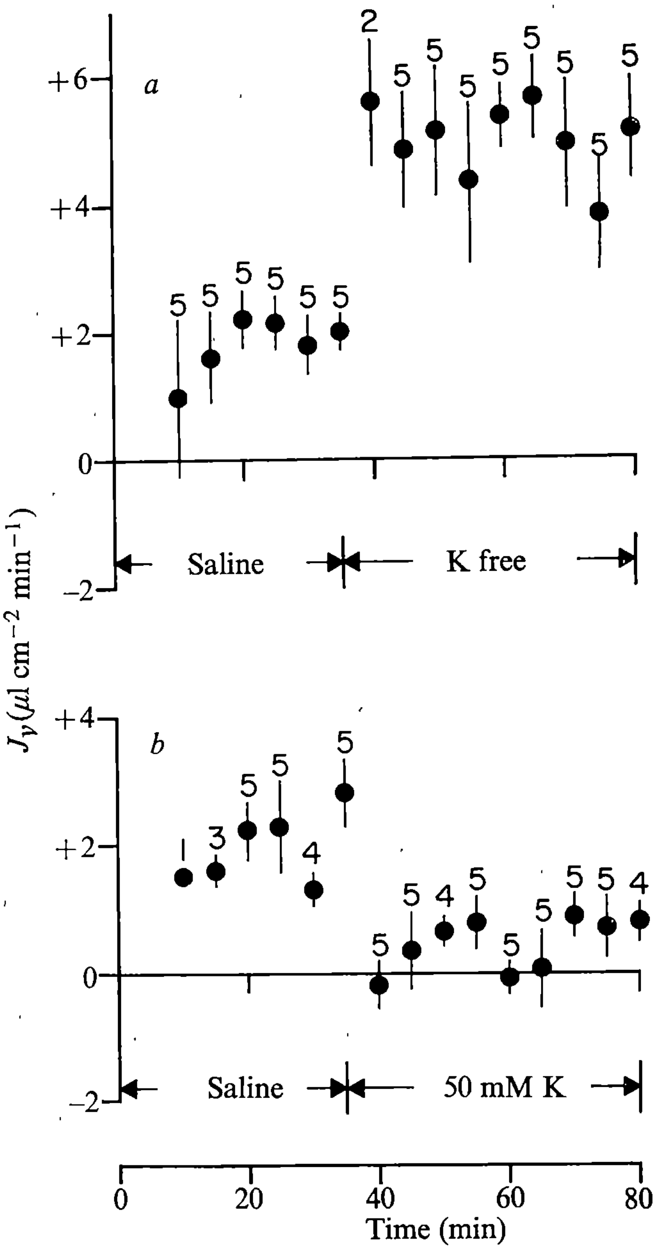

Fig. 2 *a*, Effect of potassium-free perfusate on net water flux across scorpion ileum. Ilea were first exposed to normal saline on the luminal surface for 35 min and were subsequently perfused for 45 min with medium lacking potassium. Normal saline was present in the serosal bath at all times. A positive net flux indicates water movement from mucosa to serosa. Symbols are as described in Fig. 1. *b*, Effect of increasing the potassium concentration of the perfusate from 8.0 mM (normal condition) to 50 mM on net water flux across scorpion ileum. Ilea were first exposed to normal saline on the luminal surface for 35 min and were subsequently perfused for 45 min with medium containing 50 mM potassium and normal sodium. Normal saline was present in the serosal bath at all times. A positive net flux indicates water movement from mucosa to serosa. Symbols are as described in Fig. 1.

Table 1 Effects of starvation and dehydration of *Hadrurus arizonensis* on sodium and potassium concentrations of centrifuged ileal contents

Ions in ileal fluid	Freshly fed*	Starved and partially dehydrated†	Starved and severely dehydrated‡
Na	123.3±17.8 (5)	177.0±38.6 (3)	468.0±112.4 (7)
K	274.9±41.5 (5)	131.8±58.1 (3)	83.2± 24.3 (7)

Ion concentrations are expressed in mM (mean±s.e.m.) and numbers in parentheses represent sample sizes.

*Scorpions fed crickets the day before sampling.

†Scorpions maintained without food at 25 °C and at about 30% relative humidity for 2 weeks before sampling.

‡Scorpions maintained without food at 35 °C and about 30% relative humidity for 4 weeks before sampling.

0.24 $\mu l\ cm^{-2}\ min^{-1}$ ($n=36$), which is not significantly different from zero ($P>0.05$). Figure 1 also indicates that when ilea were perfused with Na-free medium (normal medium on serosal side), the net flux of water from mucosa to serosa was eliminated ($J_v = +0.28\pm0.22$ $\mu l\ cm^{-2}\ min^{-1}$; $n=44$; $0.20>P>0.10$). An analysis of variance test comparing J_v for the control group and net water flux for the Na-free preparations showed the two groups to be significantly different ($P<0.005$).

When potassium ion was eliminated from the saline perfusate and sodium ion remained normal (281.5 mM) net water flux from the mucosal to serosal side of the preparation increased significantly ($P<0.005$) above the control value of $+1.79\pm0.26$ ($n=30$) to 4.92 ± 0.29 ($n=42$) $\mu l\ cm^{-2}\ min^{-1}$ (Fig. 2, top). An increase in luminal potassium concentration from 8.0 to 50.0 mM at constant luminal sodium concentration (281.5 mM) resulted in a significant decrease ($P<0.005$) in mucosal to serosal J_v from a control value of $+1.95\pm0.23$ ($n=23$) to $+0.43\pm0.14$ ($n=43$) $\mu l\ cm^{-2}\ min^{-1}$ (Fig. 2, bottom). The latter value is still significantly greater than zero ($P<0.01$). Control J_v values from the above three experiments, compared using analysis of variance, were not significantly different ($P>0.05$).

Scorpions that had eaten the day before sampling illustrated ileal sodium and potassium concentrations of 123.3±17.9 mM ($n=5$) and 274.9±41.5 mM ($n=5$), respectively (Table 1). Starving and dehydrating animals at temperatures up to 35 °C and for periods up to 4 weeks significantly increased the ileal sodium concentration ($n=15$; $P<0.05$) and significantly decreased the potassium concentration ($n=15$; $P<0.01$). In addition, the ratio of sodium to potassium was reversed. In freshly fed scorpions, Na/K was 0.46, whereas in starved and dehydrated scorpions Na/K was 5.6 (an ionic ratio that produced a net flux of water from lumen to blood in Fig. 2, bottom).

This is the first detailed study of a water transport mechanism in the ileum of a terrestrial arthropod, although Wigglesworth and Ramsay have suggested[9,10] that some water absorption occurs in this portion of the insect gut. Our data suggest that the ileal absorption of water in the desert scorpion occurs through a sodium-dependent, potassium-inhibited transport process. This mechanism is clearly adaptive as dehydration and starvation lead to intraluminal sodium and potassium concentrations which favour the uptake of water. In freshly fed animals excessive hydration could be reduced by the inhibitory interaction of potassium ion on the sodium-dependent water movement. Water balance in these organisms may depend on the relative sodium/potassium ratio present in the ileum. This will require further study.

The anatomical location of the inhibitory effect of potassium on sodium-dependent water movement remains unclear. The scorpion ileum, in contrast to that of insects, is unchitinised and has a tall columnar epithelium[11]. Therefore, a standing osmotic gradient[12-14] in the long intercellular spaces created by an electrogenic, energy-requiring lateral membrane cation pump could satisfactorily generate the transmural water fluxes observed. The rate of sodium efflux by the cation pump would be a function of the intracellular sodium concentration, which, in turn, would depend on the luminal concentration of this ion. Potassium ion, derived from the ileal lumen could compete with sodium for attachment to this lateral membrane cation pump and convert its electrogenicity into a simple K–K exchange involving no net ionic fluxes. A reduction or elimination of net transmural water flow would then result from a decrease in the intercellular standing osmotic gradient. In contrast, competition between sodium and potassium for a shared carrier process in the apical membrane, followed by active sodium efflux across the lateral membrane could equally well account for the effects of ions on water flow described here. Further studies of ion fluxes in the scorpion ileum are clearly needed to establish more thoroughly their role in transmural water movements.

We thank Drs R. H. Alvarado and R. McGaughey for equipment and facilities and Mr William King for analysing blood ion concentrations. We also thank Drs R. H. Alvarado and R. C. May for criticism of the manuscript. Parts of this study were funded through an NSF grant (to N.F.H.).

Fast block to polyspermy in sea urchin eggs is electrically mediated

THE prevention of polyspermy in sea urchin eggs is accomplished in two steps: a "fast" block, occurring within a few seconds of the entry of the fertilising sperm, and a "slow" block, associated with the cortical reaction (compare refs 1–4 with 5 and 6). Results presented here confirm the existence of the fast block and demonstrate that it is caused by the electrical depolarisation of the egg plasma membrane that accompanies the entrance of the fertilising sperm.

Eggs of *Strongylocentrotus purpuratus* were hand centrifuged and agitated mechanically with a jet of seawater, to remove their jelly coats. Some of the dejellied eggs adhered to the bottom of Falcon plastic Petri dishes, such that a microelectrode could be inserted. All experiments involved eggs with a stable resting potential of greater than −60 mV (Table 1). These values of resting potential are close to that calculated from independent ion tracer flux studies done on these eggs (my work in preparation with K. R. Robinson). A single microelectrode was used for both recording voltage and passing current, by means of a conventional bridge circuit. Experiments were done at 15 °C, in natural or artificial seawater, Tris-buffered at *p*H 8. In all experiments, the concentration was about 10^6 sperm per ml, which is within the range that can produce polyspermy in some batches of eggs, but not in most. Polyspermy was determined by observation of first cleavage: monospermic eggs divide into two equal cells, whereas polyspermic eggs

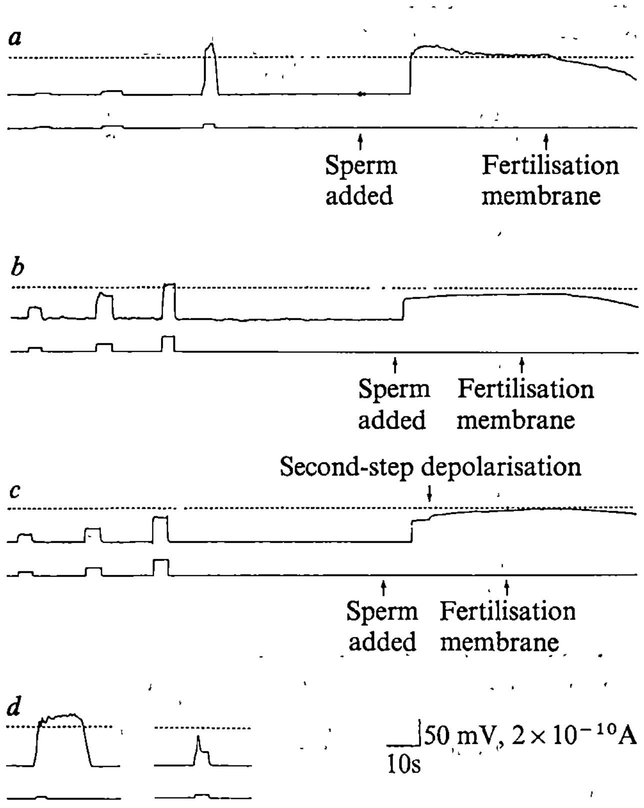

Fig. 1 Action potentials and activation potentials in *S. purpuratus*. The top trace is voltage against time; the bottom trace is current against time. The dotted line indicates 0 mV. Before addition of sperm, each egg membrane was tested for electrical excitability by applying a series of small depolarising current pulses. *a*, Egg with regenerative response to current pulse; monospermic activation potential. *b*, Egg with non-regenerative response; monospermic activation potential. *c*, Egg with non-regenerative response; polyspermic activation potential. *d*, Other examples of the regenerative response; a strong response outlasting the stimulus, a weak response.

cleave abnormally, dispermic eggs usually producing three or four cells at once[7,8].

Figure 1 shows intracellular electrical records from three eggs before, during and after addition of sperm. The fast depolarisation after the addition of sperm has been called the "activation potential"[9-15]. Within 3–30 s after the introduction of sperm near the egg, the egg membrane depolarises to a plateau at −30–+20 mV, and then after about 1 min begins to repolarise.

An interesting correlation was found between the plateau level of the activation potential (measured 3 s after its rise) and the occurrence of polyspermy (Table 1). Eggs with activation potentials which reached a plateau more positive than 0 mV were never polyspermic (none out of eight cases) and those which reached a plateau less positive than −10 mV were sometimes polyspermic (seven out of 13 cases). These results suggest that the entry of extra sperm is prevented by the more positive-going activation potential.

Figure 1*c* shows an activation potential in a polyspermic egg. About 5 s after the initial rise, there was a distinct second step depolarisation (see arrow). Eleven polyspermic activation potentials were observed (seven listed in Table 1, four not shown). All 11 showed this second step, and sometimes a third step. Ten monospermic activation potentials, as in Fig. 1*b*, were observed; of these, eight definitely did not show a second step. Two cases did show a second step; their nature is obscure. (In cases like that in Fig. 1*a*, with an oscillating plateau level, the steps could not be counted.) These results indicate that the second step depolarisation is associated with the entrance of a second sperm. The voltage at which this second step occurs is always more negative than −10 mV, suggesting that when the egg membrane is depolarised beyond −10 mV, sperm penetration is less probable.

Figure 2*a* shows that when current was applied to hold the unfertilised egg membrane at a potential more positive than +5 mV, sperm did not fertilise the egg. In spite of the presence of many active sperm adhering to the egg surface, no fertilisation membrane formed, and no electrical event resembling an activation potential occurred. In some experiments, the potential was held for more than 5 min, with repeated additions of sperm; but still no fertilisation occurred in the voltage-clamped eggs. (Surrounding eggs formed fertilisation membranes within 1 min of the first addition of sperm.) As soon as the current was turned off, fertilisation occurred: the egg depolarised, showed a typical activation potential, formed an apparently normal fertilisation membrane with the usual time course, and, if the activation potential was of the one-step form, first cleavage was normal, indicating that only one sperm had entered the egg. The same result was obtained with holding potentials ranging from +5 to +130 mV. In other experiments, the potential was held for about 10 min, without addition of fresh sperm, after which most sperm had become less active and incapable of fertilising eggs. When the current was turned off, the egg membrane returned to its original resting potential and showed the electrical properties characteristic of the unfertilised state. Morphologically, there was no sign of activation, and no development occurred. If more sperm were added, fertilisation and development proceeded in the usual way.

Fertilisation is prevented at +5 mV; but it occurs at −10 mV, as determined by the experiments reported in Table 2. The egg was depolarised enough to block fertilisation, and sperm were added. After 3–5 min, the voltage was lowered to a point where fertilisation occurred. Each experiment sets an upper and a lower limit on the threshold voltage for suppressing sperm entry. This is between +5 and −10 mV; at intermediate potentials, entry of sperm may depend on their concentration and activity, and on individual variation among eggs. This threshold is consistent with the following observations on activation potentials. (1) Eggs whose activation potential plateau (measured 3 s after the initial rise) was more positive than 0 mV, are

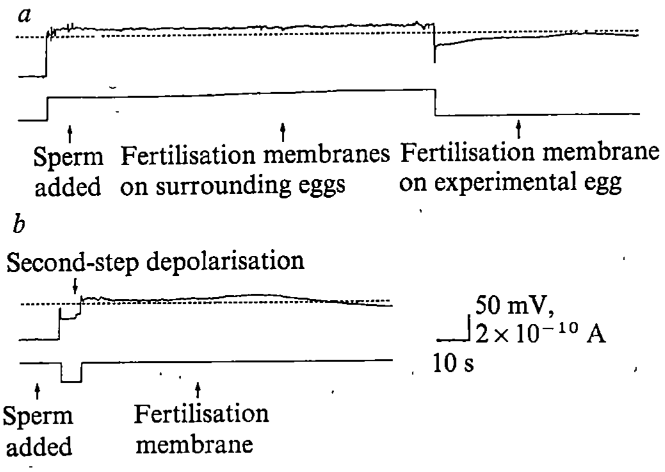

Fig. 2 Demonstration of potential dependence of sperm entrance. The top trace is voltage against time; the bottom trace is current against time. The dotted line indicates 0 mV. *a*, Suppression of fertilisation by positive holding potential. *b*, Induction of polyspermy by negative holding potential. In (*a*) the amount of current required to maintain the holding potential increased about 10% during the first 1–2 min after the current was turned on. This increase was seen even if sperm were not added. In some experiments, sperm were not added until this initial adaptation of the egg membrane was complete. The addition of sperm did not cause any change in the amount of current required to maintain the potential.

Table 1 Activation potentials for monospermic and polyspermic eggs

Egg	Resting potential (mV)	Regenerative response	Activation potential plateau (mV)	First cleavage	No. of steps in rise of activation potential	Voltage at second step (mV)
A	−75	Strong	+23	M	—	—
B	−69	Strong	+17	M	—	—
C	−68	Strong	+15	M	—	—
D	−76	Strong	+14	M	—	—

T	−65	None	−29	P	2	−26
U	−78	NT	−35	P	3	−35, −24

The activation potential plateau was measured 3 s after the initial rise. Eggs were classified as monospermic (M) if first cleavage produced two equal cells; otherwise, they were classified as polyspermic (P). The regenerative response of the unfertilised egg was classified as strong if in response to a 5-s current pulse of 3×10^{-11} A, the membrane maintained a positive potential for the duration of the pulse. None means that the response was completely, or almost completely, non-regenerative. Weak means that there was some regenerative response, but it was not strong. NT, Not tested.

always monospermic. (2) The entrance of the second sperm in polyspermic eggs occurred at a voltage more negative than −10 mV.

Application of current to bring the plateau of the activation potential to a more negative level facilitated entry of additional sperm (Fig. 2*b*). After the activation potential began, current was applied to hold the potential at −30 mV. A second-step depolarisation occurred, then the current was turned off. Observation of first cleavage showed that this egg was polyspermic, whereas 98% of the surrounding eggs in the dish were monospermic. This experiment was repeated seven times, with holding potentials of −30 ± 5 mV. In all cases, experimental eggs were polyspermic and surrounding eggs were monospermic.

These experiments demonstrate that the electrical depolarisation occurring at fertilisation constitutes a fast block to polyspermy. It was frequently observed that when the electrically monitored egg was polyspermic, other eggs in the dish were also polyspermic (except in cases where current was applied to make an egg polyspermic). Therefore, the lack of a fast block to polyspermy is a property of a batch of eggs. Loss of the capacity to block polyspermy might be a symptom of egg deterioration, either in the adult, or after removal from the adult.

The rise of the activation potential can occur within 3 s of insemination. Part of this time is necessary for the sperm to swim to the egg surface and to attach to the vitelline membrane. Only then does the sperm fuse with the egg plasma membrane. Therefore, it can be concluded that the fast block to polyspermy is established in less than 3 s after fusion of the fertilising sperm. Quite possibly, the rise of the activation potential is a direct consequence of the disturbance of the egg membrane by sperm fusion. If this is the case, it follows from the rate of rise of the activation potential that the fast block to polyspermy is established in less than 1 s after fusion. (The rise from resting level to −10 mV takes between 0.1 and 1 s.) The membrane remains in the depolarised state for about 1 min, after which the cortical reaction has occurred, thus providing a permanent block to polyspermy.

In each example in Fig. 1, a series of small depolarising current pulses was applied to the egg before sperm were added. In the case shown in Fig. 1*a*, the stimulus pulse induced a regenerative response of the egg membrane. This response showed a threshold at about −50 mV, and sometimes outlasted the stimulus (Fig. 1*d*); it has been observed in other echinoderm oocytes and eggs[15–17] and has been studied in sea urchin eggs by K. Takahashi (personal communication). It is an action potential of the sort seen in nerve and muscle (as distinct from the activation potential). Figure 1*b* and *c* illustrates eggs which did not show a regenerative response to depolarisation. These eggs showed less positive-going activation potentials after sperm addition, compared with the egg in Fig. 1*a*. This relationship between the presence of the regenerative response and the height of the activation potential is also shown in Table 1. The correlation indicated that the activation potential is caused partly by a regenerative response of the egg membrane. The data in Table 1 suggest that the sperm fusion depolarises the egg to a level of about −30

Table 2 Voltage threshold for suppression of fertilisation

Egg	Suppressing potential (mV)	Non-suppressing potential (mV)
A	+6	−6
B	+3	−11
C	+2	−10
D	+1	−10
E	+5	−7
F	+3	−12
G	+5	−6
H	+6	−5
I	—	−2

The egg membrane was held at the suppressing potential and sperm were added. About 1 min later, all the surrounding eggs had formed fertilisation membranes. 3–5 min after addition of sperm, the potential was reduced to the non-suppressing level: within 1–2 min, the experimental egg formed a fertilisation membrane. After removal of the electrode, balance of the WPI bridge circuit was tested by applying a current pulse of the same magnitude used in the experiment. If the imbalance was greater than 2 mV, data were not used. Error associated with the single microelectrode technique was small, because of the small currents used ($0.3\text{–}3 \times 10^{-10}$ A), and the high input resistances of the cells (200–2,000 MΩ, depending on the degree of regenerativeness of the egg's response), compared with the resistances of the microelectrodes (40–80 MΩ).

to −20 mV. Then, in eggs which have the capacity to produce a regenerative response, the sperm-initiated depolarisation is amplified, bringing the egg membrane potential to a level which excludes additional sperm.

This work was done in the laboratory of S. Hagiwara, and was supported by the NIH and NSF. In addition to Dr Hagiwara, I thank R. Eckert, L. F. Jaffe, S. Miyazaki, P. O'Lague, A. Ono and J. B. Patlak for help and interest.

Translation of RNA from unfertilised sea urchin eggs does not require methylation and is inhibited by 7-methylguanosine-5′-monophosphate

AT fertilisation, the rate of protein synthesis in the sea urchin embryo becomes several times greater than that observed in unfertilised eggs[1–4]. This increase does not require the synthesis of messenger RNA (mRNA), since it occurs both in the presence of actinomycin D (ref. 5) and in enucleated parthenogenetically activated egg fragments[6]. These observations led Spirin[7] to postulate the existence of preformed "maternal" mRNA in the eggs. Recent experiments have directly demonstrated the presence of mRNA in sea urchin egg cytoplasm by isolating it from postribosomal cytoplasmic fraction and translating it in a heterologous cell-free system[8].

The mechanism(s) responsible for the increased rate of protein synthesis at fertilisation is still not understood. Some investigators have attributed this increased rate to the removal of an inhibitor of protein synthesis from the egg ribosomes[9,10]. Clegg and Denny[11], however, have reported that ribosomes isolated from unfertilised eggs translate rabbit globin mRNA as efficiently as ribosomes isolated from zygotes when supplied with ascites cell postribosomal supernatant and reticulocyte initiation factors. These authors concluded that the low protein synthetic activity in unfertilised eggs is not attributable to the presence of inhibited ribosomes[11].

Activation of mRNA by adenylation may also be important in the increased rate of protein synthesis[12,13]. The mRNAs coding for histones are never adenylated[14], however, but make up a considerable proportion of maternal mRNA[8,15] Adenylation thus does not have any role in the translational activation of this class of mRNAs, although it may be involved in increasing the stability of other mRNAs[16]. In this paper we discuss two other mechanisms for the activation of maternal mRNA which involve the methylation of the 5′-terminal nucleotide or the addition of 5′-terminal 7-methylguanosine.

The 5′ termini of many viral and cellular mRNAs have been shown to contain a 7-methylguanosine residue linked, by way of a triphosphate, to the 5′-hydroxyl of the adjacent nucleotide ($m^7G^{5'}ppp^{5'}Xp$) (ref. 17). Removal of the 5′-terminal $m^7G^{5'}p$ from globin mRNA prevents its translation[18]. Moreover, Both *et al.*[19] have shown that the presence of the methyl group in the 5′-terminal guanosine is required for translation of some viral RNAs. These RNAs can be obtained without a methyl group in the 5′-terminal guanosine by synthesising them *in vitro* in the presence of an inhibitor of methylation, S-adenosylhomocysteine (SAH)[20]. Wheat germ extracts can methylate these RNAs specifically to yield the structure $m^7G^{5'}ppp^{5'}G$ in the case of reovirus RNA, which can then be translated[19]. In the presence of SAH, however, the RNA is not methylated and cannot be translated[19,20]. Both *et al.*[19] considered the possibility that methylation may be involved in the activation of maternal mRNA at fertilisation.

The assay used so far to translate maternal mRNA could not discriminate between mRNAs methylated in the 5′-terminal

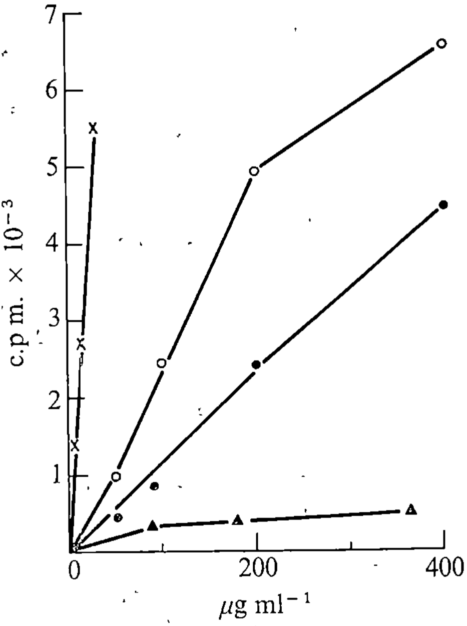

Fig. 1 Stimulation of protein synthesis in a wheat germ cell-free system by RNA isolated from unfertilised sea urchin eggs. Eggs were collected from *Lytechinus pictus* by injection of KCl and washed as described previously[8]. About 10 ml of pelleted eggs were homogenised at 0 °C with 10 strokes of a loose fitting Dounce homogeniser in 35 ml of a buffer containing 200 mM NaCl, 5 mM magnesium acetate, and 20 mM Tris, *p*H 7.6. A post-mitochondrial fraction was obtained by centrifugation at 17,000*g* for 15 min. This fraction was adjusted to contain 1% sodium dodecyl sulphate and 10 mM EDTA, then warmed to room temperature and deproteinised with phenol–chloroform–isoamyl alcohol (25:24:1) (ref. 28). RNA was recovered by ethanol precipitation and separated into poly(A)+ and poly(A)− fractions by chromatography on oligo(dT)–cellulose[22]. A portion of the poly(A)− RNA was further fractionated by sucrose gradient centrifugation. The RNA sedimenting in the 6–12S region of the gradient was recovered by ethanol precipitation. All RNA preparations were reprecipitated from ethanol three times before translation in a wheat germ cell-free system[21]. Each assay contained in 25 µl: 7.5 µl of wheat germ extract, 1.2 mM ATP, 0.25 mM GTP, 15 mM creatine phosphate, 0.34 units of creatine phosphokinase (Sigma), 22 mM HEPES–KOH buffer *p*H 7.1, 3 mM magnesium acetate, 0.1 M KCl, 2.6 mM DTT, 1.8 mM mercaptoethanol, 50 µM unlabelled amino acids minus lysine, and 2.5 µCi of ^{3}H-lysine (38 Ci mmol^{-1}). RNA was added to give the concentrations indicated. The incubation was carried out for 60 min at 24 °C and 5-µl samples were taken in duplicate for counting as described previously[21]. A background of 800 c.p.m. obtained in an incubation without added RNA was subtracted from each value. Nonspecific stimulation resulting from the addition of ribosomal RNA (rRNA) was monitored by the addition of 16S RNA isolated from *E. coli* ribosomal subunits by phenol extraction and sucrose gradient centrifugation. ×, Poly(A)+ (total); ○, poly(A)− (6–12S); ●, poly(A)− (total); ▲, *E. coli* 16S rRNA.

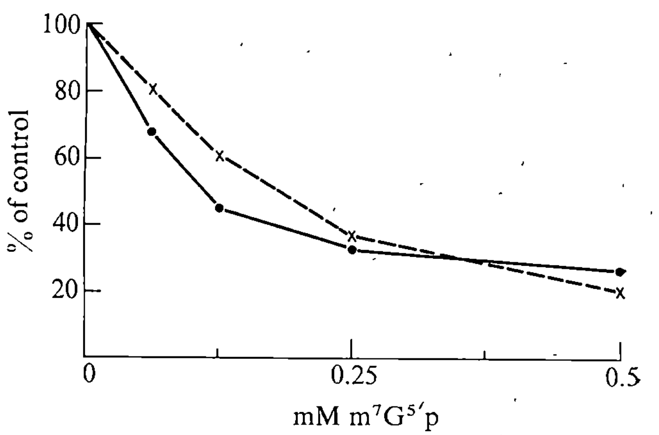

Fig. 2 Inhibition by $m^7G^{5'}p$ of the translation of poly(A)+ RNA isolated from unfertilised sea urchin eggs (●) and HeLa cells(×). The incubations were carried out as described in Fig. 1. Sea urchin egg poly(A)+ RNA was added to give 95 µg ml^{-1} and HeLa poly(A)+ RNA to give 36 µg ml^{-1}. Translation is expressed as a percentage of c.p.m. of incubations carried out in the absence of inhibitor. These values were 10,700 c.p.m. for sea urchin and 11,900 c.p.m. for HeLa RNA when corrected for the endogenous protein synthesis of the wheat germ extract.

guanosine and unmethylated mRNAs because of the endogenous methylating activity of the wheat germ extract already discussed. We have thus translated maternal mRNA in the presence of SAH to prevent its methylation during cell-free translation. In subsequent experiments we used a specific inhibitor of the translation of mRNAs with the 5′-terminus $m^7G^{5'}ppp$ (ref. 21) to show that all the maternal mRNAs translated in a wheat germ cell-free system already have this 5′-terminal sequence before fertilisation.

Eggs of *Lytechinus pictus* were homogenised and RNA prepared as described in the legend of Fig. 1. The RNA was fractionated into polyadenylated (poly(A)+) and non-polyadenylated RNA (poly(A)−) by chromatography on oligo(dT)-cellulose[22]. The poly(A)+ RNA stimulated protein synthesis 10–15 times over the endogenous level of the wheat germ extract. Somewhat greater stimulation is obtained with poly(A)+ RNA from HeLa cells (Fig. 2)[21]. The poly(A)− RNA stimulates protein synthesis much less than the poly(A)+ RNA as a result of the large amount of non-translatable ribosomal and transfer RNA in this fraction. This stimulation is, however, consistently higher than that obtained with *E. coli* 16S ribosomal RNA (Fig. 1). Better stimulation of protein synthesis is obtained by translating the fraction of poly(A)− RNA which sediments between 6S and 12S during sucrose gradient centrifugation (Fig. 1). This fraction is enriched for histone mRNA[23].

Translation of egg RNA is not affected by the presence of SAH (Table 1), indicating that methylation is not required for the translation of this RNA. On the other hand, addition of $m^7G^{5'}p$ inhibits translation of poly(A)+ sea urchin RNA to the same extent as poly(A)+ RNA from HeLa cells (Fig. 2). This latter RNA has been shown to have the 5′-terminal sequence $m^7G^{5'}ppp$ (ref. 24). We have recently shown that the translation of all HeLa poly(A)+ RNA species is equally inhibited by $m^7G^{5'}p$, by analysing their translation products synthesised in the presence of inhibitory concentrations of $m^7G^{5'}p$ (ref. 25). This nucleotide has no effect on the translation of satellite necrosis virus RNA in the wheat germ cell-free system[21], or of encephalomyocarditis virus RNA in an HeLa cell-free system[25]. Neither of these viral RNAs has the 5′-terminal sequence $m^7G^{5'}ppp$ (see ref. 25 for references).

Table 1 The effect of S-adenosylhomocysteine (SAH) on translation of sea urchin egg RNA

RNA	Concentration (µg ml^{-1})	^{3}H-lysine incorporation (c.p m.) Control	+0.32 mM SAH
Poly(A)+ (total)	95	9,455 (8.6×)*	10,589 (8.0×)
Poly(A)− (6–12S)	400	6,173 (3.9×)	6,958 (4.0×)

Experimental procedures are described in the legend of Fig. 1. The concentration of RNA is the final concentration in the assay mixtures. The concentration of SAH used (0.32 mM) inhibits the methylation of unmethylated reovirus RNA, which is required for its translation[19].

*Figures in parentheses indicate stimulation over endogenous incorporation (stimulation = (c p.m.+RNA)/(c.p.m.−RNA).

The experiments reported rule out methylation of mRNA as a significant mechanism for the increased rate of protein synthesis at fertilisation of sea urchin eggs. In addition, it is unlikely that a 5′-terminal guanosine, which already contains a methyl group, is added to egg mRNA during the incubation in the wheat germ cell-free system. The reovirus RNA synthesised *in vitro* consists of a mixture of molecules with the 5′ termini $m^7G^{5'}ppp^{5'}G$, $G^{5'}ppp5'G$, and pp5′G (ref. 20). Both *et al.*[20] have shown that only those molecules which already contain the $m^7G^{5'}ppp'G$ termini can bind to ribosomes and be translated by the wheat germ cell-free system in the presence of SAH. Therefore, the observation that egg mRNA is translated equally well in the presence or absence of SAH suggests that this RNA already contains the 5′-terminal $m^7G^{5'}ppp$ sequence found in most eukaryotic mRNAs. This is supported further by experiments showing that the translation of maternal poly(A)+ RNA is inhibited by $m^7G^{5'}p$ (Fig. 2).

We suggest that chemical modification of maternal mRNA does not have a significant role in the activation of protein synthesis at fertilisation. Maternal mRNA exists in the egg as ribonucleoprotein complexes[8]. The activation of protein synthesis at fertilisation may be a result of changes in the macromolecules associated with mRNA. Alternatively, the increased rate of protein synthesis may simply reflect the general metabolic activation of the zygote. A state of low respiratory activity occurs at the end of sea urchin oogenesis[26], although unfertilised eggs contain concentrations of ATP and GTP as great as embryos[27]. It has been proposed that cell-surface macromolecules are involved in maintaining the low metabolic state of unfertilised eggs[28]. Fertilisation leads to an increased rate of overall cellular metabolism, which can support an increased rate of protein synthesis. If this latter explanation is correct, it should be possible to isolate ribonucleoproteins from unfertilised eggs and translate them *in vitro*. We are at present carrying out further studies designed to test this possibility.

RNA synthesis in fully-grown mouse oocytes

IT is now well documented for various species that the progress of early development depends to a large extent on materials synthesised and stored in the oocyte during oogenesis. A well studied example of this phenomenon is the synthesis and accumulation of both ribosomal and "informational" RNA in amphibian oocytes[1–3]. The extent of the contribution of oocyte RNA to early mammalian development is, however, not completely clear, since mouse embryos initiate rRNA synthesis at least as early as the four-cell stage of embryogenesis[4,5] and, unlike certain lower forms, the progress of early cleavage in the mouse is interfered with by inhibitors of RNA synthesis[6–8]. On the other hand, it is clear that growing mouse oocytes synthesise and store RNA[9–12], such that the ovulated egg contains approximately the same amount of RNA on a volume basis as the amphibian egg (calculated from refs 13 and 14).

Shortly after birth, the mouse ovary is populated with thousands of small oocytes arrested in late prophase ('dictyate') of meiosis. Commencement of oocyte growth is apparently regulated within the ovary, the number of oocytes entering the growth phase being a function of the size of the pool of non-growing oocytes[15,16]. The oocyte and its surrounding follicle grow coordinately, progressing through a series of definable morphological stages[17]. The oocyte completes its growth in the adult mouse before the formation of the follicular antrum; consequently, the

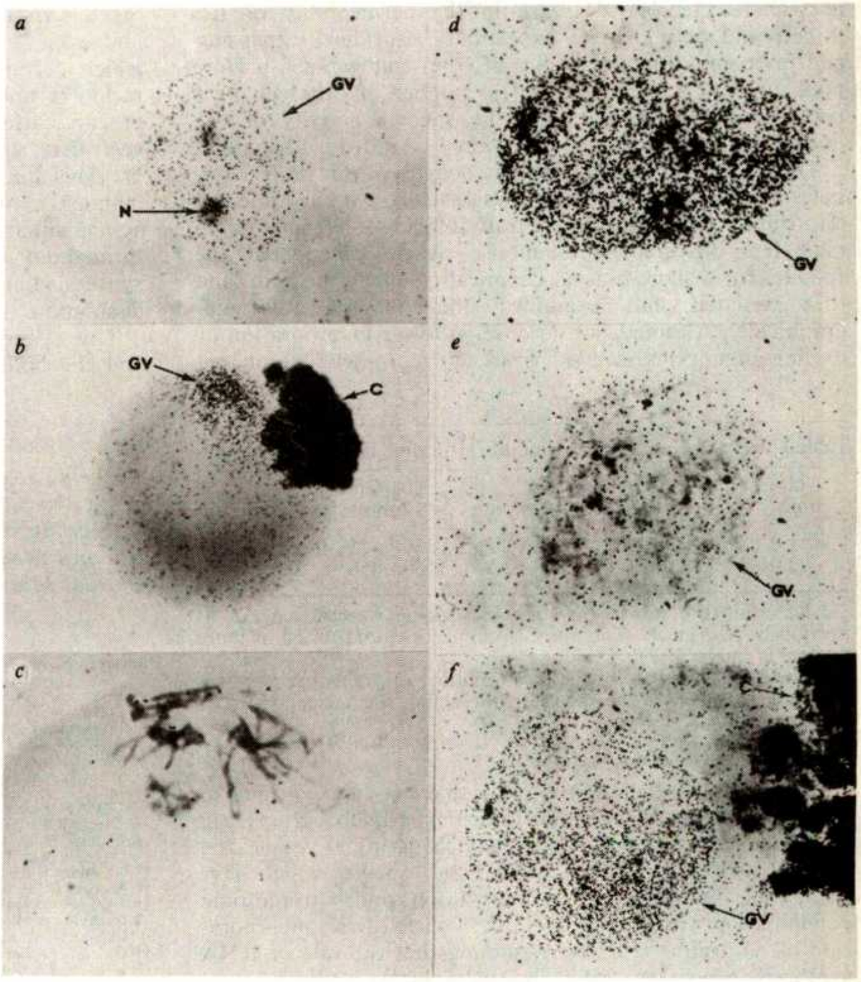

Fig. 1 Autoradiographs of mouse oocytes isolated from antral follicles micro-injected with ^{3}H-uridine or of mouse oocytes cultured *in vitro* with and without cumulus cells in the presence of ^{3}H-uridine. *a–c*, Follicles were dissected manually from the ovaries of adult (8–12 weeks of age), randomly bred, female Swiss mice (CD-1, Charles River Laboratories) and maintained in a chemically-defined culture medium[24]. The size of individual follicles was measured with an ocular micrometer attached to an inverted phase microscope. Each follicle was transferred, together with a small amount of medium, to a depression in an agar plate using a glass suction micropipette. A glass puncture micropipette attached to a Sensauer micromanipulator was used to inject approximately 1.0 nl of ^{3}H-uridine (10 mCi ml^{-1}, 26.2 Ci mmol^{-1}, New England Nuclear), made-up in culture medium, into each follicle. Follicles were then transferred through two washes of medium and cultured for 1 h at 37° C in an humidified atmosphere of 5% CO_2 in air. The entire injection and wash procedure required approximately 1 min for each follicle treated. At the end of the culture period, follicles were physically disrupted individually and the oocytes were placed on albumin-coated slides, cover slipped, and fixed by drawing a solution of alcohol–acetic acid (3 : 1 by volume) through. The slides were then frozen, cover slips flickedoff, and the slides washed and coated with Kodak NTB 2 liquid emulsion. Slides were stored in the dark at 4 °C for 5 d and were developed using standard procedures. In some cases preparations were stained with Giemsa (Harleco No. 620) at a 1 : 50 dilution with 0.1 M phosphate buffer, *p*H 6.8, for 30 min and/or treated with ribonuclease (0.1%, Sigma) for 4 h at 37 °C. Light microscopy was performed using a Zeiss Photomicroscope II. *a*, Oocyte from antral follicle, approximately 500 μm in diameter; *b*, Oocyte from antral follicle, approximately 450 μm in diameter, with adhering cumulus cells; *c*, Oocyte from antral follicle, approximately 500 μm in diameter, which has undergone germinal vesicle breakdown and chromosome condensation. *d–f*, Oocytes were obtained by puncturing ovaries from adult Swiss mice[25]. Oocytes containing an intact germinal vesicle, freed of or surrounded by cumulus cells, were collected using a mouth-operated micropipette and washed in culture medium. Cell culture was carried out in embryological watch glasses in medium containing ^{3}H-uridine (50 μCi ml^{-1}, 26.2 Ci mmol^{-1}, New England Nuclear) under paraffin oil at 37 °C in a humidified atmosphere of 5% CO_2 in air. Oocytes were cultured for 2 h, collected and washed, and those cultured in the presence of cumulus cells were denuded by repeated pipetting. The oocytes were then treated for autoradiography as above. *d*, Oocyte cultured in the presence of cumulus cells; *e*, Oocyte cultured in the absence of cumulus cells; *f*, Oocyte cultured in the presence of cumulus cells, with adhering cumulus cells. GV, germinal vesicle; N, nucleolus; C, cumulus cells.

majority of follicle growth occurs after the oocyte has stopped growing[18]. This report shows that mouse oocytes continue to synthesise RNA even during the period of follicular antrum formation when oocyte growth has ceased, a finding which differs with the current view that RNA synthesis in mouse oocytes is inhibited at the time of, and subsequent to, antrum formation[9,11].

We find that when ^{3}H-uridine is administered intraperitoneally to adult mice, and its incorporation into oocyte RNA is evaluated soon after by autoradiography of ovarian sections, there is a positive correlation between oocyte size and uridine incorporation within the oocyte's nucleus (germinal vesicle) in follicles lacking an antrum. Those follicles containing an incipient or highly developed antrum display virtually no grains over the oocyte's germinal vesicle or nucleolus. These observations are essentially identical to those of several other investigators and have led previous workers to conclude that at the time of antrum formation RNA synthesis within the oocyte is suppressed[9,11]. This means that for a period of several days, while the follicle undergoes tremendous growth, the fully-grown oocyte possessing an intact germinal vesicle and nucleolus is quiescent with respect to RNA synthesis. Alternatively, these observations could reflect, not the absence of RNA synthesis in oocytes of antral follicles, but rather, a precursor pool of UTP of such low specific activity that oocyte RNA synthesis goes undetected. A decrease in the permeability of the follicle and/or oocyte to exogenous ^{3}H-uridine, expansion and/or compartmentalisation of the endogenous uridine pool of the oocyte, or any of a number of other changes could lead to a decrease in the specific activity of the oocyte's UTP pool at about the time of antrum formation.

To explore the possibility that oocytes within antral follicles actually continue to synthesise RNA, we have injected ^{3}H-uridine directly into antral follicles (450-500 µm in diameter) dissected from mouse ovaries, incubated the follicles for a short time in chemically defined medium, and then isolated and examined the oocytes autoradiographically. Although we do observe lower incorporation of uridine in oocytes isolated from antral follicles compared with preantral follicles, it is clear that oocytes continue to synthesise RNA throughout follicular growth; grains are found concentrated within the oocyte's germinal vesicle and nucleolus (Fig. 1). On the other hand, oocytes which have undergone germinal vesicle dissolution and chromosome condensation within the follicle show virtually no incorporation of ^{3}H-uridine (Fig. 1). Assuming that the rate of RNA synthesis in oocytes within isolated follicles is the same as that *in vivo*, these results suggest that previous investigations, which involved injection of ^{3}H-uridine into the animal, rather than into isolated ovarian follicles, failed to detect RNA synthesis in oocytes of antral follicles as the result of precursor pools with too low a specific activity to enable measurement. Additional support for this suggestion comes from experiments carried out with isolated mouse oocytes cultured *in vitro* in the presence of ^{3}H-uridine. Although oocytes freed of cumulus cells by repeated pipetting show only low levels of uridine uptake and incorporation, oocytes surrounded by cumulus cells show increased uptake of uridine and heavy incorporation over the oocyte's germinal vesicle and especially over the nucleolus (Fig. 1 and Table 1). These experiments not only point to the importance of interactions between oocytes and cumulus cells, at least in so far as the entrance of exogenous uridine into the oocyte's intracellular pool is concerned, but also demonstrate clearly that fully-grown oocytes isolated from antral follicles synthesise RNA as long as there is an intact germinal vesicle and nucleolus. In experiments not presented here (Wassarman and Letourneau, unpublished), we find that RNA synthesis ceases concomitant with the onset of meiotic maturation of the oocyte, which includes dissolution of both the germinal vesicle and nucleolus.

Table 1 Uptake and incorporation of ^{3}H-uridine into mouse oocytes

Culture time (h)	C.p.m/Oocyte* +Cumulus	C.p.m/Oocyte* −Cumulus	Grains/GV† +Cumulus	Grains/GV† −Cumulus
1.0	16.0 ± 2.1	10.2 ± 2.2	320 ± 55	110 ± 40
2.0	62.6 ± 14.8	9.8 ± 1.9	1550 ± 450	280 ± 60

* Determination of TCA-soluble ^{3}H-uridine was carried out as previously described[26]. The mean ± s.e.m. for a total of 50 or more oocytes is shown.

† These values represent the mean number of grains per germinal vesicle for 20 oocytes. The values do not include the nucleolar area of the germinal vesicle.

The findings reported here are of particular interest in connection with studies of RNA synthesis during oogenesis in *Xenopus laevis*. For some time it was considered that fully-grown amphibian oocytes are quiescent with respect to RNA synthesis[19–21], attributable, perhaps, to the presence of a specific inhibitor of rRNA synthesis[22,23]. Recent work has, however, shown that these oocytes are not metabolically dormant, but synthesise total RNA at a rate at least as great as smaller oocytes[13]. Two factors which contributed to the impression that fully-grown oocytes do not synthesise RNA are a greatly reduced uptake of exogenous precursors by fully-grown, compared with smaller, oocytes and expansion of the oocyte's endogenous precursor pool which accompanies oocyte growth; both factors can lead to low or undetectable levels of incorporation of radioactive precursors into RNA. The observations reported here suggest that similar factors have influenced the results of previous studies of RNA synthesis during oogenesis in the mammal and have led to an incorrect assessment of the actual situation. Mouse oocytes actively synthesise RNA throughout the period of follicle growth and terminate synthesis only at the time of germinal vesicle and nucleolus dissolution.

matters arising

Spreading rate in Iceland

WALKER has proposed a new interpretation of Icelandic tectonics in which he recognises the existence of a number of parallel or *en echelon* rift zones[1]. He showed that the aggregate width of the active zones is greatest in southern Iceland and, by postulating that this width is proportional to spreading rate, inferred that the spreading rate in southern Iceland may be three to four times faster than in northern Iceland or the adjacent mid-ocean ridges.

There is one serious objection to this idea. An excess spreading rate in the southern part of Iceland would generate a greater length of lithospheric plate, and either this would have to be taken up in a zone of plate consumption, or else it would result in major compressive deformation of at least one of the plates. There is no evidence that either effect occurs, and I suggest the following explanation of the observations.

The increased widths of young rock outcrops and the greater number of active volcanic centres and thermal fields in the south of Iceland, cited by Walker in support of his hypothesis, are in fact very good evidence of increased magmatism, though they do not necessarily imply an increased spreading rate. The excess material produced can be accommodated by crustal thickening rather than accelerated spreading, thus avoiding the plate-tectonic complications mentioned above. There is abundant geophysical evidence that there is in fact a thickened crust under Iceland as a whole[2], though it is not clear whether the thickening increases towards the south. It seems quite possible that the resultant thicker lithosphere would distribute tectonic stresses over a wider area, giving rise to a pattern of rift zones such as that observed by Walker, and obviating the need to assume that the width of the active zones is proportional to spreading rate.

The same reasoning may be applied to Afar and the Azores, each of which has an excessively thick crust[3,6] and complex rift zones (ref. 4 and D. C. Krause and B. A. McGregor, unpublished) analogous to those described for Iceland. Schilling[5] has proposed that the thicker crusts in all three areas arise from excess magmatism generated by mantle blobs or plumes, and Walker's observations of increased magmatism in southern Iceland represent a partial confirmation of that, and suggest that it is in southern Iceland that the present plume discharge is centred.

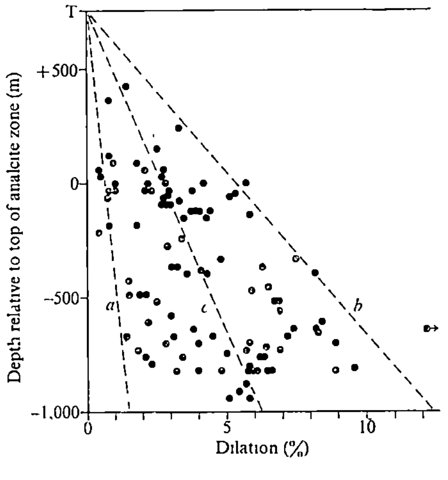
WALKER REPLIES—I fully accept the awkward implications of excess spreading in the southern part of Iceland, as raised by Searle. Some excess spreading could, however, be accommodated by an outward bulging of this part of Iceland, but a determination of its extent must await the delineation of magnetic strip anomalies around the east of the country. Some excess material produced by volcanism could be accommodated by the observed crustal thickening.

An alternative possibility is that basalt is destroyed on a large scale low down in the Icelandic crust, and this is supported by a significant anomaly in the geology of Iceland. This anomaly, the existence of which has apparently not hitherto been pointed out, is the low dyke intensity gradient in the Icelandic dyke swarm. It should be explained that quantitative studies of the Tertiary swarm have been made at many sites in the fjordlands of eastern Iceland[1,2], and everywhere reveal that the dyke intensity increases linearly downwards. On Fig. 1 all the best dyke intensity data, quoted as a percentage dilation, are plotted against depth relative to the top of the analcite zone; this zeolite zone boundary is the most convenient datum level, and is believed to lie 750 m below the original (pre-erosion) top of the Tertiary crust. Much scatter appears on Fig. 1, because at any one level the dyke swarm varies in intensity according to the position of the measuring site relative to local sub-swarms. The intensity gradient varies between 1% dilation per 140 m and 1% per 1,100 m depth, and the median gradient is ~ 1% per 280 m depth.

Fig. 1 Plot of variation in percentage dilation of the dyke swarm against depth in the Tertiary lava pile of eastern Iceland, relative to the top of the analcite zone. Each dot is based on the measurement of dyke thicknesses in a strip of well-exposed country on average 1 km long. *a*, 1% dilation per 1,100-m gradient; *b*, 1% per 140-m gradient; *c*, 1% per 280-m gradient.



A requirement of crustal spreading by the conventional dyke injection model is that the dyke swarm intensity should attain 100% at the base of the crust. Extrapolation of the measured intensity gradient yields 100% dilation at a depth between 14 and 110 km, or 28 km if the median gradient is taken. The crustal thickness is not known for eastern Iceland, but from similar areas elsewhere in Iceland is likely to be ~ 15 km (refs 3, 4). A discrepancy therefore clearly exists: if the median intensity gradient is taken, then > 10 km of crust would seem to be missing.

The magnitude of the discrepancy is critically dependent on the nature of crustal layer 3: whether it consists of metamorphosed basalts[3], or is largely made of intrusive sheets[5]. Layer 3, the lowermost crustal layer, with a P-wave velocity averaging 6.5 km s^{-1}, is found beneath the whole of Iceland and in eastern Iceland occurs on average ~ 3 km below sea level (or 4 km below the original top of the crust). At the top of layer 3 the extrapolated dyke intensity is between 3.6 and 29%, or 14% taking the median gradient. If layer 3 consists largely of an intrusive sheet swarm, then the basaltic lavas in the layer are in effect greatly attenuated by the sheets and the discrepancy is therefore greatly increased: if the median gradient is taken, then several tens of kilometres of crust may be missing.

There is another relationship which seems to support the same general conclusion. It depends on how the total width, D, of dykes injected in a rift zone compares with the total thickness, L, of lava flows produced within the same time period Crustal spreading models assume that $L=D$, which is the ideal situation for steady-state spreading. From the author's experience of volcanism in Iceland it seems more likely, however, that $L > D$, since the typical eruption produces lava totalling tens of metres thick near source, compared with a width of 2 or 3 m for the dyke feeder. An imbalance still remains when dykes in non-eruptive fissures are included.

There is no *a priori* reason why L and D should be equal; L is controlled more by the thermal regime in the mantle immediately below Iceland, whereas D is controlled more by the global stress system, although there is some latitude for a local increase by outbulging and other readjustments within Iceland. If $L > D$, then the crust must inevitably thicken with time. The fact that the Icelandic crust does not thicken in this manner indicates the operation of a counteractive effect destroying crustal material.

Two types of destruction can be envisaged. One type is a general 'ablation' or sapping of material from the base of the crust; the generation of acid magmas by the partial fusion of basalt may be a byproduct of it. The other type is a periodic foundering of big crustal blocks into the upper mantle. The average P-wave velocity in the upper mantle beneath Iceland is only 10% higher than that in crustal layer 3, and the density contrast is likely to be of comparable magnitude. In some circumstances a higher degree of partial melting in the upper mantle might so reduce its density as to cause a density inversion to arise, such that a large scale foundering of layer 3 becomes possible.

There are two prerequisites for the development of a density inversion, namely an appropriate buildup of heat in the upper mantle, and an efficient cooling of the crust so as to preserve its relatively high density. Regarding the latter, the nature of magmatism in Iceland is such as to generate rapidly great volumes of cold rock in the upper part of the crust within and near the active rift zones, and to depress these cold rocks rapidly towards the mantle. The cold rocks consist partly of lava flows which cool rapidly in the air, and partly of dykes intruded above layer 3 or sheets intruded at the top of layer 3, where water cooling by circulating groundwater is extremely effective. Viewed broadly, a high heat loss rate from the Icelandic mantle hot spot is achieved by three main mechanisms besides conductive heat flow: the outpouring of lavas, the emplacement and water cooling of high level minor intrusions, and the rapid downsagging of cold crustal rocks towards, and perhaps their incorporation in, the mantle.

One can speculate that a major foundering episode took place in the southern half of Iceland between 3 and 5 million years ago, and was responsible for a major episode of crustal flexuring (that which formed for example the Lagarfljót flexure zone in eastern Iceland[2]), and for the birth of some of the multiplicity of rift zones in the resulting thinned crust of southern Iceland[6], besides perhaps facilitating outbulging to accommodate the increased spreading there.

Aromatic structures in coal

THE demonstration by Hayatsu *et al.*[1] that dichromate oxidation of coal allows isolation of clearly identifiable hetero-aromatic entities is important because very little is so far known about such structures in coal. But it does not by any means invalidate our inference[2] that the skeletal structure of coal is predominantly non-aromatic, and is, in fact, entirely consistent with that view.

Bearing in mind how susceptible coal is to oxidation by air at temperatures as low as 70 °C, autoclaving it with aqueous dichromate at 250 °C for 36 h is hardly a mild treatment, and raises the distinct possibility of pyrolytic cleavages and major structural rearrangements. We note, in this connection, that there is a large body of evidence that coals other than anthracites begin to suffer substantial thermal decomposition well below 200 °C.

Assuming that the carboxylic acids identified by Hayatsu *et al.* did not form pyrolytically set up polynuclear 'artefacts', considerable interest attaches to the carbon balance which quantifies their findings. From the nature and yield of their oxidation products we calculate that at most 45% of the original carbon in the coal was recovered in the carboxylic acids. The remainder was lost to CO_2 and since dichromate does not, as Hayatsu *et al.* correctly point out, cause significant ring degradation, this must have come from non-aromatic (Sp^3 carbon) structures. Moreover, since the carboxylic moieties must, for the same reason, also have formed from aliphatic and/or alicyclic linkages, at least 25% of the carbon in the carboxylic acids must likewise be assigned to the Sp^3 valence state. Overall, then, the results obtained by Hayatsu *et al.* indicate that some 65% or so of the total carbon in coal exists in the Sp^3 state—which coincides almost exactly with our estimates from hypohalite oxidation of coal.

It appears that all coal oxidation studies, regardless of what oxidants and reaction conditions are used[3–5], lead to substantially similar products and strikingly similar $Sp^3:Sp^2$ carbon ratios (see Table 1). Were one to assume that coal is mostly comprised of polycyclic aromatic structures, one would therefore be forced to conclude that weak oxidants, such as sodium hypochlorite ($E_B^0=0.89$) or dichromate ($E_B^0=1.2$) can oxidise polycondensed aromatics as readily as alkaline potassium permanganate ($E_B^0=1.69$) or concentrated nitric acid—a conclusion that is inconsistent with what Hayatsu *et al.* correctly designated for dichromate oxidation. If nothing else, the sensitivity of coal to oxidation and the fact that the strength of the oxidant is not a prime determinant of the vigour of the reactions should be enough to suggest a predominantly non-aromatic structure. Relatively asymmetrical, branched 'diamondoid' skeletal structures, which are much more easily oxidisable than polycondensed aromatics with conserved symmetry, would certainly be more consistent with experimental observations.

In these circumstances, we conclude that discovery of C_{10}-, C_{14}- and C_{18}-polycyclics among the oxidation products of coal, if confirmed by less drastic means than those used by Hayatsu *et al.*, only requires a review of earlier reports that oxidation never delivers anything beyond single-ring compounds (and CO_2).

Table 1 Distribution of carbon in oxidation products (as percentage of coal carbon, Pittsburgh seam)

Products	Alkaline $KMnO_4$ (various conditions)	$NaOH+H_2O+O_2$ Press 7–25 atm 100–250 °C	$Na_2Cr_2O_7+H_2O$ Autoclave 250 °C	$NaOCl+H_2O$ 60–65 °C Open flask

HAYATSU ET AL. REPLY—First, with respect to the ease of oxidation of coal by air at 70 °C we need only quote from ref. 1: "For example, at 180 °C and oxygen concentrations <20%, conversion to humic acids is negligible, and significant reaction rates at this temperature are only observed when [O] >50%".

Detailed pyrolysis studies of the bituminous coal we used for our experiments showed no evidence of thermal decomposition until the coal was heated well above 250 °C.

Second, the estimate of the degree of aromatic structure from our data is much too low for the following reasons: (a) Because of the large concentrations of salts resulting from oxidation with $Na_2Cr_2O_7$, yields were not quantitative and were estimated to be ~75%. As we mentioned in our paper the amphoteric acids were not isolated from this oxidation but were identified in the product from a photochemical oxidation with much less interfering residues; (b) a significant fraction of the aromatic compounds appeared in a neutral fraction, and (c) as Friedman has shown, aromatic rings containing phenolic groups would have been destroyed by $Na_2Cr_2O_7$.

By a method based on the stoichiometry of fluorination reactions (J. Huston, R. G. Scott, and M. H. Studier, unpublished) we have calculated the aromaticity to be 69%.

Third, we agree that the strength of an oxidising agent is less important than its specificity in studying coal structure. Friedman[2] has demonstrated the selectivity of aqueous sodium dichromate in an autoclave at 250 °C without pyrolytic cleavage or structural rearrangements occurring. Several authors[3-5] have shown the nonspecificity of aqueous NaOCl, the reactions of which are the basis of Chakrabartty's and Berkowitz's postulate that coal is primarily non-aromatic.

We feel it more likely that coal consists of aromatic units bridged largely by aliphatic and hydro-aromatic groups than that it has a 'diamondoid' structure.

Trapped helium and argon and formation of the atmosphere

FISHER[1] reports ^{4}He/^{40}Ar ratios from analyses of the glassy margins of several deep sea basalts which are higher than can be generated by the *in situ* decay of K, U and Th in the mantle if one uses conventional estimates for the K/U and Th/U ratios in the mantle. He then concludes that "the data rule out all models which ascribe the terrestrial atmosphere to any type of degassing of a mantle which is chondritic or crustal with respect to the K/U ratio". While this sweeping conclusion may ultimately prove correct, Fisher's argument is suspect since it involves an assumption which is probably false. The assumption is explicitly stated: "The rare gases found in deep sea basaltic glasses are clearly those trapped within the rock on its eruption, due to the high hydrostatic pressures and rapid chilling, and as such represent mantle-ambient gases".

Oceanic basalt magmas are commonly taken to be fractionated (by partial melting) samples of the mantle. Ozima and Alexander (unpublished) have argued that the partial melting process produces large enrichments of light rare gases relative to the heavy rare gases in the melt phase. For example, Gramlich and Naughton[2] have shown that Iherzolite nodules, which they conclude represent unfused residue from the partial melting process, contain ^{4}He/^{40}Ar ratios lower than reasonable values. If the residue is depleted in ^{4}He relative to ^{40}Ar, simple mass balance requires that the melt phase be enriched in ^{4}He relative to ^{40}Ar. While data from the glassy rims do probably represent lower limits on the ^{4}He/^{40}Ar ratios in the magma, the magma values are only bad upper limits on the mantle–ambient values. The magma ^{4}He/^{40}Ar ratios do not, therefore, rule out the degassing models mentioned above.

[2] Gramlich, J. W., and Naughton, J. J., *J. geophys. Res* , 77, 3032–3042 (1972).

FISHER REPLIES—The suggestion of Alexander[1] (based on unpublished work of Ozima and Alexander) that the ^{4}He/^{40}Ar ratio may be quantitatively enriched in the mantle–magma segregation process is certainly interesting, though unproven. Alexander's suggestion that Gramlich and Naughton[2] concluded that their samples represent residue from the partial melting process with He depleted relative to Ar, and therefore that the melt phase must be enriched in He relative to Ar, ignores Gramlich and Naughton's actual interpretation of their data: that their gas ratios were probably "altered during a high temperature episode such as that existing during transport in the erupting lava"[2].

We know that such a high temperature episode existed (the eruption itself), and that this would segregate He from Ar; therefore we cannot use these data as evidence for another and previous segregation process, as Alexander would like. The simplest interpretation of my data remains that the measured ratios represent those in the source material except as modified during eruption; that is, they are lower limits to the mantle–ambient ratios. Experimental investigations that might prove the reality of the Ozima–Alexander model will be welcomed.

Alexander (personal communication) has pointed out an error in Fig. 1 of my paper[3]: the values for all curves below 10^7 yr should be levelling off, not decreasing. This does not affect in any way the arguments presented either there or here.

Ambiguous cognitive contours

BRADLEY and Dumais[1] have presented figures that induce ambiguous subjective contours, which tend to alternate between two (or more) perceived forms. Bradley and Dumais suggested that because these figures are not "stimulus-bound", they cannot be accounted for by a physiological model, but arise when alternative perceptual hypotheses are tested[2]. Although this account is plausible, a more physiological explanation may also exist. The alternation of perceived forms resembles an effect described by Campbell *et al.*[3,4]: if two gratings that have sinusoidal luminance profiles are projected so that their axes are at an angle to one another, the gratings tend to be seen in alternation, one replacing the other at intervals of several seconds. Campbell *et al.* suggest that this occurs because while one grating is perceived, the channel that is most sensitive to that grating becomes adapted. When adapted, its sensitivity decreases[5], allowing the other grating to predominate.

When observed steadily, Bradley and Dumais' patterns undergo a similar alternation. This is seen most easily in their star pattern, in which the two triangles predominate alternately. It is difficult or impossible to maintain the perception of one triangle, although if they had a cognitive origin, one would expect to be able to do so. Furthermore, an adaptation hypothesis can better account for the fact that the figure that is predominant at a given moment appears brighter. If adaptation takes place, it is reasonable that the less strongly adapted figure should be brighter. It thus seems premature to conclude that this phenomenon cannot eventually be accounted for by a physiological model.

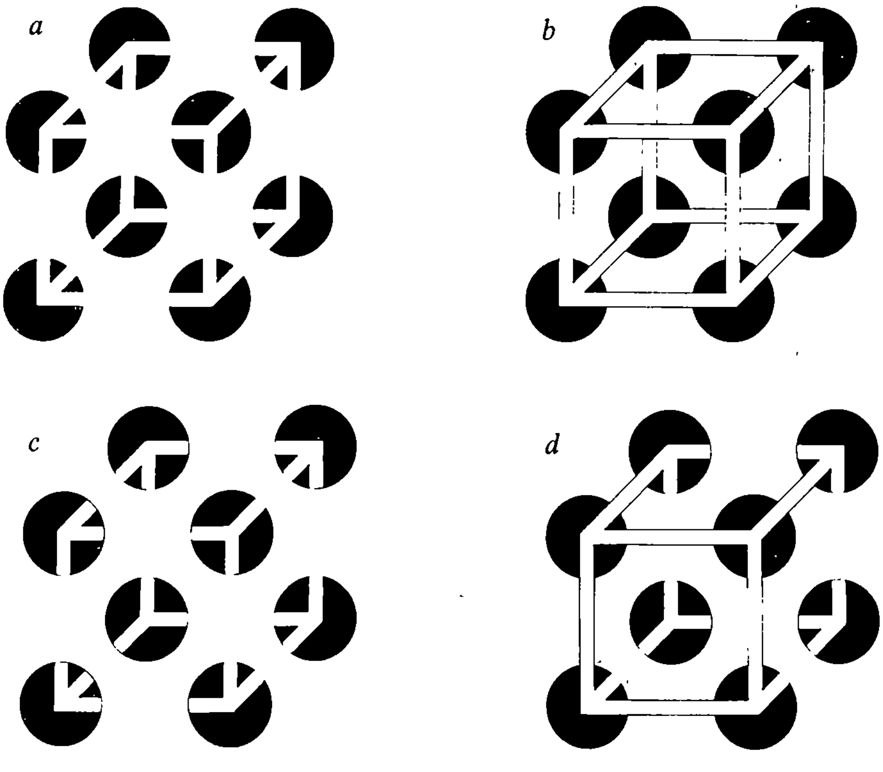
BRADLEY, DUMAIS AND HEYWOOD M. PETRY REPLY.—If Cavonius is correct in attributing the alternating organisations of our ambiguous configurations to the adaptation of "the channel that is most sensitive to that grating" (ref. 1), then such configurations should alternate independently of the viewer's knowledge of the possible organisations. It is not difficult, however, to construct figures which are highly resistant to alternations until the viewer is sensitised to the existence of alternative organisations. An example of such a figure, called the subjective Necker cube[2], is presented in Fig. 1*a*. If observers are permitted to look at this figure for an extended period, most will eventually report seeing a cube overlying eight black disks and a white background (as in the unambiguous version of Fig. 1*b*). The whiter-than-white bars of the cube seen extending between the disks are, of course, illusory and are bounded by subjective contours.

Having achieved this cube-in-front organisation, most observers will maintain it indefinitely. If shown the unambiguous cube-in-back organisation of Fig. 1*c*, however, they then report being able to see the cube in Fig. 1*a* in that position as well, with subjective contours now bounding the interior edges of the 'holes' of the occluding surface rather than extending between the disks. Of course, once aware of these two organisations, the observer will then experience spontaneous alternation between the cube-in-front and cube-in-back. Although this might be accounted for by an adaptation hypothesis, such an hypothesis could not account for the initial absence of alternation. Furthermore, the observer can be 'cued' to a third possible organisation; that depicted in Fig. 1*d*. In this case, the observer will see both straight and curved subjective contours in Fig. 1*a*, because the 'straddled' organisation cued by Fig. 1*d* puts part of the cube in front and part in back. It seems reasonable to suppose that perceptual phenomena which are strongly affected by set or expectation probably have a cognitive origin.

Fig. 1 Unambiguous versions of three possible organisations of the subjective Necker cube. *a*, Original ambiguous version; *b*, cube-in-front; *c*, cube-in-back; *d*, straddled.



This view does not preclude the possibility of a physiological explanation of subjective contours. It does, however, require that any such explanation be able to incorporate the effects of cognitive variables (set, expectation, attention and so on) on the manner in which subjective contours are perceived in ambiguous displays.

Insectivorous grouse

IT is, perhaps, unfortunate that we did not publish the results of incubating hens and other adult grouse separately in our paper on insects as food of adult grouse[1]. In 1974, droppings from four incubating grouse on wet moors (at Moor House, Cumbria) were examined and contained similar proportions of insect remains (mainly tipulids) as did non-incubating birds. Similarly, females with young of different ages all showed tipulid remains in their droppings. Thus Moss and Watson[2] can rest assured that incubating and brooding female red grouse do, at least on occasion, feed on tipulids in addition to vegetation.

Moss and Watson go on to state "there is no evidence that tipulids are ever in short supply on wet moors". We have information to the contrary[3–5]. In addition, both *Molophilus ater* and *Tipula subnodicornis*, the main species involved, fluctuate markedly in numbers and larval densities between 2,500 m^{-2} and 50 m^{-2} in the former and 250 m^{-2} and 5 m^{-2} in the latter have been documented by us on several occasions.

The relationship between grouse numbers and tipulid densities on wet moors is unknown. Even the cautious research workers might consider investigating the possibility of such a relationship, particularly since it has been shown that N and P, which are in much higher concentrations in tipulids than in *Calluna*, are important to grouse[6].

reviews

IBP–nitrogen fixation

Christina Kennedy

Nitrogen Fixation by Free-Living Micro-organisms. (International Biological Programme 6.) Edited by W. D. P. Stewart. Pp. xxi+471. £13.50. *Symbiotic Nitrogen Fixation in Plants.* (International Biological Programme 7.) Edited by P. S. Nutman. Pp.xxviii+584. £22.00. (Cambridge University: Cambridge, London and New York, 1976.)

An outstanding feature of the IBP synthesis meeting on nitrogen fixation held in Edinburgh in September 1973 was its international character. That very strength created a potential weakness as far as publication of the proceedings was concerned, and I remember sometimes labouring over abstracts at that meeting wondering just what it was that I had come to learn about. Messrs Stewart and Nutman, the editors, are therefore to be congratulated on the high standard of English and easy readability of both these volumes which are largely based on that IBP meeting. Both volumes contain a mixture of review articles, original research papers and a few compiled results of surveys. The reader must beware, however, of chapter titles that belie their actual contents.

The first two sections of volume 6 give roughly equal time to the two major groups of free-living nitrogen fixers, certain bacteria and blue-green algae. The reports of field research in Brazil (Dobereiner and Day, ch. 3) and in the UK (the longstanding Broadbalk experiments at Rothamsted; Day *et al.*, ch. 5) are elegant examples of how to assess the ecological importance of bacterial nitrogen fixation, but this section would benefit from an overview of the relative importance of the various groups of free-living nitrogen-fixing bacteria. There is also very little about the regulation or physiology of fixation in bacteria other than azotobacters.

If we are left wondering about the overall contribution of non-symbiotic bacteria to the world's agricultural nitrogen balance, there can be little doubt about the usefulness of blue-green algae in certain agricultural situations. These are extensively covered in volume 6 and complemented by the excellent chapters in volume 7 on the symbiotic associations of blue-green algae with plants. It is a pity that all this work is not included in the same volume in spite of the different modes of fixation.

Volume 6 continues with a section on the use of acetylene reduction as a measure of nitrogen fixation which, although useful, is not the last word, as equally valuable descriptions of this technique are described throughout research articles in both volumes. The final biochemistry section contains some well-written, if outdated, reviews and research reports on nitrogenase (this faster-moving branch of nitrogen fixation has been often reviewed recently). Still timely is ch. 26 on reductants for nitrogenase. Hardy *et al.* remind us (ch. 24) that there is another world of relevant research on the chemistry of dinitrogen complexes.

Two chapters in the biochemistry section of volume 6 describe the serological identification of rhizobia and leghaemoglobin biosynthesis and therefore could usefully have been swapped for the opening three chapters on the genetics of nitrogen fixation in free-living bacteria found in volume 7 (also a little late to be useful since most of the data has appeared elsewhere by now). We find that *Rhizobium* genetics is in a primitive state by comparison.

The rest of volume 7 describes nitrogen fixation in symbiotic systems, both legumes and non-legumes. It includes sections on legume inoculation (reviews and research reports), legume field experiments (mostly research reports on plant yields versus inoculation or fertilisation), and reactions of legumes to environmental stress (including legume physiology) The final section includes non-leguminous root symbioses and the aforementioned blue-green algal–plant associations. The negative results of chapter 39 should kill the oft-sought, oft-cited nitrogen fixing role of nodules found on certain tropical leaves.

On the whole these volumes contain an unprecedented collection of information and references. Access could have been improved by better indexing, especially since some chapter titles are misleading. Since the books will probably be bought as the set, cross-indexing would have been more useful than the multi-lingual tables of contents. They are burdened with the usual disadvantages of large-scale publishing enterprises in being too expensive and too late. The meeting was in 1973 and as a consequence neither volume refers to areas of more recent importance: the role of glutamine synthetase as a regulator of nitrogen fixation, fixation by *Rhizobium ex planta* (or even in callus culture) or nitrogen fixation by *Spirillum lipoferum* in maize plants.

Finally, volume 7 closes with excerpts from the meeting's last session which was a colourful, sometimes heated, sometimes amusing discussion of possibilities for extending nitrogen fixation to other plants. Unfortunately that atmosphere dosen't come through. The written version of Ray Valentine's comments that "exploratory work . . . is not necessarily expensive" just doesn't make it since what he really said was "doing this stuff will only cost a few bucks." ☐

Dr Kennedy is a senior scientific officer in the Agricultural Research Council's Unit of Nitrogen Fixation at the University of Sussex, UK.

New power horizons

G. R. Bainbridge

Energy: The Solar Hydrogen Alternative. By J. O'M Bockris. Pp. xviii+365. (Architectural Press: London, February 1976.) £13.50.

Practical scientists and engineers, energy planners and policy makers, to whom the author says his book is directed, will have no difficulty while reading it in coming to the conclusion that economic, large scale solar energy and hydrogen fuel systems are still many decades away. The uncertainties about continuing supplies of fossil fuels, including the problems of extracting, transporting and applying them economically will lead to increasing research and development work into several alternatives: in particular, solar and hydrogen.

The students of energy conversion, the environmentalists and people concerned in an effort to prepare for the coming era of difficulty, in which a change in energy source has possibly to be made from the diminishing fossil fuels, might reasonably be excused if they remain confused after trying to read the multi-faceted presentation from cover to cover. The book contains a bit of everything in energy; atomic, wind, geothermal, hydro and tidal illustrations are all martialled sequentially, as well as the main subjects of the book, to help to answer a whole host of questions about the rate at which abundant 'clean' energy might substitute for diminishing resources of coal, oil and natural gas. The oil and gas, warns the author, may be scarce and expensive within a few decades and the demise of coal may be only a few decades later. Nuclear fission and fusion systems will have their problems and may not be sufficient if the time before there is a real need for them is shorter than some people expect.

The propositions concerning doom in the 21st century due to increasing CO_2 and aerosols in the atmosphere, from the burning of fossil fuels, affecting world climate are brought out, as are the prospects of NO, CO and SO_2 causing substantial health hazards. The idea of the delayed and therefore necessarily nimble changes in technology and engineering being achieved to avoid catastrophe by providing abundant new forms of energy, are not expected to be realised. Practical population control and the highly efficient recycling of materials to avoid shortages are not viewed hopefully. Experience indicates that modifications in the world energy mix and social behaviour patterns are slow and will continue to be so.

How soon in the future will ideas of the solar–hydrogen economy be strongly tested? Will the money, the manpower and materials necessary be made available by Governments for building large remote land-based, or offshore, atomic and solar power stations? If they can be, the scale of expenditure is bound to be limited. The reader may have doubts about this happening significantly in view of the recent slowing down of fission and fusion power research and development work. The stages outlined by Bockris seem then to be far too ambitious and to deviate too far from a main line of attack on the main solar electric and hydrogen production problems.

On these matters the reader is best left to form a personal judgement, to assist which some of the multitude of references so excellently given could be consulted, at a rate averaging about 1.6 per page of text. □

Solar connection

Possible Relationships Between Solar Activity and Meteorological Phenomena. Edited by W. R. Bandeen and S. P. Maran. Pp. ix+263. (NASA: Washington, DC, 1975; sold by US Government Printing Office.) $4.00.

THIS book marks the official publication of the proceedings of the NASA Symposium on possible relationships between solar activity and meterology held at the Goddard Space Flight Center in November 1973. I share the disappointment of NASA's Scientific and Technical Information Office concerning the delay in publication, as this was clearly an important conference in defining the starting ground for much of the current work on solar–weather links. Publication in 1974 would have been of great value to those investigating these links who were unable to attend the conference. Two years later, its value is much diminished.

Since the proceedings have been available in preprint form since June 1974, at no charge, and the book costs $4, it might seem that the only recommendation for this edition is that it is more compact than the preprint. The papers are often brief to the point of superficiality and in many cases very subjective, whereas the field of study is very rapidly becoming a much tighter and more objective discipline than it was up until recently. S. I. Rasool aptly summarises the conference: "What we do not want is a symposium where there are 5-minute presentations and where one cannot ask a question without a microphone". Nor, in 1976, do we want a book which reports uncritically the proceedings of such a symposium on this important topic.

John Gribbin

Authoritative text on quantum electronics

Quantum Electronics: A Treatise. Edited by Herbert Rabin and C. L. Tang. Vol. 1: Non-Linear Optics, Part A Pp xi+472+9. $35; £17.50. Vol. 1 : Non-linear Optics Part B. Pp. ix+473–753. $22 50; £11.25. Academic: New York and London, December 1975.)

THE nine chapters of these long-awaited volumes cover substantial ground, enough, as Bloembergen remarks in a general introduction, to catch the spirit of non-linear optics without exhausting its content. Common chapter organisation and notation, frequent cross-referencing, a universal index, all in attractive format, make for good consultation.

Part I (Non-linear Optical Susceptibilities) is mostly taken up with an encyclopaedic survey by Christos Flytzanis of the Theory of Non-linear Susceptibilities. The author presents their phenomenological properties and evaluations in massive mathematical detail. Generalisations then give way to minute discussion of individual models relating to rarefied and condensed media. Some 500 references complete the review. The Measurement of Non-linear Optical Susceptibilities by Stewart K Kurtz complements the previous theory. After a prefatory review of Gaussian beam optics and light propagation in anistropic media, there follow practical descriptions of the absolute methods of phase matching, parametric fluorescence and Raman scattering; and the relative methods of Maker fringes, and wedges.

Introducing Part II (Non-linear Optical Processes), Two-Photon Absorption Spectroscopy by H Mahr is a lucid account of the underlying physics of symmetry, polarisation and resonance applied to molecular and electronic transitions. Experimental results in solids, liquids and gases are surveyed. I. L Fabelinskii reviews experiments and practical theory relating to the Stimulated Mandelstam–Brillouin Process Studies of electrostrictive coupling, stimulated temperature process, non-linear absorption are related to a variety of stationary and transient phenomena. A short essay by C. L. Tang on Spontaneous and Stimulated Parametric Processes explains the basic theory and experimentation of parametric fluorescence, and discusses its applications. Concluding Part II, Chen-Show Wang writing on The Stimulated Raman Process presents theoretical studies of the Raman coupling of pump and scattered light with mechanical mode excitation, both in forward and in backward transient stimulated scattering. Related effects and experimentations are briefly discussed.

Part III (Applications) opens with a substantial review by S. A. Akhmanov, A. I. Kovrygin and A. P. Sukhorukov of Optical Harmonic Generation and Optical Frequency Multipliers. This chapter concentrates on the theory and design of optical frequency multipliers, and divides into steady-state and transient generation, the latter including ultrashort laser pulses. In Optical Parametric Oscillators (Robert L Byer), theory and experimentation are elegantly blended into a complete exposition of operation characteristics, devices and materials In the final chapter by John Warner, the technique of Difference Frequency Generation and Up-conversion are briefly explained, the latter mainly for signal and image detection.

These volumes should form an authoritative text for some years.

P. G. Harper

Mathematical explanation

Introduction to Mathematical Biology. By S. I. Rubinow. Pp. xiii+386. (Wiley-Interscience: New York and London, December 1975.) $27.00; £13.55.

THIS book is based on a course designed to develop in graduate biology students at Cornell University an awareness of and familiarity with some mathematical techniques and methods applied to biology. Apart from brief mention of the application of the least squares method to linear regression and the extraction of the parameters of multi-exponential processes by the 'peeling' method, statistical and numerical analytical techniques for processing experimental data are not featured. The author clearly believes, however, that mathematical biology should be firmly based on experimental observation. Consequently, no attempt is made to describe methods involving analogue or digital computers for handling speculative mathematical models of biological systems.

The book deals with the mathematical explanation of five selected biological phenomena in some depth: cell growth, enzyme kinetics, tracers in physiological systems, biological fluid dynamics and diffusion in biology. The style is economical so that, for example, steady-state and pre-steady-state kinetics, cooperativity and allostery and the effects of inhibitors and modifiers are treated in 53 pages in the chapter on enzyme kinetics.

Where possible, the author applies fundamental concepts to a variety of biological problems. For example, an explanation of Fick's laws of diffusion leads to consideration of topics as diverse as the relationship between diffusion constant and molecular weight, pheromone interaction between animals, membrane transport, diffusion through a slab, axonic ion flow, ultracentrifugation and diffusion across capillary walls. Three other features of the book deserve mention. When a new term is introduced and defined, it is printed in bold-faced type which will facilitate revision by students. Each chapter ends with a number of problems of graded mathematical difficulty. The solutions with full explanations are given towards the end of the book.

Finally, although the author states that this is not a textbook in mathematics, there are two useful mathematical appendices for readers who have forgotten basic techniques such as the handling of matrices and determinants. Unfortunately, students of the biological sciences who could and should read this book are likely to find the price a deterrent. It deserves a place in science libraries and hopefully will be well thumbed with use by students and lecturers.

D. T. Elmore

PMO theory

The PMO Theory of Organic Chemistry. By Michael J. S. Dewar and Ralph C. Dougherty Pp. xiii+576 (Plenum: New York, 1975.) $14.50.

IN the preface, the authors disclaim any intention of rewriting the whole of organic chemistry in terms of perturbational molecular orbital (PMO) theory. The text illustrates principles of such widespread application that it seems that only time has prevented them from so doing. The first three chapters introduce the theory of the method in a most readable manner. The principles are well presented, and the material could stand up in its own right as a separate text. The bulk of the text comprises three chapters with far-reaching titles —Chemical Equilibria (ch.4), Chemical Reactivity (ch.5) and Light Absorption and Photochemistry (ch.6). The final chapter is concerned with transient ions, and seems too specialised for the general audience at whom the work as a whole is aimed. Inevitably some of the material will provoke controversy, and there is a rather cavalier treatment of alternative approaches to some of the problems For example, the summary dismissal of the Hoffmann–Woodward approach to Pericyclic Reactions, and the absence of any reference to R. W Taft in the section dealing with substituent effects would be remarkable if it were not so predictable. The book succeeds admirably in its stated aim of demonstrating the power of the PMO method, and does so in such a readable manner that it will be appreciated by a wide audience.

L. Phillips

Infrared astronomy

Infrared: The New Astronomy. By David A. Allen. Pp. 228. (Keith Reid: Sheldon, Devon, November 1975.) £6.50.

THIS is an unusual book, a semi-popular one written completely from the viewpoint of the observational astronomer. It charts the rise of a new field, infrared astronomy, with which the author has been actively involved for a decade. After introductory chapters outlining a few background ideas, the techniques of observation (formidable if the only dewar you have ever handled is a thermos flask), the main observing sites, and the early history, the book discusses the different types of source seen in the infrared: solar system objects, stars and protostars, and galaxies and quasars. All are discussed on the basis of whether they are detectable in the infrared, and more particularly whether they are unusually strong emitters there. This seems to be the weakness of the observer's viewpoint, especially when he is specialising in a fairly narrow range of wavelengths (most of the book concerns the range 1–20 μm). No theoretical framework is provided which explains why different types of star or galaxy are of interest. So this is a book which requires a rather extensive knowledge of astronomy to appreciate its qualities.

The chapters on the different types of star which radiate in the infrared, either because they are cool or more often because they are partially shrouded in dust, are outstanding, and constitute a valuable review of, and introduction to, the field.

That on galaxies and quasars, on the other hand, opens weakly: "A galaxy is some breccia constructed of all the types of object we have encountered in the last four chapters". No real effort is made to distinguish between different types of galaxy. Under "Compact Galaxies" we find I Zw 1727+50, which is also a BL Lac-type object: the "Markarian galaxies" mentioned are also, in fact, Seyferts And the chapter ends with a decidedly casual (and even for June 1974, inaccurate) account of the microwave background.

If Dr Allen were writing the book today, I think he might devote a larger fraction to wavelengths between 30 μm and 1 mm, where many of his sources emit most of their energy. He might also devote more space to the clouds of dust and molecules out of which form the young stars on which he is so expert.

This is a book for the professional astronomer (for whom an excellent feature will be the comprehensive list of references) or the knowledgeable amateur. How the style appeals to you will depend on your taste for extravagant metaphor. For example, synchrotron radiation is explained as "those piercing shrieks emitted by high energy electrons when they embark on their helter-skelter paths in magnetic fields"

M. Rowan-Robinson

Lemurs

Lemur Biology. Edited by Ian Tattersall and Robert W. Sussman. Pp. xiii +365. (Plenum: New York and London, 1975.) $27.54.

THIS is a progress report of recent studies. To emphasise the breadth of modern interest in lemurs, studies from several disciplines have been drawn together. There are five sections: an introduction to lemur biology (the history of the study of lemurs; the Madagascan environment); systematics and evolution (comparative studies of chromosomes and teeth), morphology and physiology (studies of cranial anatomy, postcranial skeleton and body temperature); behaviour and ecology (studies of several little-known lemurs inluding *Indri, Phaner, Hapalemur* and *Propithecus*); and an epilogue on conservation and extinction. The editors emphasise that "the interpretations in each of these fields are dependent on knowledge of each of the others". It therefore seems reasonable to expect them to promote the cross-fertilisation of disciplines by ensuring that individual contributions are understandable to the non-specialist. Although most papers are admirable in substance they leave the non-specialist confused by repeatedly using specialised jargon (for example, terms from cytogenetics, dental and postcranial morphology, behaviour) which is either inadequately defined or not defined at all. Most readers, being less familiar than the authors with Madagascar, may also find difficulty in following the text because of the lack of maps showing topographical reference points and the distribution of species. The usefulness of this style of book is limited unless it is something more than a collection of papers of the type found in specialist journals.

In spite of those criticisms I enjoyed *Lemur Biology*. Its breadth of coverage is refreshing and instructive There has clearly been a delay in publication and the preface sensibly records the most recent developments.

John M. Deag

Down to Earth

Man's Relation to the Universe. By Bernard Lovell. Pp. vi+118. (Freeman: San Francisco and Reading, November 1975.) $5.95.

DURING 1973, Professor Bernard Lovell delivered a series of lectures on astronomy and space research to students at Buffalo University. The content of these lectures is available in an informative little book which carries the somewhat misleading title of *Man's Relation to the Universe*

Indeed the first chapter is very much down to Earth, with an unusual and entirely welcome discussion about the financial cost of space-age astronomy. We are told such horrors as the (certainly astronomical) cost—$400 million—of the Soviet 236-inch telescope, although to put it all in perspective, the UK government turns out to spend only 0.02% of the gross national product on all forms of astronomical research.

Stepping into near space Professor Lovell skillfully summarises the results gleaned by the recent space probes to Mercury, Venus, Mars and Jupiter. The explosion of information about these planets is bewildering, but the author delivers a well-balanced and cautious appraisal of contentious issues, such as the 'water on Mars' controversy, but without losing a sense of excitement and enthusiasm.

Moving farther afield, stellar and galactic evolution are described, and modern discoveries such as quasars, pulsars and (possibly) black holes all get a mention The discussion is somewhat formal, but never dull or over extended. In spite of the title, there is very little hard philosophy, except on cosmological issues such as the big-bang creation event.

I very much enjoyed reading this book. Laymen of a scientific inclination may find rather too much technical discussion to cope with the content without preparation. Scientists and students will find it a straightforward and engaging introduction to the techniques and results of modern astronomical research.

Paul Davies

Aquatic fungi

Recent Advances in Aquatic Mycology. Edited by E. B. Gareth Jones. Pp. 749. (Elek Science: London, December 1975.) £21.

THE idea for this volume grew from the success of seven sessions devoted to aquatic fungi at the First International Mycological Congress held in Exeter in 1971, and some of the chapters are papers presented at the Congress. It is disappointing that it has taken four years for the book to appear, so that some of the advances are by now hardly recent.

About half of the book, Section I, is devoted to marine fungi; the rest, Section II, to freshwater forms. The marine fungi are considered under two arbitrary divisions—A, Ascomycetes, Fungi Imperfecti and Basidiomycetes; and B, Lower Fungi. Section IA has chapters on lignicolous fungi, mangrove fungi, oceanic yeasts, fungal degradation of oil, physiology, and cytochemistry of spores. I particularly enjoyed the account by J. W. Fell of oceanic yeasts, some of basidiomycetous affinity, which brought together, in a coherent way, material from widely scattered literature of a group which will be unfamiliar to many. Section IB, mostly covering zoosporic forms, includes a general account of marine 'phycomycetes', an essay by F. K. Sparrow on the present status of classification in biflagellate fungi (not exclusively marine), and chapters on fungal diseases of marine animals, physiology of marine 'phycomycetes', fine structure, and ecology. The freshwater Section is also divided into two arbitrary divisions. The section on Ascomycetes, Fungi Imperfecti and Basidiomycetes has chapters on morphology and biology, fungi from cooling towers, sewage, an interesting account of the role of Hyphomycetes as intermediaries of energy flow in streams, and on the interactions between river fungi and DDT. The 'lower fungus' section includes chapters on the morphology of Chytridiomycetes in relation to substrates, fungi on algae, ecology, physiology, aspects of fish disease, ultrastructure, and a valuable review of the Trichomycetes by R. W. Lichtward. Aquatic Actinomycetes, although accepted as prokaryotic, are included in a useful chapter by L. G. Willoughby.

The general impression of the book, apart from the uneven quality inevitable in symposium-type publications, is that it will provide useful reference material for those working on aquatic fungi. The photographic illustrations leave much to be desired, especially with respect to size, layout and quality of reproduction. The use of unglazed paper and the faint printing has rendered many of the electron micrographs virtually useless, as is shown in the otherwise excellent article by Heath on ultrastructure of freshwater Phycomycetes. Many of the plates have obviously been made up by their authors to fill a whole page, but have been reduced by the publishers to take up only a small fraction Much of the space 'saved' by this unfortunate economy has been wasted by the use of large print and author citations in voluminous tables. Moreover, there are numerous misprints The book will prove far too expensive for many individuals to buy.

John Webster

obituary

The news of **Michael Polanyi's** demise caused deep sadness in the hearts of his many friends and admirers. There were, and are, few people in our century whose interests were as extended as were his, whose friends were as devoted to them as were those of "Misi".

Polanyi was born in Budapest, Hungary, on March 11, 1891. He took his degree as an MD in Budapest at the age of 22, but wrote his first paper (on the hydrocephalic liquid) long before that, at the age of 19. His interest then centred on biology, principally human biology, but his articles soon became sprinkled with references to, and conclusions drawn from, physical chemistry, and, in particular, the second law of thermodynamics. The first such paper was written in collaboration with a life-long friend, J. Baron, but the other papers written during the first world war, when he served in the army, were by him alone. They were concerned not only with applications of the second law, but also with the foundations of the third law, then called Nernst's Theorem. His last article during the war period, however, was on a subject which remained long close to his interest: the theory of adsorption.

Soon after the end of the war, Polanyi moved to Germany—for a year to Karlsruhe, where he met his wife, then to Berlin where he worked first at the Kaiser Wilhelm Institut für Faserstoffchemie (chemistry of fibres), and then at Haber's Institute, the institute for physical and electrochemistry. He moved to Manchester, England, in 1933, when Hitler came to power, a reason very similar to that which had originally prompted him to leave Hungary.

The breadth of Polanyi's interests manifested itself in his days as a scientist by the wealth of subjects to which he made important contributions. Several of them continued to attract his interest virtually all through his scientific career. His first articles on the subject mentioned before, the adsorption of gases to solid surfaces, were written in 1914 and 1916, the last one referring to this subject in 1946. His chief interest was, however, concentrated on the rate of chemical reactions. He contributed decisively both to the theory and to the development of experimental methods to investigate them. His first paper on the subject was written in 1920, a theoretical paper which was later fully justified by quantum mechanical considerations in 1925 and his concluding paper on this topic dates from 1949. In addition to these, he contributed significantly to our understanding of the strength of materials and the role of the crystalline glide-planes in this connection, to the X-ray analysis of fibres and crystals, also of poly-crystalline materials and, finally, to simple chemistry (and perhaps to other subjects which this writer fails to recall).

Two thirds of Polanyi's scientific articles written after 1920 (he published 201 such articles) were published jointly with collaborators, some of whom have acquired world fame. He not only stimulated interest in his collaborators, he also established close personal relations with most of them and they maintained their devotion to him and his ideas throughout his life. This applies also to the present writer.

Eugene P. Wigner

Were it not that he was one of the great polymaths of this century, it would be surprising, as it was apparently regrettable to some of his science colleagues, that Michael Polanyi, after coming to the University of Manchester in 1933 as Professor of Physical Chemistry with a great international reputation in science, should in 1948 have been appointed as Professor of Social Studies. Yet it is intriguing to speculate as to why he made the decision, with the general approval of his University and the warm welcome of the economists there, to shift the balance of his intellectual interests. Running through his writings in economics—USSR Economics in 1935; Patent Reform 1944; Full Employment and Free Trade in 1945; Profits and Polycentricity in 1946; and The Span of Central Direction 1948—there seems to be one leading strand: how best to reconcile the safeguarding of individual liberty with the controls upon the individual inseparable from a complex and organised society or, as he succinctly put it, the relation between spontaneous and social order.

Within two years of reaching Manchester he had produced his small but pathbreaking book *USSR Economics.* It was the result of a flash of understanding of the kind which genius enjoys. He saw that the idea of rational planning of the whole of the economic system by Governments was a complete illusion. Then, with remorseless logic, he asked himself: if central economic planning is indeed a chimera, what is it that Governments which set out to engage in it, are in fact doing? And, prophet as he was, he foresaw the answers. In countries, such as Russia, where the ideas were then being ruthlessly pursued, the result would be the creation of a slave state. In other Western countries (and he had in mind among these Britain) where individual freedom was more deeply entrenched and tenaciously defended, the attempts of Governments at central planning would simply lead to great muddle, with increased public intervention in industrial investment, economic debility, widespread price controls and inflation.

This central discovery he filled out in his later writings. He sought to explain by word, and by an ingenious film, the subtleties and efficacy of free market operations. Admitting to weaknesses in a system of private enterprise he developed ideas, along Keynesian lines, for the prevention of mass unemployment and for the more active encouragement of technical advance. He displayed in novel ways how, as an industrial organisation grows in size, it tends towards inefficiency in operation. He argued for the crucial role of profits in a free economy: "There exists no fundamental alternative to the system of money-making and profit-seeking".

After 1948 his mind moved into more abstract and philosophical fields. But in a remarkably short time he had left behind him a set of writings which economists in the future will turn to and find rich and stimulating.

John Jewkes

Though Michael Polanyi wrote a number of studies in the philosophy of science, his contribution rests mainly upon a single work, *Personal Knowledge,* first published in 1958. In both style and content it ran strongly counter to the logicist trends of the time, and was not easily assimilated into professional philosophy of science, though it was greatly appreciated by many working scientists. Written in a limpid, urbane style, drawing upon a wider range of experience than was usual in philosophy of science, it might be properly thought of as setting a trend towards 'science criticism', bearing a somewhat similar relation to science that literary criticism does to literature.

Two philosophical themes dominated this work, and all Polanyi's reflection on the nature of science; the theme of 'tacit knowledge' and the theme of the analogy of perception. Polanyi never tired of emphasising in many contexts that we know 'more than we can tell', a truth not only of the practical arts but as he persuaded many of his readers, of the intellectual arts as well. Explicit scientific knowledge rests for its intelligibility and grounding upon an undetermined basis of tacit knowledge, which if made explicit rests again upon its own basis of the tacit. Explicit knowledge is public knowledge, but tacit knowledge is private, and both sorts of knowledge are encompassed within science.

The relation of explicit knowledge to its penumbra was to Polanyi either identical with or perhaps only similar to the relation between focal and subsidiary awareness in perception, attending from something to something else. He elaborated this metaphor in a number of works.

That science was a part of society, that it was within the larger society a society itself, but a society with a peculiarly morally demanding mode of being, was both exemplified by the man himself, and the central message of his philosophical work.

Rom Harré

announcements

Appointments

Dr Peter W. Likins, of the University of California, Los Angeles has been named dean of Columbia University's School of Engineering and Applied Science.

Dr Michael A. Moore of Sussex University to Professor of Theoretical Physics at the University of Manchester.

Dr R. J. Ellis to a personal Professorship of Biological Sciences at Warwick University.

Dr Hugh Burkhardt to Professor of Mathematical Education at Nottingham University.

Sir John Habakkuk, Vice-Chancellor of the University of Oxford, has been elected Chairman of the Committee of Vice-Chancellors and Principals of the Universities of the United Kingdom for the year 1976–77.

Awards

Professor N. Kurti of the University of Oxford has been made a Chevalier de la Légion d'Honneur.

Professor C. T. Dollery of the Royal Postgraduate Medical School has been made a Chevalier de l'Ordre du Mérite.

Dr Charles Elton of the University of Oxford, **Dr Rene Dubos** of the Rockefeller University and **Dr Abel Wolman** are the recipients of this year's Tyler Ecology Award.

International meetings

27–28, **The Handling of Toxico- Information,** Bethesda (Dr A. Wykes, Toxicology Information Program, National Library of Medicine, 8600 Rockville Pike, Bethesda, Maryland 20014).

Person to Person

Information is required on national and international efforts to popularise science, on famous science writers from all over the world and on awards given to science writers. Scientists who communicate to laymen please send their opinions to Zaka Imam, Assistant Editor, Science Reporter, Council of Scientific and Industrial Research, Rafi Marg, New Delhi 110001, India.

Astronomer attending international meeting wishes to exchange 3-bedroomed house (sleeps 6 and baby) in Sussex for house or flat (sleeping 5 and baby) near Grenoble, France, for one month during August 1976 (until about 3rd September—meeting ends on 2nd). Enquiries to Dr R. C. Smith, 38 The Avenue, Lewes, Sussex BN7 1QU, England.

There will be no charge for this service. Send items (not more than 60 words) to Martin Goldman at the London office. The section will include exchanges of accommodation, personal announcements and scientific queries. We reserve the right to decline material submitted. No commercial transactions.

June 2–4, **Frequency Control,** Atlantic City, N.J. (Dr John R. Vig, USAECOM, ATTN: DRSEL-TL-MF, Ft. Monmouth, N.J. 07703).

July 17–22, 1977, **Macromolecules,** Dublin (Symposium Officer, Macro Dublin 77, Institute for Industrial Research and Standards, Ballymun Road, Dublin 9, Ireland).

September 6–9, **Structure and Kinetic Approach of Plasma Membrane Functions,** Grignon, France (Deadline for application: May 15) (Dr Alain Paraf, Station de Virologie et d'Immunologie, Route de Thiveral, 78850 Grignon-Thiveral, France).

September 22–23, **Laboratory Animal Housing,** Washington DC (E. W. Grogan, Executive Secretary of ILAR, National Research Council, 2101 Constitution Avenue, N.W., Washington, DC 20418).

September 22–24, **Congress of the European Chemoreception Research Organisation,** Reading, UK (Deadline for registration: June 30) (Dr G. H. Dodd, Department of Molecular Sciences, University of Warwick, Coventry CV4 7AL, UK).

October 11–15, **Structure and Uses of Biopolymers** (Professor Alan G. Walton, Department of Macromolecular Science, Case Western Reserve University, Cleveland, Ohio 44106).

October 18–20, **Platinum Co-ordination Complexes in Cancer Chemotherapy,** Dallas (Deadline for abstracts: June 30) (Third International Symposium on Platinum Co-ordination Complexes in Cancer Chemotherapy, Wadley Institutes of Molecular Medicine, 9000 Harry Hines, Dallas, Texas 75235).

November 9–10, **Techniques for the Retrieval of Chemical Information,** London (Dr John F. Gibson, The Chemical Society, Burlington House, London W1V 0BN, UK).

What follows the squabble?

THE engineering profession in Britain has been in disarray for some time over its structure. There are fifteen separate institutions, each of which fulfils the double role of acting as a learned society and looking after the professional interests of its particular members. Ten years ago the Council of Engineering Institutions (CEI) was formed as the first move towards providing some sort of unified body that could represent engineers to government, in international circles, or just to each other; there was never any intention that the institutions should lose their separate identities as a result of these moves.

Unfortunately, the CEI has turned out to be just what its title says it is—an assemblage of institutions, each with its own pride, prejudice, president, executive secretary, council and awareness of the size of its membership, be it above or below the average. Thus the small institutions have been worried about being steamrollered in the CEI, while the big ones have been worried that they can be outvoted. As a result, progress towards establishing a real voice for the engineering profession as a whole has been slow and marked by considerable bitterness which led late last year to the Institution of Electrical Engineers (one of the biggest institutions) giving a year's notice of intention to quit the CEI.

Maybe this threat has had a salutory effect at a time when the CEI's statutes are now being prepared for approval by the Privy Council. In the months of negotiation ahead compromises are on the cards all round, in the knowledge that the Privy Council is hardly likely to endorse a constitution to which at least one major institution objects (and the mechanical engineers seem to be equally unhappy).

Engineers can ill afford the time and emotional, even conspiratorial, energy that is being spent by their representatives in arguing over the CEI. If conciliatory gestures fail in the near future it is inevitable that demands for a public enquiry into the organisation of the engineering profession will grow, and with good cause. There are obvious attractions to handing the whole mess over to a small committee whose members have no axe to grind, and gracefully accepting their solution. But if this is done, it is important that the terms of reference of the public enquiry should be right. What is really needed is not a convenient way of patching together a group of institutions by neatly balancing voting procedures and carefully avoiding putting a bunch of president's noses out of joint. The body that should be created is a Council of Engineers to which individuals would have a stronger sense of loyalty. Some argue that modelling such a council on the General Medical Council would be a good thing, producing a lean organisation with some lay membership, concerned with qualifications, discipline, education and so on. Certainly some bread-and-butter matters such as the nature of engineering qualifications and their interchangeability within the European Economic Community need attention, and such a body would devote much of its time to these affairs. But engineers should not pass up the opportunity to go further and use the council to provide an accessible profession-wide forum.

Engineers are often not people with the broadest vision, indeed sometimes their vision seems narrower even than that of scientists. In times of plenty this may not seem to matter too much—there will always be work available and few will question the benefits of technology. The problem surfaces only when times are hard, and it may be characterised as a loss of nerve. Technology is then not only an easy target for cutbacks but is accorded the blame for many of our woes. On the whole engineers do not seem to have come to terms very well with new moods in society, and one of the reasons for this is probably that there is not a great enough number of them prepared to read, think and talk together about the place of the engineer in society. This surely must be done on as wide a basis as possible, using the resources that all sectors of the profession can bring. While there is dissent about the CEI it cannot be done effectively. A public enquiry should at least be aware that some needs of the engineering community go beyond those of simply voting, acquiring a string of qualifications and doing a day's work. ☐

The difficulties facing West German science

What is the current state of science in West Germany? **Rainer Flohl** reports on a situation which scientists in other developed countries may find familiar

SCIENTIFIC research in West Germany is going through a difficult period. It is suffering from financial restrictions similar to those in many other countries. More importantly, it has been affected by the structural changes in West German universities over the past few years. Indeed, after a belated advance in the mid-1960s, when it received increased government support, West German science again stands on the brink of disaster. The winner of the Nobel Prize for Chemistry, O. E. Fischer of the Munich Technical University, has asserted that West German universities are losing ground in international terms. He compares research units in West German institutions of higher learning to empty shells, and the strong teams in Anglo-Saxon countries to battleships. German scientists cannot hold their own against this kind of opposition: the once-successful *Geheimratsystem* has disappeared, and with it has gone the glamour which had attracted scientists to West Germany from all over the world.

The overthrow of that system was in fact a reaction to the growing demands of an ever more complex science. The anticipated consequences—intensified cooperation among scientists, greater "teamwork", more criticism and self-criticism—have failed to materialise. But this failure was disguised in the early 1960s when increased financial support for science led to a certain amount of progress. Now the deterioration is apparent, though the true situation is not generally understood. There are three reasons for the deterioration: the aforesaid structural change; the overburdening of universities with teaching; and the financial crisis, which has drastically exposed the weak position of science.

The overburdening with work of teachers in higher institutions is the result of the explosion of further education, which even now continues to attract more and more students to universities. Growing numbers of university teachers were needed to instruct the students. These teachers wished not only to teach, but also—in the German tradition of "unity of research and teaching"—to carry out research for themselves. This has led to a doubling of the number of scientists in the Federal Republic over the past few years. The means for research work have not risen proportionately, so the average research worker has less money than at any previous time. Besides this, the lecturers have had to spend more time on their teaching. Only in this way could they keep up with the rising number of students, whose education—for political reasons—appears to be more important than research work. The time available for research has been reduced because the democratisation of higher education demands too many meetings and additional administrative expenses.

The financial crisis has led to a drastic reduction in the funds available for research. Many programmes have had to be arbitrarily curtailed. In 1975 approximately 30 to 40% of allocated funds were withdrawn; there will be no change in the situation in 1976. People have accepted the change without complaining. Unrest at the universities has subsided. The only remaining tensions are in the departments responsible for teacher training; but fully qualified students have increasing difficulty in finding work, which makes them insecure. Many of them blame the so-called *Radikalenerlass* rather than their own poor marks for their failure. The *Radikalenerlass* was an administrative regulation designed to prevent professed enemies of the constitution—in particular members of the Communist Party—from getting jobs in the public service. Many rumours arose because of the generally clumsy and bureaucratic methods used to check public service applicants. It was said, among other things, that a signature on a pamphlet was sufficient to get an applicant rejected. The regulation has recently been abolished, or rather administered in a different manner.

The Federal Republic has encountered these problems at a time when there were justifiable hopes of improving the effectiveness of scientific research. The two most important organisations conducting pure research in the Federal Republic—the German Research Organisation (DFG) and the Max-Planck Institutes (MPG) — had elected new Presidents who were well-qualified and open to new ideas for reform. Professor H. Maier-Leibnitz, President of the DFG, which receives about DM600 million a year from the Federal and State governments for the furthering of basic research, has a wealth of experience and success as a practical scientist: he built the Federal Republic's first experimental reactor in Garching near Munich, and it was due to his initiative that the Franco-German high flux neutron reactor was later erected in Grenoble. Not least because of suggestions from Professor Maier-Leibnitz, both instruments became focal points of research, and he became an international figure through his contribution to neutron optics. The President of the Max-Planck Institute, Professor Reimar Lüst, is also a physicist. Formerly President of the European Space Research Organisation (ESRO) and Chairman of the German Science Council, Lüst was the first man to use barium clouds for the discovery of astrophysical phenomena. The Max-Planck Institute also receives DM600 million from the Federal and State governments from funds set up to finance independent institutions.

Only time will tell whether Professor Maier-Leibnitz and the German Research Council will manage to restore science to its former position and thus unlock the creativity which is essential for successful research. The Max-Planck Institutes' first priority is to protect scientists from the dead hand of the bureaucracy. But both institutions face exceptional problems,

Students at Saarland University: for them, what sort of future?

especially as the "reform" of the universities has blocked posts for the new generation of scientists, however well-qualified, since large numbers of mediocre young scientists secured life-long tenure in earlier years.

At the beginning of April the German Research Council published its *Grauen Plan* ("Gray Paper") analysing the present state of research in the Federal Republic. From its assessment of the present situation, and the many obvious deficiencies thus revealed, it derives suggestions for improving research, though it accepts that not all the ideas it puts forward can be carried out. The Paper covers the years 1976 to 1978, and is the most detailed and honest document yet compiled about German research. The main section deals with the structure of the universities and the financing of research. For the first time, moreover, scientists from universities were consulted in the drawing up of the document: out of 1,300 scientists approached for their views on the state of research in universities and the condition of their own field of work, 1,000 responded. The results of this inquiry are also included in the Paper, which in parts is more a catalogue of inadequacies than the report of an enquiry, though it should not be overlooked that particular institutes are in fact in the lead internationally.

To overcome at least the financial stagnation of research, Professor Maier-Leibnitz called upon the Ministers of Culture and Science in the Federal Republic and its component States to increase the capacity for work in the country's universities, by promoting and supporting important research and at the same time making use of existing but insufficiently used research facilities. In this way, with less resources, a considerable improvement in quality could be achieved—something which had been greatly neglected during the continuous expansion of higher education. An increase in the budget of 10% (DM60 million) would be sufficient to begin with, which amounts to only ½% of the DM13,000 million which is spent annually on higher education in the Federal Republic.

In this connection it must soon be clarified whether the balance between applied research and pure research is to be maintained in Germany. The former has expanded rapidly over the past few years through government grants. Those private institutions entrusted with the furtherance of science have so far refrained from open criticism of this development. To understand the problem it is only necessary to consider the vast sums which have been spent on applied research. Whereas the state granted DM850 million in 1974 to further general research in universities and private institutions, it allocated DM3,200 million for advanced programmes of applied technology (nuclear research and technology, space research and technology, data processing, marine research and other technology).

Criticism of the disproportion between applied research and pure research may be justified when it is considered that Germany is living on the results of past research, without worrying about the future. No politician seems to give serious consideration to the scientific source for the technology of the 1980s. This behaviour is reminiscent of the carelessness with which people treated questions of raw materials and the environment until recently. Many scientists are worried about the situation: it puts the Federal Republic at a disadvantage internationally; it also threatens those industrial nations which are short of raw materials, whose economies depend on the progress achieved in their laboratories.

The final decision on the relationship of pure research to applied research lies with the political authorities. They have never shown any special enthusiasm for pure research, which has little propaganda value for them in comparison with basic technological projects. Publicity and politics are not, as is often claimed, the enemies of science; they are simply indifferent to pure research. The "Gray Paper" ought to bring about a change of attitude. But will any of the politicians read it? □

The state of health of NIH

Colin Norman in Washington looks at the National Institutes of Health, just investigated by a Presidential Commission

ON various occasions in the past few years, the National Institutes of Health (NIH), one of the largest and most prestigious biomedical research centres in the world, has been beset with personnel and budgetary upheavals. Two NIH directors have been fired, ostensibly for political reasons, repeated clashes between Congress and the Executive branch over the overall health budget have frequently thrown planning at NIH into utter confusion, and many of the agency's programmes have been suffering from chronic shortages of cash while others have been receiving relatively generous support. It has not been a very happy place.

The problems which have plagued NIH and, by extension, the universities and medical schools whose work NIH supports, stem from a variety of sources. They range from the fact that NIH's budget has climbed to more than $2,000 million a year, which makes the agency politically very visible, to false public hopes that medical science can produce swift solutions to complex health problems. But the chief irritant is clearly the 1971 National Cancer Act.

The instrument which officially launched the federal war on cancer, the act abruptly changed many established methods of supporting, planning and managing biomedical research. It also elevated the National Cancer Institute (NCI) to a privileged position in NIH, and caused vast sums of money to be poured into cancer research while other areas of biomedical research have been growing slowly, if at all. But the Cancer Act, more than any other single factor, has sharply focused political attention on NIH's affairs.

Early in 1974 when morale at NIH was at a low ebb, following some particularly severe upheavals, Congress, at the instigation of Senator Edward M. Kennedy and ultimately with the support of the then Secretary of Health, Education and Welfare, Caspar Weinberger, passed a bill establishing a Presidential Commission to investigate NIH's affairs and make recommendations for relieving some of the strains. Chaired by Franklin D. Murphy, a former medical school dean who is now chairman of the Times Mirror Corporation in Los Angeles, the panel conducted an exhaustive 15-month inquiry, taking evidence from scores of witnesses and commissioning several independent studies of key aspects of federal health policy. It submitted its long-awaited report to President Ford and Congress on April 30.

A plea for more stability in funding, and for NIH to be left under the control of scientists rather then politicians, the report with its voluminous appendices offers few radical suggestions for changing NIH's operations. Its central message is summed up in the introduction : "The United States can take pride in a remarkably productive biomedical and behavioural research effort. The panel is convinced that despite the appearance of strains in the structure and some dislocation in the parts, the edifice is sound".

Though some people have been quick to criticise the report as being a self-serving document (five of the seven panel members were drawn directly from medical schools), it nevertheless offers some constructive analysis of NIH's activities. Perhaps its most far-reaching and controversial suggestion is that a tentative stem should be taken to re-integrate the National Cancer Institute into the rest of NIH. This should be accomplished, the panel suggests, by re-constituting a powerful committee which now oversees the working of the National Cancer Act into a more broadly based body with jurisdiction over the entire NIH effort.

To understand why such a seemingly mild suggestion is controversial, it is necesary to appreciate some of the history of the National Cancer Act and present cancer politics. The act stemmed largely from the recommendations of a blue-ribbon panel of scientists and lay members chaired by Benno C. Schmidt, a New York industrialist with influential political connections and a persuasive manner. The panel, which reported in December 1970, argued that NCI should be separated from the NIH bureaucracy, be given a separate budget and that its director should be appointed directly by the President. An independent status, the panel argued, would give cancer research greater visibility and enable NCI to adopt a more sharply focused research effort.

The plan was fought at the time by many scientists who were alarmed at the prospect of separating cancer research from closely related fields of study, and when Congress passed the National Cancer Act, it kept NCI within NIH, but only just. The NCI director is appointed directly by the President, and the NCI budget is drawn up and submitted separately from the budgets of other NHI institutes. The Act also established a powerful, three-member President's Cancer Panel to oversee the working of the act and to provide an extra link between NCI and the White House. Benno Schmidt was appointed chairman of the Cancer Panel. He has since devoted much of his time and considerable talents to his duties.

Since passage of the Act, the NCI budget has grown swiftly, though not as rapidly as the Act envisaged. Between 1970 and 1975 NCI's budget rose by 280%. In the same period, the budget for the National Heart and Lung Institute doubled (research on cardiovascular diseases was given a boost by a bill passed by Congress in 1972), but the budgets for all the other eleven institutes combined rose only by 20%. Cancer's share of the total NIH budget climbed from 16.6% to about 35%. At the same time, NCI began funding a growing share of its research activities by contracts rather than grants, a move which created some discontent in the biomedical research community.

Considerable resentment has been expressed at the privileged position of NCI, and the fact that the growth in support of cancer research has seemingly been made at the expense of other less politically favoured areas of research. Nevertheless, the cancer budget has considerable popular support and is defended by a powerful coalition of politicians, cancer researchers and others, not least of whom is Benno Schmidt. It would be politically difficult simply to merge NCI back into NIH, which is why the panel is very cautious in its recommendation.

It begins by noting that it "both recognises and supports the priority for cancer research established by the Congress", and suggests that the special status of NCI be retained "at this time". It recommends, however, that the President's Cancer Panel be reconstituted by statute as the President's Biomedical Research Panel, with responsibilities extending over all functions of NIH. Its membership should be broadened, it should provide a link between NIH and the White House, and offer advice on the total biomedical research effort. Finally, the panel suggests that "this proposal provides the opportunity, if experience so dictates, to fully integrate the national cancer programme with the other programmes of NIH in due time". The panel's report notes that Benno Schmidt, who was one of the seven panel members—further testimony to his influence over biomedical research matters—did not participate in decisions leading to this recommendation.

Panel proposals

THE following are among the more important recommendations of the President's panel.

- The President's Cancer Panel should be reconstituted and its responsibilities should extend over all NIH programmes.
- A new NIH advisory board should be established to provide advice to the Director of NIH and a measure of public input into NIH policy.
- No new research institutes should be established, and consideration should be given to amalgamating some existing institutes.
- The research programmes of the Alcohol, Drug Abuse and Mental Health Administration should be strengthened, but the panel decided, by a 4 to 3 vote, to recommend against transferring them to NIH.
- Investigator-initiated grants, rather than contracts, should continue to be the chief means of supporting research by NIH.
- The Director of NIH should have at his disposal a contingency fund of not more than 1% of NIH's budget, to initiate new studies.
- Legislation should be passed to preserve the secrecy of peer review deliberations and to protect the confidentiality of grant proposals until they have been funded.
- NIH should resist pressures to participate in long-term patient care.

The panel members were: Franklin D. Murphy, Times Mirror Corporation (Chairman); Ewald W. Busse, Duke University Medical Center; Robert H. Ebert, Harvard Medical School; Albert L. Lehninger, Johns Hopkins University Medical School; Paul A. Marks, Columbia University College of Physicians and Surgeons; Benno C. Schmidt, J. H. Whitney and Co.; and David B. Skinner, University of Chicago Hospitals and Clinics.

The proposal is likely to be controversial for several reasons. First, many scientists who have been resentful of the privileged position and burgeoning budget of the cancer programme will not be happy to see the panel responsible for much of that growth placed in charge of the rest of NIH. In that regard, however, it should be noted that while Schmidt has skilfully fought for the interests of the cancer programme, he has also spoken out on many occasions against letting NCI's budget grow at the expense of other areas of NIH. A second factor is, however, potentially more disturbing. The establishment of a powerful committee to oversee the programmes of NIH, though it will have no direct executive power, could seriously undermine the authority of the NIH Director. Though the present incumbent, Dr Donald S. Fredrickson, said in an interview last week that he would willingly work with such a panel if it is established, he would clearly not relish the thought of there being two Popes in charge of NIH and finding that he is the one in Avignon.

Another major point which the panel addresses is the confusion introduced into NIH planning by the repeated scraps between Congress and the Administration over the budget for the Department of Health, Education and Welfare, of which NIH is a part. Every year, Congress approves a larger budget for HEW than the president requests, and the matter becomes a political football with vetoes, budget deferrals and so on clouding the picture. Consequently, NIH frequently doesn't receive its budget until the fiscal year is nearly over, and it doesn't know until the last moment how much money is going to be available.

Fredrickson acknowledged last week that such uncertainties are a "very serious problem for NIH". But it is difficult to see a solution. Certainly, the panel's recommendations are unlikely to be accepted. The panel, in short, suggests that Congress and the Executive Branch should approve a new budgeting system for NIH which would allow forward funding of multiyear grants and contracts through a single appropriation instead of the present system under which new budgets must be approved each year. That system would, however, introduce more inflexibility into the federal budget, and would thus run counter to the desires of this Administration. The proposal, moreover, could just as easily apply to the rest of the Federal Government's $20,000 million-a-year research budget, so the Administration would be wary of setting a precedent.

Finally, it should be noted that the strains within NIH and the rest of the biomedical research community have been less apparent in recent months. In part, that is due to the introduction of some new policies, such as a new granting arrangement in NCI to replace some contracts, and improvements in the quality of peer review of contract proposals. It is also due in part to the appointment last year of Fredrickson as NIH Director. A skilled administrator who has earned the respect of both scientists and politicians, Fredrickson has had a considerable calming influence. Nevertheless, many of the fundamental problems which have led to discontent in the past remain, and it is unlikely that the panel's pitch for more independence for NIH will solve them. □

USA

Human rights guidelines adopted

Colin Norman reports on moves in the United States to combat the repression of scientists

FOLLOWING a recent spate of complaints that it has been too timid in speaking out against violations of human rights, particularly those of scientists, the National Academy of Sciences has adopted a set of guidelines to govern its actions when future infringements are brought to its attention. One of the Academy's most outspoken critics on such matters, Dr Jeremy J. Stone, Director of the Federation of American Scientists, last week welcomed the guidelines as offering a "constructive approach".

Proceeding from the observation that "violations of human rights . . . occur in many—perhaps all—countries", the guidelines suggest that the Academy should try to battle such violations by "persuasion on moral humanistic grounds". But they add that this approach "may require fortification by stronger measures".

The Academy operates for the US government a number of scientific exchange agreements with other countries, which gives Academy officials considerable contact with their foreign counterparts. In the past, the Academy has used such contacts to make private, face-to-face representations on behalf of beleaguered scientists, particularly repressed Soviet intellectuals. But only in the case of Andrei Sakharov has the Academy issued a public protest, and a number of scientists, both inside and outside the Academy, have recently criticised it for not speaking out more forcefully on other occasions.

The guidelines state that the Academy will continue to remonstrate influential officials in other countries, choosing individual cases of scientists and engineers to protest. "We will continue to use the quiet informal contact as our principal mode of communication with peer groups and governments in other countries", the guidelines state, but they add that "we do not eschew entreaty by public vehicles; indeed, we anticipate that such action will occasionally be appropriate". The strongest leverage which the Academy has in such negotiations is the threat of withdrawal from participation in exchange agreements, and the guidelines recognise that such a measure is available. Indeed, "it is always implicit in the background, but (it is a measure) that we can use only rarely".

In a related development, Academy members adopted a resolution at the annual meeting last month affirming principles of freedom of inquiry and expression. They urged colleagues around the world to join them in sending the following (or similar) signed statement to the Academy:

> I hereby affirm my dedication to the following principles.
>
> ● That the search for knowledge and understanding of the physical universe and of the living things that inhabit it should be conducted under conditions of intellectual freedom, without religious, political or ideological restrictions.
>
> ● That all discoveries and ideas should be disseminated and may be challenged without restriction.
>
> ● That freedom of inquiry and dissemination of ideas require that those so engaged be free to search where their inquiry leads, free to travel and free to publish their findings without political censorship and without fear of retribution in consequence of unpopularity of their conclusions. Those who challenge existing theory must be protected from retaliatory reactions.
>
> ● That freedom of inquiry and expression is fostered by personal freedom of those who inquire and challenge, seek and discover.
>
> ● That the preservation and extension of personal freedom are dependent on all of us, individually and collectively, supporting and working for application of the principles enunciated in the United Nations Universal Declaration of Human Rights and upholding a universal belief in the worth and dignity of each human being."

An Academy official said last week that the Academy will act as repository for such statements and make public the response. Confidentiality will be guaranteed to those who request it.

Signed statements should be sent to the National Academy of Sciences, 2101 Constitution Avenue NW, Washington DC 20418. □

COMECON

As a result of the recent meeting of the Comecon Executive in Moscow, coordination of economic plans will provide the chief means of cooperation for the Comecon countries between now and 1980. A programme for this integration produced last June includes specialisation and cooperation on key scientific and technological problems, and a strengthening in the energy, fuel and raw materials sectors.

One of the main fields of cooperation is atomic power engineering. According to the Joint Forecast for the Development of Nuclear Power Engineering in Comecon for the period up to 1990, the combined capacity of atomic power plants in the Comecon countries by 1980 will be some 30 million kW. As with most Comecon projects, the Soviet Union plays the leading role in such developments, but the contribution of the other member countries to joint research and the exchange of nuclear technology is stated to be "constantly increasing". In 1975 this mutual exchange is said to have increased by 23%. Though no precise basis for this figure is specified, an increasing amount of work in this field is apparently being carried out beyond the Soviet frontiers.

Thus a joint investigation into nuclear breeder reactors by the Institute of Nuclear Research (Swierk, Poland) and the Institute of Nuclear Power of the Byelorussian Academy of Sciences is being carried out at Swierk, using the *Maria* reactor. Some bipartite agreements in this field have also been signed between individual member countries. These include a programme of cooperation between the Czechoslovak and Hungarian Atomic Energy Commissions covering reactor physics, the development of nuclear instruments and the development of nuclear power stations. Talks between J. Neumann and Gyoergy Osztrovszki, the Commission Chairmen, included discussion of the Heller-Forgo system of air-condenser cooling for reactors. Similar bilateral discussions have also been held between Bulgaria and Rumania.

The Conference of Comecon nuclear power engineers, which met earlier this year in Rheinsberg, East Germany, made no absolute claims for future expansion: the share of nuclear energy in the growth of electrical energy in the Comecon bloc over the last five years was 17%, it was said, and this "should" increase to 27% in the next five years. The general picture, however, is one of optimism. Poland is introducing a special training scheme for nuclear engineers at the Cracow Academy of Mining and Metallurgy, using a 100 kW nuclear reactor provided by Swierk, and the Soviet Union is expanding the field of cooperation outside the Comecon block, assisting the Finns in the construction of a nuclear power station at Loviisa.

Cancer research provides another major field of cooperation. A conference in March of this year, held at the National Institute of Oncology in Budapest, laid down guidelines for future cooperation and integration. Hungary is to be in charge of pharmaceutical research and the testing of drugs, and the Soviet Union, notably the Moscow Oncological Institute, is to continue its research into the feasibility of neutron therapy, in which it is claimed that "substantial progress" has already been made. A Comecon X-ray morphological and diagnostic laboratory has been opened in Obninsk, and the possibilities of using π-mesons and proton radiation for the treatment of carcinomas is under consideration. This line of research, it is postulated, could be carried out with the cooperation of the Dubna Nuclear Research Institute.

The conference considered it particularly important to extend its contacts with the international cancer research organisations. WHO, the International Oncological Union, and the European Cancer Research Organisation already have links with certain Comecon States; the new proposals, however, suggest information-sharing between these bodies and the Comecon programme as a whole, presumably through the Moscow Oncological Institute, which acts as a coordinating centre and clearing-house for Comecon cancer research.

- One promising outcome of the recent agricultural crises in the Comecon block is the availability to the USA of credits from the sale of "agricultural surpluses" to Comecon countries. In the case of Poland, some of these credits are to be used to establish the "Maria Sklodowska-Curie" fund to finance joint research, the exchange of specialists and the organisation of conferences, thereby providing a fresh stimulus to Polish–US scientific contacts. Recent joint undertakings between the two countries include a joint expedition to the North-West Atlantic to study plankton resources, and hence the possibility of developing new fishing grounds in the area.

- At a meeting in Luxembourg in February of this year, Gerhard Weiss, the Chairman of the Executive Committee of Comecon, and Gaston Thorn, the President of the Council of (Prime) Ministers of the European Community, discussed a number of fields of cooperation between Comecon and the EEC, including standardisation, conservation, and statistics. Regarding conservation, the Comecon countries and Yugoslavia have now affirmed their willingness to see closer cooperation with the EEC. This emerged at a symposium in Dresden on technical questions relating to production processes with little or no waste products. Dr Hans Reichelt, the East German Minister for Environmental Protection and Hydroeconomy, welcomed Mr Brezhnev's proposal that an all-European Congress on cooperation in environmental protection should be held in the near future.

- The Royal College of Psychiatrists in the UK has adopted a resolution reiterating its condemnation of the abuse of psychiatry for political purposes in the USSR, and has pledged itself to do all in its power to secure the passing of a similar resolution by the World Psychiatric Association at its next World Congress in Honolulu in 1977. The proposed resolution runs counter to the expressed opinion of Dr Denis Leigh, the Secretary General of the WPA, who would prefer that all resolutions should deal with general ethical principles and avoid questions connected with religion, national policies, political belief and so on. He told the English-language journal *Soviet News* in December that he felt it important that the Soviet Union should be represented at the Honolulu Congress, and described the Soviet Society of Neuropathologists and Psychiatrists as "one of the most loyal" members of the World Psychiatric Association.

Vera Rich

SWEDEN

Science from the top

Wendy Barnaby reports from Stockholm on the International Foundation for Science's aid programme.

Few activities can cause such disillusion as the giving of foreign aid. Programmes hailed initially as life-savers often peter out with the sponsor complaining of lack of cooperation by the receiver, who in turn accuses the sponsor of paternalism or outright exploitation. Often the least satisfactory outcomes seem to bedevil the wealthiest sponsors. Money means organisation and, *ipso facto*, the diversion of creativity away from aid-giving into the maintenance of the organisation itself.

If wealth tends to bring problems, the International Foundation for Science (IFS) should on the face of it have more success than most aid organisations. Its total revenue for 1976 is expected to be Sk3,560,000 (about $790,000). The organisational side of the IFS looks healthy, too: it was formally established at a meeting in Stockholm last September as an afterthought to the initiation of some 45 projects. The only full-time employees are five administrators.

Each project is actually a research grant given to a young scientist from an underdeveloped country on the condition that his or her work is relevant to the needs of the country and carried out in it or some other underdeveloped land. The grants are given annually and are renewable for four years. The original intention behind the scheme was to try to stop the brain-drain of young African, Asian and Latin American scientists to developed countries because of the paucity of equipment and contacts at home. The grants—there are now 100 of them—have all so far been given within the broad field of biology applied to food production.

This encompasses six specific areas. The first is the development of local fish-farming through research on fish, of which an example is a grant of $13,000 given to a project in Nigeria's Federal Department of Fisheries to study the distribution of the popular cat-fish in order to collect fingerlings for stocking ponds. The second area is the improvement of small animals (mainly goats and sheep) of domestic and local importance—for example the research being done at the National Agricultural University in Lima to use agricultural waste products as more ficient food for guinea pigs, which are the main source of animal protein for the poor population in the upland region of Peru. The IFS has contributed $4,600 to the project. It also supports work on the morphology, physiology and pathology of vegetables, tubers, pulses and forage crops, such as that at the University of Malaya in Kuala Lumpur, to study the protein values of locally grown leaves, stems and tubers from cassava. This study—to which the IFS has given $2,300—is aimed at improving cassava for direct human consumption or for the production of leaf protein concentrate.

Studies of mycorrhiza (the symbiotic association of a fungus with the roots of a seed plant) in connection with afforestation form the fourth area of interest. At the Forest Products Research Institute, Kumasi, Ghana, research is being done into the most suitable fungi and the performance of field innoculation of pines with mycorrhizal fungi, the mass production of suitable fungi and the performance of the innoculated pines. The results will, it is hoped, contribute to Ghana's re-afforestation programme, and the IFS has supported it with $13,000. The fifth area is the improvement of traditional food fermentation processes—for example, a project under way at the University of Ain Shams in Cairo, Egypt, in which the waste materials from industrial food processing are being examined to see if they are suitable for controlled microbial growth which could lead to the economic production of protein. The IFS has given the project $7,000. The investigation of organic compounds from natural products traditionally believed to have medicinal applications is the sixth area. Here, the IFS has for example given $6,300 to research at the Haile Selassie I University, in Addis Ababa, Ethiopia, into the structure, properties and possible toxicological effects of a local plant used against tape-worm infections.

The fact that the grants are given in so many different places is not the only international aspect of the IFS. The funds are also contributed from many countries, mainly through national academies or other bodies representative of natural or social science or technology. In 1976, Sweden is expected to contribute just over half the total budget, Canada nearly one-fifth, and France, Belgium, the Federal Republic of Germany, the Netherlands and Japan will make up the rest between them. The President of the organisation—and the moving force behind its inception—is Swedish Professor Sven Brohult.

The specific projects mentioned so far illustrate the IFS pattern of a small grant being given to an individual scientist already employed at a research institute in an underdeveloped country. The organisation's involvement does not end there, however. Applications for grants in each of the six areas of interest are perused by scientific advisory groups, who recommend on their adoption to the Grants Committee. The advisers (who work for the IFS voluntarily) are scientists employed on research within the area whose applications they judge, and travelling in the course of their work to the regions in which projects are being carried out. In this fashion, the IFS is building up a network of contacts between researchers working in the same field in neighbouring countries who were not previously aware of each other's existence.

The IFS is so far committed to the potential of developed countries' science for aiding underdeveloped countries, a commitment which grew naturally out of its attempt to stop the brain-drain and one which can be strongly defended given the fact that so many researchers from underdeveloped countries have already been educated abroad. With this commitment goes a "science from the top" approach: support of researchers educated in science working by traditional methods in the hope that their work will ultimately benefit the other sectors of society. This is less fashionable now than the "science from the bottom" approach: educating the masses to contribute to the improvement of their condition through science, as for example Chinese peasants reporting on signs they see in the fields of approaching earthquakes. Ideally, each approach should complement the other. In the meantime, however, the IFS is seen to be doing something worthwhile. ☐

Sven Brohult, IFS President, and Olle Edquist, former Executive Secretary

IN BRIEF

Sea conference ends

The latest eight-week session of the 156-nation Law of the Sea Conference ended in New York last Friday with several bitterly-debated issues still outstanding. When the next round of talks is convened at the same venue in August, subjects for further discussion will include the extent of national jurisdiction and sovereignty over economic zones, the rights of landlocked states, the most suitable form of disputes procedure, and freedom of access for scientific research—a particularly contentious area offering scope for espionage and mineral plunder, in the view of some third world nations. Nonetheless, the divergent views of the underdeveloped and industrial states have closed slightly at least on the issue of control over deep sea mineral exploitation, and a compromise solution seems within reach. As the conference ended the Soviet Union protested at recent US legislation to extend its fishing limits to 200 miles by March 1977. One view, however, is that the US move would hasten that similar unilateral action which other worried states would probably have taken anyway.

Fluorocarbon report delayed

A crucial report by the National Academy of Sciences on the possible effects of fluorocarbons on the ozone layer has been delayed by up to three months because of new data which suggests that the threat may not be as serious as first predicted. It seems that chlorine, liberated from fluorocarbons, in the upper atmosphere, may react with nitrates to form a moderately stable compound. If correct, the theory, which is backed up by some direct measurements, means that the reaction would provide a "sink" for destructive chlorine atoms, reducing their effect on the ozone layer substantially. The Academy report, which was in the final stages of drafting when the new data came in, has been delayed until July.

Monitoring the stratosphere

Spurred by the recommendations contained in February's US Government decision granting Concorde commercial access to the United States for a 16-month trial period, Britain and France have entered a joint programme with the US to monitor the stratosphere. Under the agreement, signed in Paris last week, the participants will aim to improve and extend monitoring techniques, and record long-term fluctuations in global ozone levels. The US recommendations followed concern that nitrogen oxides in supersonic aircraft exhaust might destroy stratospheric ozone through reactions like those involving fluorocarbons from aerosol sprays.

Mutiny on the Bounty

THOMAS H. JUKES

SCIENTISTS have laboured long and mightily in the past half-century to help farmers increase food production, and to identify and prevent nutritional deficiency diseases. Their efforts were so successful that a surplus of food piled up in the USA, although not in most other countries, and there was a great deal of overeating. Simultaneously, many infectious diseases ceased to be significant causes of mortality, as a result of public health measures, including immunisation, and the discovery of chemotherapeutic drugs and antibiotics. Deaths from cardiovascular disease, cancer, hypertension and other degenerative diseases went to the head of the statistical tables. It is an obvious and easy oversimplification to blame these on food because of their association with obesity, especially the cardiovascular group. But the fact that overeating leads to fatness is no reason for blaming the food rather than the gormandiser.

When the choice between guns and butter was rhetorically offered by Goebbels to the German public, little did we expect that, a few years later, butter would be placed with guns among the enemies of human beings. Yet *Nature* (April 15, page 565) wants every cow to carry a government health warning for making butterfat. The warning should be on the bathroom scales, not on the cow. The warning would be just as logically placed on every nubile woman, for human milk contains fats similar to those in cow's milk, and we are told that pre-arteriosclerotic changes can start at a very young age. I doubt that this suggestion will get very far.

In fact, when I was asked recently what foods were not under suspicion of being unsafe to eat, I could think of only one: sawdust. Fats, of course, are deadly; the saturated kind cause heart disease and cancer, and the unsaturated ones destroy vitamin E. Sucrose is belaboured as being addictive and diabetogenic, except, apparently, when it occurs in orange juice (5% sucrose) and pineapple juice (8% sucrose), or when it is brown instead of white. School children who eat candy bars are being reprimanded by adults who smoke cigarettes and drink vodka on the rocks. School authorities are shutting down the vending machines, so that enterprising pupils are bootlegging soft drinks.

We eat too much protein, of course, about twice as much as we need, and we had better feel as guilty as possible about this. The US House of Representatives just passed a bill to prevent the Food and Drug Administration from restraining the promotion of para amino benzoic acid as a vitamin, much to the joy of the "health food" stores. For if food makes you sick, vitamin pills must make you well, even non-vitamin pills that are only good for bacteria.

Food additives must go, say the consumerists, and the large companies follow suit by devising all-natural breakfast foods; nothing artificial added, no preservatives. Why let the big and growing market for "natural foods" go elsewhere? Sodium propionate stops bread from going mouldy, but it is artificial, even though it is normally present in cheese, so out it goes. Never mind the fact that some moulds produce carcinogens. Bacon is the villain, it contains nitrites, which form nitrosamines. However, more than two-thirds of the nitrites entering the average stomach come from saliva, and 86% of the nitrates, from which nitrates are formed in the mouth, come from vegetables.

Sawdust and bran alone remain, because we need more fibre to keep the bowels active, and thus prevent cancer. This is proved by the fact that there is very little cancer in Africa, where there is lots of movement. Oh, well! The English have always been preoccupied with that function, ever since the days of Beecham's Pills and Kruschen Salts.

Maybe we were better off when we counted nickels instead of calories.

correspondence

International exchange

Sir,—The fourth European Drosophila Research Conference met in Umeå Sweden, in the Spring of 1974. It was a very interesting conference, which was attended by more than 150 Drosophilists from all over Europe. However, a certain disappointment was apparent among many of my colleagues, because no Drosophilists from the Soviet Union attended.

The fifth Conference will be held in Louvain-La-Neuve, Belgium, at the beginning of next September. As the organiser of the conference I really hoped that, as well as the other European Drosophila geneticists, a delegation from the USSR could attend the conference. Therefore, at the suggestion of an American colleague, I wrote last July to Academician Belyaev, who is President of the Soviet Society of Genetics, in order to obtain from him a list of his colleagues who might wish to attend the conference. I received a list of about 20 names last September.

At the beginning of January, I sent a first announcement and preliminary registration forms to all of them. At the same time I wrote to the Chairman of the USSR Academy of Sciences, inviting officially a delegation from the USSR to attend the conference. I got some answers from the Drosophilists of the USSR who were eager to attend.

Recently, however, I received a very short letter from the foreign relations department of the Academy telling me that the scientists of the Academy do not plan to attend the conference. It is hard to believe that it constitutes a final answer, especially as the XIV International Congress of Genetics is supposed to be held in the USSR in 1978. Are we to understand that the exchanges between geneticists from West and East Europe are only one way?

Louvain-La-Neuve, Belgium

Birds on the Chagos Bank

Sir,—The recent communication from Hirons *et al.* (April 1, page 387) prompts this response. Their suggestions relative to rats and birds at Great Chagos Bank raise several questions. "Feral brown rats" (are those *Rattus norvegicus*?) are alleged to prevent full utilization of Eagle and Egmont islets by seabirds. The suggestion is made that " 'warfarin' and Liverpool virus" be utilized to remove the rats.

While many studies of island situations have indicated the predatory impact of rats on nesting seabirds, this is not a universal relationship. Our own studies at Enewetak Atoll in the Marshall Islands have failed to produce evidence of predation by rats (*R rattus* and *R. exulans*) on such colonies, which include one of more than 10,000 sooty terns.

Eradication of rats is difficult. If the rat colony is at all sizeable, the presence of the "warfarin" resistant gene is likely; and problems might well be encountered. I wonder whether the Liverpool virus is being confused with Salmonella bacteria, a now discounted mode of control. In this connection, the WHO caution against their use should be noted (FAO/WHO Expert Committee on Zoonoses, *Wld Hlth Org. techn. Rep. Ser.*, No. 378, 1967; WHO Scientific Group, Ecology and Control of Rodents of Public Health Importance, *Wld Hlth Org techn. Rep. Ser.*, No. 553, 1974).

This suggests that the terrestrial ecology of those islets should be adequately understood before drastic management efforts are attempted. Knowing more of the "recent surveys" would be most helpful.

Cows and heart disease

Sir,—If a non-medico may presume to comment on coronary heart disease (Editorial, April 15), surely it is not the sacred cow that needs to carry a government health warning, but the golden car. Ignoring the nauseating exhaust products of the latter, I refer to the long term debilitating influence of car commuting. And not merely to confined physical inertia, but to the tremendous stresses involved in coexistence with one's neighbour within the relentless daily stream of traffic. To have a cyclist's eye-view in Boston, for example, is to see men possessed to a degree dangerously approaching that of mechanised Gadarene swine.

You say "Strangely, there is no evidence of a similar trend [of increasing incidence of CHD] for women". Is this because Equal Opportunity has not yet advanced far enough to take women from the physical toil of housekeeping and put them on equal wheeling with male commuters? But for the normal (or not so normal these days!) healthy body, let taste, not diet, remain the final arbiter. No doubt those in bondage to the golden car will regard this as mere folly and scandal, yet that symbol of supposed "freedom" increasingly becomes the premature reaper, whether we are saturated or unsaturated.

Isolative sound-change

Sir,—I should like to propose the following explanation for the isolative vowel sound-change from Anglo-Saxon *ā* through Middle English ǭ to Modern English *ō* (as in *mote*) instanced by Alan Ross (April 22, page 664).

If you open your mouth, say "ah", and continue the utterance while gradually allowing your mouth to relax and close you will find yourself recapitulating, in the course of seconds, the same sequence of sound changes as your correspondent cites as having occurred over centuries, and for the same basic reason, namely a gradual tendency to open the mouth less wide to make the vowel sound—in a word, laziness (It is interesting to compare the current marked tendency for the modern Persian *ā*—which is nearer to "aw" than to "ah"—to lapse into ū, for example, *Teherān* to *Teherūn*).

In some areas of England, where vowels are stronger, the transition has not yet reached the third stage. To give a ready example, listeners to the BBC television series "When the Boat Comes in" may have noticed that the pronunciation there of *boat* still approximates to the Middle English *bǭt*—as its surviving spelling indeed suggests it should.

I believe that the laziness principle also explains the tendency to lapse from *fire* to *far*, and so on. And surely it accounts for the tendency for our short vowels—*a* as in *Indian*, *e* as in *absent*, *i* along with *o* as in *station*, and *o* as in *onion*—to lapse into the basic *un*-sound found onomatopoeically in *grunt* But I would not suggest that it could account for all isolative vowel changes, because undoubtedly there is a complex of physical and psychological factors involved.

CO$_2$ variations and the Southern Oscillation

from John Gribbin

THE so-called "quasi-biennial" oscillations of the atmospheric and oceanic system, which produce variations in weather parameters with 'periods' of anything from a year to at least half-a-dozen years, but usually averaging between two and three years, are among the best known and most intensively studied climatic phenomena—but not necessarily the best understood. One very important member of this family is the Southern Oscillation, which is most clearly identified by variations in pressure with a timescale of two to two and a half years over the Southern Hemisphere; these variations are often very highly correlated between the two key areas around Jakarta (Indonesian low) and Easter Island (South Pacific high), and to a lesser extent the variations can be correlated with features of the Northern Hemisphere circulation. The Southern Oscillation is not, then, some local or even hemispheric phenomenon, but rather a particularly obvious manifestation of the general tendency of the atmosphere/ocean system to vary on this kind of timescale, and study of just how this oscillation does interact with other parts of the atmosphere/ocean system is important in the context of understanding quasi-biennial oscillations in general—and, ultimately, producing better forecasts.

Lamb has succinctly summed up the situation (*Climate· Present, Past and Future,* **1,** Methuen, 1972): "the Southern Oscillation and its roughly 2- to 3-year periodicity can clearly be taken to involve an alternation in the pattern and rate of heat distribution affecting much of the world and its wind circulation . . . the Southern Oscillation should be seen as related to the liability of the equatorial Pacific to some of the biggest and most extensive anomalies of sea surface temperature in the world". These anomalies have one very obvious and significant effect in the phenomenon known as El Nino, which brings high rainfall to generally arid regions of the equatorial Pacific, and although the link between this phenomenon and the Southern Oscillation is not entirely clear, anomalous conditions at the Easter Island high do seem to be involved.

It is with the importance of an understanding of the Southern Oscillation to our understanding of the whole atmosphere/ocean system in mind that the contribution by Bacastow on page 116 of this issue of *Nature* should be read. Bacastow claims that after a great deal of filtering to remove both seasonal effects and the long-term increase attributed to man's activities the record of carbon dioxide variations in the atmosphere indicates a correlation with the Southern Oscillation. Critics might take Bacastow to task for making the most of somewhat limited statistical evidence which he admits involves adjustments in some cases so that "the fit appeared reasonable to the eye", and which even then end up with correlations which although high enough to be interesting are not conclusive on the basis of these limited data alone. In addition, the very small variation in carbon dioxide levels (less than one third of 1%) seems to occur before the changes in the Southern Oscillation which might be expected to drive them. Nevertheless, although it seems unreasonable to suggest that the carbon dioxide variations might drive the oscillation, there remains the important possibility that both are being driven, or at least modulated, by some outside influence which has yet to be identified.

The somewhat tentative nature of the model proposed is, however, indicative of the tentative state of our understanding of the way the atmosphere and ocean interact. It is easier to appreciate that a thorough understanding of atmospheric variations can only come hand-in-hand with a thorough understanding of oceanic variations, but much harder to see where to begin to tackle the enormous problems involved in developing such an understanding. If the views of some climatologists are to be taken at face value, there is now also an element of a race against time to determine the natural patterns of such change before they are destroyed by man's activities—the controversy about carbon dioxide levels and man being a case in point—and prediction of these anthropogenic effects can only be achieved after an understanding of the natural processes has been developed. The specific case of the interaction between the Southern Oscillation and carbon dioxide uptake of the southern ocean is of direct relevance to the controversy over carbon dioxide pollution and its effects on the atmosphere and oceans; the broader view—what drives all these quasi-biennial oscillations—is perhaps of even greater importance now that the world food production and distribution systems can be so easily shaken by "bad" weather, as we have seen in recent years. ☐

More speculation on human evolution

from Robin Weiss

WHILE fossil finds hit the headlines, comparative biochemistry also has its place in the discourse on the origins of our species Two papers in this issue of *Nature* take up this discussion, one from the viewpoint of amino-acid sequences in proteins, the other of nucleotide sequences in DNA Romero-Herrera *et al.* (page 162) discuss the amino acids residing at two positions in the highly conservative muscle protein, myoglobin, which accepts oxygen from the blood. On the basis of the amino-acid residues in positions 23 and 110 of the myoglobin chain, these authors draw up 'cladograms' or evolutionary trees that might indicate the relationship of man to the higher apes The most economical cladogram in the sense of providing the minimum number of point mutations in the gene for myoglobin shows the orang-utan diverging from the other higher apes and man before the gibbon does. The problem with 'economy' of mutation is that it assumes that mutations are always selectively disadvantageous. This may be true for myoglobin, but residues in several proteins must be analysed before one cladogram can emerge as the clear choice.

Benveniste and Todaro's paper, also in this issue of *Nature* (page 101), concludes that during most of the Pliocene era, man's direct ancestors lived in Asia, or at least not in Africa. Therefore they would argue that the recent fossil finds by Richard Leakey in Kenya and by Johanson and Taieb in Ethiopia (announced at a news conference two months ago, but not yet published) that appear to push African records of *Homo* back into the Pliocene may not be the ancestors of our present day species.

Benveniste and Todaro's conclusions arise from ingenious arguments based on tenuous evidence. They have used the technique of DNA hybridisation by which the melted strands of DNA will reanneal with complementary sequences. When melted DNA from two species is allowed to reanneal only complementary nucleotide sequences will do so, and the degree of mismatching within those sequences can be measured as the depression in melting temperature in the 'hybrid' DNA compared with that of truly homologous DNA Thus the degree of genetic relatedness of species is determined by the extent of DNA hybridisation, and by the temperature at which 50% of the hybrid becomes dissociated. Benveniste and Todaro's annealing studies of DNA prepared from tissues of humans and apes broadly confirm earlier work, notably of Kohne and his associates at the Carnegie Institute of Washington, that the non-repetitive DNA sequences of man are more closely related to those of the African great apes, the chimpanzee and gorilla, than those of Asian apes. So far so good, in that these sophisticated biophysical studies of genetic material are consistent with, though perhaps less discriminating than, the morphological studies of classical primatologists or the eyes of children visiting the zoo.

Benveniste and Todaro then proceeded, however, to analyse a tiny fraction of DNA representing about 10^{-7} of the non-repeating sequences, and possessing the coding capacity for a small protein at the most This set of sequences is distantly related to part of a C-type virus endogenous to baboons, that is, a virus whose genes are incorporated into the host DNA and which is therefore inherited as a Mendelian trait. By synthesising a radioactive DNA 'probe' complementary to the genes of the activated baboon virus one can screen for related 'viral' sequences by annealing the probe to DNA prepared from normal tissues of other species of primates, including man. About 9% of the probe anneals to chimpanzee and gorilla DNA but only 3% to human DNA and to that of Asian species of ape. The extent of annealing is so small and the mismatching so great, that the melting temperature of the hybrid DNA can only be estimated by a crude extrapolation. Benveniste and Todaro do not think that man is more closely related to Asian apes than African ones since the overall cellular DNA hybridisation patterns indicate the converse. Their thesis is that African apes have conserved a larger fragment of DNA related to the baboon virus than have either Asian apes or man; that this conservation of viral DNA sequences results from natural selection due to some factor in the African as opposed to the Asian environment; that this factor is the baboon virus itself (and that of ancestral baboons) transmitted as an infectious agent; and that the conserved DNA sequences somehow confer immunity to infection of the host by the baboon virus. If man was not exposed to the baboon virus during the Pliocene era, there would be no selection to conserve these DNA sequences and they would diverge as fast as 'viral' sequences have done in other non-African Old World primates.

To launch such a complicated hypothesis on the difference between 9% and 3% of grossly mismatched homology of DNA sequences seems far-fetched. But Benveniste and Todaro show that it fits a general pattern in that sequences in Old World monkeys that are more closely related to the baboon virus have also diverged at a much higher rate among Asian species than among African species. Moreover the evolutionary arguments do not seem to me implausible, indeed they are familiar. There is some evidence in other species (chickens, for example) that endogenous viral gene expression can confer resistance to re-infection and there is also striking evidence from Benveniste and Todaro's previous studies (*Nature*, **252**, 456; 1974) that a C-type virus related to the baboon virus has been transmitted to the genome of the ancestor of the domestic cat (of North African origin) but not to an Asian species of the same genus.

Entertaining as these arguments are, on the basis of the evidence presented here they might have been more wisely restricted to the laboratory coffee room. The argument for man's Asian origin is based on the weak homology of a small fraction of a viral probe. There are no data to determine whether the conserved sequences in different African primates represent the same portion of the probe and indeed the viral sequences 'conserved' by natural selection actually diverge more rapidly than the non-repetitive host DNA as a whole.

An implicit corollary of Benveniste and Todaro's hypothesis is that man is susceptible to horizontal infection with C-type viruses of the baboon type, and that these viruses could be pathogenic to man. C-type viruses closely related to baboon viruses have been isolated from human leukaemic cells by Gallo and his associates and from fibroblastic cells by Panem and Kirsten. I have argued previously that zoonosis, ancient or modern, may be an important concept in the transmission of pathogenic C-type viruses, and that we should not be too perturbed to find that 'human' isolates resemble animal viruses Benveniste and Todaro's paper hints that they may now be coming to the same opinion. □

A hundred years ago

At the Crystal Palace Aquarium the hatching of the spawn of Axolotls has been successfully accomplished. There are three young "broods," and some still unhatched spawn, so that the changes in growth during the first few weeks can be seen all together.

A PLAGUE of Field Voles (*Arvoricola agrestis*) has recently visited some of the pastoral farms of Upper Teviotdale and the adjoining districts, which has led to the appointment of a committee of the Farmers' Club of the Locality for the purpose of estimating the amount of damage done. This was found to be very considerable, the vermin eating the pale and succulent bases of the grass, as well as the young shoots. No great destruction of other vermin has occurred in the district, so it cannot be said that the Voles have become particularly abundant from that cause. Similar plagues have before now occurred in the New Forest.

THE *Geographical Magazine* for May contains an article on the prospects for the Arctic Campaign of 1876. While we must be prepared for the necessity of the ships spending a second winter in the north, the writer thinks that possibly the *Pandora*, which goes out this month for news and letters, may meet them coming out of Smith Sound, "with their work done, their great enterprise completed." There is also an article, with map, on the Island of Socotra, which the British Government have arranged to occupy, and another by M. Venyukof on New Maps of Mongolia.

from *Nature*, **14**, 35, 36, May 11; 1876.

Sociobiology: a reply

WE are sad and disturbed at the tone of the article by Robert May (*Nature*, **260**, 390; 1976) on E. O. Wilson's *Sociobiology: The New Synthesis*. A widespread debate, originating in America, is taking place around this book and its adoption as a text for college courses. May's article attempts to sidestep the issues being raised by this debate and to remove the discussion to the rather more traditional and secluded arena of scholarly exchange. The term 'debate' in this context is, we recognise, distasteful to many scientists with a traditional view of science and we use it advisedly. We feel, however, that the effects of science upon everyday thought and upon political doctrines are issues that cannot be resolved by courteous sword-crossing within the language of 'pure' science itself.

On the contrary, the issues raised evoke the deepest feelings about power and its abuse, and about social injustice in ways that inevitably force a confrontation between individuals and groups holding disparate sets of values. We must learn to see what May describes as 'a certain incivility' as a function of the importance of such debates/confrontations. Since consideration of the social bases and the social effects of science should be recognised as being integral to science and its practice, such impassioned and political arguments should appear more regularly in the columns of *Nature* and *Science*

More importantly, May's focus on the so-called incivilities deflects attention from the serious nature of the issues posed by the publication of Wilson's book. The group of American critics (the Sociobiology Study Group of Boston Science for the People) to whom he refers, see in Wilson, essentially correctly we believe, a prime example of the scientific specialist (the naturalist in the broad classical sense) whose prolonged study of the bee and the ant have fostered in him a rather conservative expectation of the human capacity and potential for change. While such conservatism may well be largely unconscious and not overtly political in expression, untold damage is wreaked on 'informed' people's capacity to think critically about social institutions. By attempting to fit *Homo sapiens* into his evolutionary biological schema Wilson jeopardises any attempt to change present patterns of social inequality. As such it seems to us that 'a certain incivility' is more than reasonable.

Wilson's American critics have raised important objections to his work. They show how his case is based on speculation. He postulates genes, or groups of genes, for such traits as spite, military discipline, blind faith, and indoctrination. He uses metaphors from human societies to describe animal societies and in so doing imputes barter, religion and magic to animals. He closes off the theory from tests against the real world by postulating, for example, multiplier and threshold effects which make every observation fit the theory. May attempts to belittle this critique. "To suggest, for example, that the evolutionary considerations which determine the mating systems of mammals and birds have any light to shed on the tensions and asymmetries observed in human sexual relationships is [according to May] to invite reflexive dismissal as a 'sexist'"! Tensions and asymmetries are delicate words indeed to express centuries of economic and social exploitation of women. And in fact, Wilson does try to establish the inevitability of sexism by asserting it has a genetic basis. In an article in the *New York Times* (October 12, 1975) he states concerning the division of labour between the sexes: "This strong bias persists in most agricultural and industrial societies and on that ground alone appears to have a genetic origin . . My own guess is that the genetic basis is intense enough to cause a substantial division of labour even in the most free and most egalitarian of future societies . . . ."

That our society should continue to be so susceptible to such arguments expresses both a past and present deference to expertise in general and a deference of social science to biology in particular. At present we learn in school level biology courses and thereafter the roster of emergent properties that distinguishes life from inorganic matter. Life transcends the purely physical and chemical laws that govern inorganic matter, although matter in motion remains its physical basis. We must ask why, in our society, the human sciences cannot emancipate themselves from biology in the same way that biology is emancipated from the physical sciences We are unique animals who, while having a physical basis in organic life, transcend it through language and culture.

The final issue is, of course, how does the cultural *status quo* change? It seems obvious to us that social change occurs when humans set about self-consciously to change unacceptable oppressive and outmoded social conditions.

ROBERT MAY REPLIES: The above letter makes plain the differences of opinion between its authors and myself as to the place of passion and politics in science In particular it is true that I represented the controversy over the political significance of *Sociobiology* as only a small (and unfortunate) corner of a large canvas; I think that is the balanced view.

It should be emphasised that, unlike other recent controversies, the dispute over the political implications of *Sociobiology* is not a clash over substantial and well-defined issues. The Science For The People people do not attack Wilson's book but rather their own chimaerical version of it; in Wilson's words they "furnish me with a political attitude I do not have and the book with a general conclusion that is not there". Readers in any doubt on this score should see the recent exchange between the US Science for the People Study Group and Wilson in *BioScience* (**26**, 182–190; 1976) and the impartial news article in *Science* (**191**, 1151–1155; 1976). □

Panacea for injured nerves

from a Correspondent

WHEN a nerve innervating a muscle is cut the effect on the postsynaptic cell is profound The muscle atrophies, as shown by a loss of mass and of proteins, there is a marked reduction in the cholinesterase activity present in the tissue, and there is a considerable increase in the number of extrajunctional receptor molecules. Since the onset of these effects is related to the length of the nerve stump left associated with the tissue, and since they can be duplicated by blocking release from the nerve terminal, it has been proposed that nerves exert trophic influences on the tissues they innervate (Guth, *Physiol. Rev.*, **48**, 645; 1968). Considerably less attention has been focused on a trophic effect in the opposite direction, from tissue to nerve, although this possibility was first implied 18 years ago (Brown, *J. Physiol., Lond.*, **142**, 7P; 1958). This situation is now being rectified.

Two approaches have been used to study this suggested transfer of information from the post to the presynaptic cells. First, morphological techniques have been used to examine the effects of damaging the postsynaptic cell on presynaptic or synaptic ultrastructure and, second, biochemical correlates to these structural changes have been sought.

The morphological data have now provided unequivocal evidence that damage to a sympathetic ganglion cell, by cutting or ligating its axons, leads to a retraction of the innervating nerve and the insertion of a Schwann cell process between the pre and postsynaptic elements (Matthews and Nelson, *J. Physiol., Lond*, **245**, 91; 1975; Purves, *J Physiol., Lond.*, **252**, 429; 1975). The synapse thus becomes ineffective in that there is no transmission through the ganglion. The reversibility of the process depends upon the method of damaging the axons. If the possibility of regeneration and reformation of functional postganglionic synapses is excluded, then functional synapses on the ganglion cells do not reform either, and many cells die (Purves, *op. cit*). The preganglionic nerves appear ultrastructurally normal although their size may have changed (Matthews and Nelson, *op. cit*). Similar effects on the innervation of motor neurones were found previously (for example, Blinzinger and Kreutzberg, *Z. Zellforsch.*, **85**, 145; 1968; Cull, *Expl Brain Res.*, **20**, 307; 1974).

If biochemical rather than morphological changes are studied, however, it becomes apparent that the innervating nerves have been altered. For example, Jensen-Holm and Juul (*Acta pharmac. toxicol.*, **28**, 583; 1970), have shown that damage of ganglion cells by guanethidine results in a loss of cholinesterase activity from both the pre and the postsynaptic elements. Black, Hendry and Iversen (*J. Physiol. Lond.*, **221**, 149; 1972) found that destruction of the ganglion cells, using 6-hydroxydopamine or anti-nerve growth factor, prevents the normal development of choline acetyltransferase, the one enzyme known to be unique to the incoming cholinergic nerves and their terminals. In each of these cases it could be argued that the loss of synaptic contact with the ganglion cells removed the source of the information which the innervating nerve required to maintain its biochemical integrity. Similar changes have also been found in motor neurones. In these experiments the effector (muscle) cell has been damaged and the biochemical response to the injury measured in the innervating nerve, but not in those which impinge upon it. It is intriguing that the response of the nerve depends upon the type of damage inflicted on the muscle. For example, atrophy induced by inactivation of the acetylcholine receptors (using an α-neurotoxin) results in a decrease of choline acetyltransferase activity in the nerve terminals and axons. In contrast, no change in the levels of the enzyme was found when muscle atrophy was induced by treatment with botulinum toxin, a poison whose exclusive action is presumed to be a block of release from the presynaptic nerve terminal (Giacobini-Robecchi, Giacobini, Filogamo and Changeux, *Brain Res.*, **83**, 107; 1975). Tenotomy-induced atrophy also results in a decreased level of choline acetyltransferase activity in nerve endings whereas that provoked by cortisone treatment does not (Diamond, Franklin and Milfoy, *J. Physiol., Lond.*, **236**, 247; 1974). Hypertrophy which resulted from hyperactivity of the muscle did not result in increased levels of the choline acetyltransferase. Thus, it is not whether you injure a muscle or not that is important, or whether you alter its mass, it is the mechanism you use to produce the functional disturbance that counts.

There are also reasons for suggesting that the neurones which synapse on the motor nerves might be altered when these nerves are damaged. Giacobini-Robecchi *et al.* (*op. cit.*) have shown that when the α-toxin, but not the botulinum toxin, is used, there is a significant decrease in the size of the sciatic nerve, its spinal roots and of the corresponding sensory ganglia.

All these results lead to one conclusion. If neurones or innervated cells are damaged in certain ways then this will ultimately modify the neurones which make synaptic contact with them. The question which currently excites a great deal of interest is how, and in what form, is the information transferred from the postsynaptic cell to the presynaptic nerve terminal and even across several synapses and well into the central nervous system?

Only one molecule, nerve growth factor, has so far been implicated in the transfer of this information. Nerve growth factor is a protein which, as its name suggests, is able to stimulate the growth of neurones but its action is limited to those of the noradrenergic and sensory nervous systems. It is also a molecule which is taken up, fairly selectively, by the nerve terminals and, possibly, the cell bodies of the neurones present in these two systems. As well, nerve growth factor is able to prevent some of the biochemical changes which result from postganglionic axotomy of noradrenergic cells (Hendry, *Brain Res.*, **94**, 87; 1975). Interestingly, this protein can also prevent the depression of ganglionic transmission which results from crushing the postganglionic nerves, if it is supplied to the ganglion at the time of nerve injury (Purves and Njå, *Nature*, **260**, 535; 1976). Thus an additional role of nerve growth factor could normally be to maintain the synaptic contacts on a cell and they, in their turn, could then help to maintain certain biochemical parameters of the postsynaptic cells. It is likely that this effect of nerve growth factor is achieved by its transfer from the nerve terminals to the cell bodies. Since there is no maintenance of synaptic junctions, nor protection from axotomy, unless exogenous nerve growth factor is administered at the time of injury, it is unlikely that normal circulating levels of the protein are sufficient to influence the cell bodies directly. It needs to be concentrated first in the nerve terminals and then carried to the cell body.

Nerve growth factor cannot, however, be a universal panacea to injured nerves and their processes Motor nerves, which respond to injury much as sympathetic nerves do, seem unable to concentrate and transport nerve growth factor (Stöckel and Thoenen, *Brain Res.*, **85**, 337; 1975). A direct sensory link transmitting this specialised information from the injured muscle to the nerve is also unlikely (Giacobini, Filogamo, Weber, Boquet and Changeux, *Proc. natn. Acad. Sci. U.S.A.*, **70**, 1708; 1973) so it is probable that the signal can be transferred directly. The nature of the signals and how they are transferred, are not known, but the identification of these signals must number amongst the most fundamental questions that neuroscientists could wish to answer. ☐

Radon to predict earthquakes

from Peter J. Smith

AMONG the many potential earthquake predictors investigated in recent years, one of the most ignored, at least in the West, is the apparently premonitory change in the emission of radon. In a brief conference abstract King (*Eos*, **56**, 1019; 1975) recently reported that monitoring of the radon concentration in soil gas was begun in May 1975 at 18 sites along an active 60-km segment of the San Andreas fault in central California and that the first results indicated "spatial and temporal variations which appear to correlate with local seismicity". At the same meeting Teng *et al.* (*Eos*, **56**, 1019; 1975) also reported that a sampling network had been established along the San Andreas fault from Cajon to Gorman in order to measure systematically the radon content of groundwater. By December 1975, however, no definitive results had emerged, although there were "some interesting variations when compared to the local earthquakes".

The latter study in particular was inspired by a long series of groundwater radon measurements made in Russia; and it would seem that until now Russia and China have been the only two countries to pursue assiduously the possibility of predicting earthquakes by radon emission variation. Following a visit to China in 1974, for example, Press *et al.* (*Eos*, **56**, 838; 1975) concluded that "some of the work in China on radon emanation as a precursory effect is to our knowledge as good as that being done anywhere in the world". Apparently, the waters in at least several tens of wells are being monitored continually (sampling normally once or twice a day) using electrometers which measure the radon-emitted α-particle fluxes.

The result of this activity is that a precursory increase (or, more rarely, a decrease) in the radon content of water has been detected for at least six Chinese earthquakes ranging in magnitude from 4.3 to 7.9. The precursor times ranged from a few days to a few tens of days, and in most cases the radon anomalies were observed within 110 km of the subsequent shock. In the case of the magnitude 4.9 earthquake of June 6, 1974, for example, the radon anomaly, observed at a distance of 49 km, appeared about 15 days before the shock and produced a radon flux 2–3 times that of the normal background.

In view of this success it seems likely that experimental interest in the radon precursor will increase rapidly in the United States and elsewhere in the near future. In the meantime, however, Pierce (*Geophys. Res. Lett.*, **3**, 185; 1976) has pointed to a consequence of variations in radon emission which could well extend observational methods beyond the direct measurement of radon itself. His premise is that an increase in atmospheric radon resulting from the release of radon from the ground should have an effect on atmospheric electricity—in particular on the atmospheric electric field and on the conductivity of the atmosphere. As long as the effect is large enough, therefore, the monitoring of such quantities should reveal the radon precursor indirectly.

To estimate just how large an effect could be expected, Pierce has set up a highly simplified theoretical model of atmospheric electricity which is meant to be "illustrative rather than definitive". The rationale behind this rough approach is that both the physics of the situation and the numerical values involved are so uncertain that a more sophisticated model would hardly be justified. Moreover, in related work, simplified models have turned out to be surprisingly effective. Be that as it may, the model predicts that a precursory increase (of 100%) in radon emission would lead to an increase in fair weather conductivity of about 50% and an average decrease in electric field of about 30% (20% by day, 40% at night). On this basis, the obvious parameter to measure is conductivity. Unfortunately, however, it is technically much more difficult to measure conductivity than electric field. The field change may be smaller but is easier to record, and 30% might just be detectable.

But only under ideal conditions. A field anomaly of 20–40% represents an absolute change of 20–150 V m^{-1}, and clouds and precipitation can produce changes of several hundred volts per metre, without a hint of radon variation, by generating space charge. Moreover, even in fair weather conditions, such agencies as waterfalls, surf, dust, power lines, aerosols and air pollutants may create space charge and hence perturb the normal field. With problems like these, ideal conditions might be considered unattainable. Nevertheless, Pierce believes that they may be nearly achieved in the rural areas of some Californian valleys in the summer. Accordingly he recommends the addition of electric field monitoring equipment to experiments such as those being carried out by King.

The difficulties with environmental conditions suggest that electric field anomalies are unlikely to be reliable earthquake predictors by themselves, although they could provide valuable support to other observed precursors. It is perhaps worth pointing out, however, that atmospheric electric field monitoring has actually been used in at least one earthquake study. Kondo (*Mem Kakioka Magn Observ.*, **13**, 11; 1968) recorded occasional field decreases of as much as 20% during the Matsushiro (Japan) earthquake swarm of late 1966. He even suggested that the changes might be related to an enhanced radon content of the atmosphere, but never pursued the idea in detail. □

Ionising helium

from Peter Knight

THE ionisation of an unperturbed helium atom, starting from its ground state, would require an energy equivalent to that of 22 photons from a 1.06 μm laser. The corresponding "22-photon ionisation" rate would depend upon the 22nd power of the intensity at modest laser intensities, provided that there are no laser temporal coherence effects (due to multimode operation for example) and provided one is far enough away from any possible atomic resonances which would modify the non-linear intensity dependence of the absorption. The fact that 22 photons from a 1.06 μm laser seem to be needed to ionise a helium atom when the laser intensity exceeds 10^{15} W cm^{-2} is, however, a surprise. A group from Saclay has recently reported results on the multiphoton ionisation of rare gases by 30 ps laser pulses at 1.06 μm (Lompre *et al.*, *Phys. Rev Lett.*, **36**, 949–952; 1976) which seem to show just that.

Their laser system produces linearly polarised radiation with a linewidth of 0.8 Å centred upon 10 643.5 Å—chosen to avoid atomic resonances. It is operated to generate single pulses of duration 30 ps so that very high peak focused intensities (typically in excess of 10^{15} W cm^{-2}) may be generated, and so that coherence effects may be avoided. The variation of the number of photoions produced as a function of laser intensity at the focal region is investigated. Then for a single pulse away from an atomic resonance one would expect from the perturbation theory of K-photon multiphoton ionisation a transition rate proportional to the Kth power of the intensity. The following table, taken from Lompre *et al.'s* paper, compares K_0, the next integer greater than the atomic ionisation energy divided by the laser photon energy, with K_{exp}, the slope of the log-plot of the number of photoions produced as a function of intensity for five rare gases.

Atom	K_0	K_{exp}
Xe	11	11±0.5
Kr	13	13±0.5
Ar	14	14±0.5
Ne	19	20±2
He	22	23±2

K_0 is essentially the minimum number of photons at the laser frequency needed to ionise an unperturbed atom.

So even at the high intensities used by the Saclay group (7×10^{14} W cm^{-2} to 1.1×10^{15} W cm^{-2}), K_0 and K_{exp} are in good agreement. This is surprising since for these field intensities, the atom certainly is not unperturbed: the peak laser electric field E approaches or even exceeds the internal atomic electric field E_0 responsible for the atomic binding. In such circumstances it is not obvious why the ionisation energy of the unperturbed atom is such a crucial factor. Theoretical work by Keldysh (English translation: *Sov. Phys. JETP*, **20**, 1307; 1965) had suggested that electron tunnelling ionisation rather than multiphoton ionisation would be dominant for $E>E_0$. The Saclay group, approaching $E>E_0$ for the first time in a multiphoton ionisation experiment see no evidence of this yet. If tunnelling occurs present theories predict an intensity-dependent K_{exp}, but this has not been observed. Clearly further experimental work is needed, but already the Saclay group's results indicate a need for new theoretical approaches to this difficult problem. In particular, the theory of tunnelling urgently needs to be re-examined. □

Junctions and synapses in development

by Eleanor Lawrence and Miranda Robertson

A meeting on Intercellular Junctions and Synapses in Development was held in Cambridge on April 6–8, 1976, under the auspices of the International Society of Developmental Biologists and University College London. The meeting was organised by Joan Feldman of University College and the proceedings will be published by Chapman and Hall.

SYNAPTOGENESIS and the appearance of other junctions during development raise such different questions that they tend to be considered separately. But answering those questions may involve much the same technology, and it is at the level of technique that the cross-fertilisation encouraged by combining them in the same symposium may prove fruitful.

Gap junctions, the main topic of the meeting, are structures still in search of a function. The structural and permeability properties of the gap junction strongly implicate it as the communication channel for the passage of ions and small molecules between cells, but—except in the myocardium—there is no direct evidence as yet for any physiological function *in vivo.*

By freeze-fracture electron microscopy gap junctions appear as patches of intramembrane particles arranged in hexagonal arrays. The model that was proposed originally for the gap-junction structure by N. B. Gilula (Rockefeller University) was of a dumb-bell shaped protein complex spanning the two apposed membranes and penetrated by a central hydrophilic pore. This model is supported by analysis of X-ray diffraction patterns of isolated gap junctions which has also revealed a six-fold symmetry around the central pore. (D. Goodenough, Harvard Medical School). C. Perrachia (University of Rochester, New York) also proposes a structure of six dumb-bell shaped subunits as an explanation of the different shapes the isolated gap-junctional particles take in the electron microscope.

Electrophoretic separation of isolated gap junction proteins suggests that there are two main subunits but their true molecular weights are far from clear mainly due to proteolysis during the isolation procedure. Attempts by Goodenough and Don Caspar (Brandeis University) to provide a definitive structure for the gap-junctional particle by the low dose electron microscopy technique used so successfully on bacteriorhodopsin, have unfortunately run into difficulties, since the hexagonal arrays of particles turn out to be not sufficiently regular to give any clear results so far.

A possible structural change which can be correlated with functional uncoupling is the apparent contraction of the gap junctional lattice on fixation, when the particles become more closely packed and smaller in diameter (found independently by Goodenough and Perrachia). Goodenough suggested that that might close the channel by blocking the central pore.

Ionic (electrical) and metabolic coupling in cell culture have been clearly correlated with the presence of gap junctions. Correction of metabolic defects in mutant cells in contact with normal cells, and other biochemical methods, have been used to demonstrate that a wide variety of small cellular molecules such as amino acids, sugars and nucleotides can cross the gap junction: cellular macromolecules do not cross. (John Pitts, University of Glasgow) Birgit Rose (University of Miami) has found a 1,000 molecular weight upper limit for synthetic polypeptides. So far she has found no similar upper limit for synthetic oligosaccharides which are apparently still going through at molecular weights of 1,300. In *Chironomus* at least, the permeability of the gap junction can be regulated by Ca^{2+}, which at sufficiently high concentrations at the junction blocks the passage of an electrical current (Rose).

Although the idea that gap junctions have an important role as a communication channel between like cells during development is attractive it is thus far unsupported by any convincing evidence. J.-P. Revel (Caltech), who claimed to have found his own results almost impossible to interpret, remarked pessimistically that the existence of a fine telephone system doesn't necessarily mean that there's anybody talking down it, or even if there is, that they're talking sense He finds that during neurulation in the chick embryo, not only do the gap junctions present in the epiblast before invagination of the neural groove disappear as the neural groove develops but the tight junctions in that region also become disrupted and all that can be seen when the neural tube closes are scattered groups of a few particles where the tight junctions should be. It is impossible to tell whether those are tight junctions disappearing or gap junctions forming or whether the gap and tight junctions are transmutable.

Anne Warner (Royal Free Hospital, London) has elected to follow the changing patterns of electrical coupling in developing axolotl and *Xenopus* embryos. She presented a beautifully clear demonstration of electrical coupling changes during somite formation in the axolotl and *Xenopus.* In both embryos, the unsegmented mesoderm cells are strongly coupled to each other. Prospective somite cells become uncoupled before or during somite formation and in *Xenopus* the cells in the newly-formed somite recouple not only to each other but to adjacent somites as well. In the axolotl the formed somites do not couple to each other. Gap junctions between coupled cells have been demonstrated in this system (Blackshaw and Warner, *J. Physiol., Lond.*, **255**, 209–230; 1976).

S. W. de Laat (Hubrecht Laboratory) directly challenged the assumption that ionic coupling seen between the cells of the first cleavage to fifth cleavage *Xenopus* embryo is mediated by gap junctions, by suggesting that the electrical coupling is due to the generally lower permeability of the intercellular membranes relative to the outer bounding membranes rather than to the presence of specialised low resistance junctions (gap junctions) in the cleavage membrane.

But during discussion it was pointed out that although these intercellular membranes are relatively particle-free, even the few particles that can be detected could account for the ionic coupling if they were acting as individual communication channels.

R. S. Decker (University of Dallas) has developed a simple and elegant system for studying the formation of gap junctions during differentiation. He has followed the progress of junction formation during hormone-induced differentiation *in vivo* (hypophysectomised *Xenopus* embryos responding to thyroxin) and *in vitro* (adrenal cortical tumour cells responding to ACTH) and has demonstrated that both RNA and protein synthesis are required.

The existence of defined junctional mutants could aid the analysis of the functional significance of the gap junction considerably. Pitts reported that no single-step mutations have yet been found. W. Loewenstein (University of Miami) has been studying the behaviour of somatic cell hybrids between communication competent normal human cells (which possess gap junctions) and communication incompetent mouse cells (lacking junctions) and finds that the early heterokaryons resemble the normal parent. But as the human chromosomes are gradually lost over the generations the cells revert to communication incompetence. Loewenstein has been unable to ascribe reversion to the loss of any particular human chromosome or chromosomes but believes that not more than two are involved.

The principal problem in synaptogenesis is not its *raison d'être* but its mechanism—how do innervating fibres recognise their target cells, how specific is that recognition and what part is played by competitive interactions between innervating fibres? C. Sotelo (INSERM) reviewed morphological evidence from mouse cerebellar mutants that in the absence of the normal postsynaptic sites, growing nerve fibres will make alternative synapses and conversely that in the absence of their normal innervation postsynaptic structures can attract nerve fibres which would not normally reach them

The existence of relatively nonspecific specialised sites intrinsic to the membrane of postsynaptic cells in the CNS was emphasised by G. Raisman (MRC Mill Hill) who described the reinnervation of denervated adult rat superior cervical ganglion cells by the vagus and the hypoglossal nerves at the sites of the postsynaptic thickenings originally occupied by preganglionic nerve fibres.

The molecular nature of the recognition system for postsynaptic membrane is unknown, although one obvious possibility is the neurotransmitter receptors themselves. Most attempts to test that possibility in the central nervous system have failed. But J. Freeman (Vanderbilt University) has succeeded in showing that the retinotectal system in *Bufo* is cholinergic, and claims that by applying the cholinergic receptor blocker α-bungarotoxin to small areas of the developing optic tectum he can create localised defects in the electrophysiological map of the visuo-tectal projection.

Detailed studies on the behaviour of receptors are much easier at the neuromuscular junction, where it is believed that the increased density of receptors at the postsynaptic membrane is a consequence of innervation rather than its cause. G. Fischbach (Harvard University) however presented evidence that chick skeletal muscle cells *in vitro* develop areas of high receptor concentration in the absence of innervation. These receptor "hot spots" are detected by intracellular recordings from the muscle as areas of heightened sensitivity to focal stimulation with ACh, which confirms Nirenberg's report that local concentrations of α-bungarotoxin receptor binding sites exist on muscle cells *in vitro*.

The stability of concentrations of receptor sites *in vivo* was emphasised by C. Slater (Newcastle General Hospital), who finds that the peaks of sensitivity that develop in denervated adult rat soleus on reinnervation with the superficial fibular nerve persist for at least a week after section of the fibular nerve.

The question of competitive interactions in the specification of neuromuscular junctions formed in developing mammals was addressed by D. van Essen (University College London), who reported that the multiple innervation found in neonatal soleus is eliminated by 2–3 weeks after birth, through the withdrawal of supernumerary terminals by the motor axons. This shrinkage occurs however even when half the competing terminals are removed by the early section of one of the ventral roots, and some muscle fibres are left vacant. In experiments in which an immature muscle was denervated and reinnervated by a foreign nerve which was then forced to compete for synaptic sites with the regenerating terminals of the original nerve, multiple innervation persisted only where the synapses were at least 1 mm apart.

The resolution of problems in synaptogenesis seems likely to be found in the properties of the membranes; the properties of gap junctions will remain a series of tantalising hints until someone can define a disruptive effect of blocking them *in vivo*. □

Radiological data collection

from a Correspondent

> A meeting on Radiological Protection Data: Collection, Recording and Use, organised by the Society for Radiological Protection was held in London on April 6, 1976.

A NATIONAL register of radiation workers is to be set up in this country, S. Rae, Assistant Director (Medical) of the National Radiological Protection Board, told the meeting. Negotiations for establishing the register, initially to cover workers in the nuclear energy industry, are now being conducted. It is hoped to extend it to include for example, industrial radiographers and miners exposed to radiation.

The purpose of setting up such a national register will be to carry out an epidemiological study of cancer mortality in radiation workers and to look for effects of occupational radiation exposure on the natural rate of cancer induction. The register will follow, for at least 25 years, the radiation exposure of a large population of radiation workers and will match this with information obtained from the records of the Office of Population Censuses and Surveys about the age at death and the cause of death of these workers.

He indicated that calculations, based on current estimates of rates of cancer induction per million individuals per rad, suggest that even with a postulated study of 10,000 workers followed for 25 years it is most unlikely that there would be a detectable increase in the number of cancer deaths from occupational exposure to radiation at the currently existing level. If, however, no excess mortality is demonstrated by such a study then we can conclude that the risk coefficients we assume and the levels of radiation exposure we endeavour to keep to are justified, and this information is well worth knowing.

R. H Clarke (Berkeley Nuclear Laboratories) described some work he had been carrying out in conjunction with Professor Mayneord on computer modelling of non-linear dose-response relationships. He quoted considerable published evidence for a non-linear, peaked, response between dose and risk and then discussed the implications of such a relationship in radiological protection. From his studies, Clarke was unable to show that the absolute expectations of malignant conditions were significantly greater for these non-linear dose-response functions than for the conventional linear hypothesis on which the recommendations of the International Commission on Radiological Protection are based.

The familiar film-badge which radiation workers have been used to wearing for so many years in this country will for many of them soon become a thing of the past. The National Radiological Protection Board is shortly to introduce a new themoluminescent dosemeter (TLD) for the majority of its customers and a prototype of the dosemeter was on display for the first time at the meeting. The dosemeter consists of a metal plate carrying two inserts of lithium fluoride-impregnated PTFE discs. The dosemeter is wrapped in black polythene film and worn in a black plastic holder

The advantage of a TLD is that it readily lends itself to automation in dosemeter issue and readout, and in dose record keeping. E. Greenslade (NRPB) told the meeting about the relatively simple interim dose record keeping service, based on film-badges, at present operated by the NRPB. This service covers some 3,800 workers at 330 establishments. The new TLD will form the basis of an automated dosemeter issue and record keeping service which will be capable of holding up to 200,000 records. L. Salmon (Atomic Energy Research Establishment, Harwell) described the data base system, DIRK, which had been developed at Harwell for the NRPB's automated TLD service. □

Evolution of type C viral genes: evidence for an Asian origin of man

Raoul E. Benveniste & George J. Todaro

Viral Leukemia and Lymphoma Branch, National Cancer Institute, National Institutes of Health, Bethesda, Maryland 20014

Old World monkeys and apes, including man, possess, as a normal component of their cellular DNA, gene sequences (virogenes) related to the RNA of a virus isolated from baboons. A comparison of the viral gene sequences and the other cellular sequences distinguishes those Old World monkeys and apes that have evolved in Africa from those that have evolved in Asia. Among the apes, only gorilla and chimpanzee seem by these criteria to be African, whereas gibbon, orang-utan and man are identified as Asian, leading us to conclude that most of man's evolution has occurred outside Africa.

THE endogenous, genetically transmitted type C viruses isolated from baboons can be used to generate nucleic acid probes which provide a new approach to the study of primate evolutionary relationships[1]. With DNA transcripts of the baboon RNA virus genome, related nucleic acid sequences can be detected as normal constituents of the cellular DNA of baboons, other Old World monkeys, and apes, including man. The amount of base-pair mismatching, as determined by the thermal stability of DNA–DNA hybrids or by the final extent of hybridisation, correlates well with the classification of primates based on anatomical considerations and the fossil record[2,3]. We have explored this in more detail by comparing the virogene sequences and the overall non-repetitive cellular DNA for 11 Old World monkey and 6 ape genera, including man.

African Old World monkeys (8 genera, including several baboon species) and African apes (gorilla and chimpanzee), possess virogenes that are useful in the taxonomic classification of these animals. The Asiatic Old World monkeys (macaques, *Cynopithecus*, and langurs), and the Asiatic apes (gibbon, siamang, and orang-utan) contain virogene sequences that possess much less sequence homology (relative to the baboon) than those of the African primates. When human DNA is examined, its extent of virogene sequence divergence agrees with that obtained for the Asian apes and is substantially different from that of either African ape.

Nucleic acid homologies among primate DNAs

The extent of reassociation and the thermal stability of DNA strands derived from different species are a measure of their evolutionary relationships[4–6]. Non-repeated sequences comprise a large fraction of mammalian DNA; each sequence is believed to occur only once per haploid genome[7]. This DNA is therefore suitable for determining the extent of nucleotide diversity that has accumulated since two species diverged from their last common ancestor.

Eleven genera of Old World monkeys (Cercopithecidae) belonging to two subfamilies (Cercopithecinae and Colobinae) and six genera of apes (including man) were examined for the extent of homology of their cellular DNA with that of a baboon, *Papio cynocephalus*. The baboon is the index species for organising the Old World primates to facilitate comparison with the data obtained for the virogene sequences. Table 1 shows that the cellular DNAs of other baboon species are, as expected, most closely related to *P. cynocephalus* DNA; *P. anubis* shows the greatest sequence homology to *P. cynocephalus* while *P. papio* and *P. hamadryas* DNA possess somewhat less. The Cercopithecinae most closely related to the baboon group include the gelada, mandrill, macaques and mangabeys. Guenon, vervet and patas monkeys are more distantly related. The cellular DNAs of the more primitive subfamily Colobinae (the leaf-eating monkeys) show less nucleic acid sequence homology to baboon DNA than does the cellular DNA of any of the monkeys of the subfamily Cercopithecinae. The apes and man form a distinct group since their DNA is even more distantly related to baboon DNA than is that of any Old World monkey; the cellular DNAs of the various ape genera hybridise to approximately 50% of baboon cellular DNA with the conditions used. Three genera of New World monkeys were also examined; these are the most distantly related of the primates tested (approximately 35% homology).

The thermal stability of nucleic acid hybrids was also used as an index of the degree of base-pair mismatching between the primate DNA strands (Table 1). Mismatching results in the formation of hybrids that melt at a lower temperature; the effect of mismatched base-pairs on the thermal stability has been estimated at between 0.7 and 1.7 °C per 1% altered pairs[8]. The decrease in thermal stability between the homologous baboon cellular DNA hybrid and the hybrids formed between baboon DNA and the DNA of the other primate species is expressed as ΔT_m. It is evident that the cellular DNAs of those primates that show progressively less homology to baboon DNA also show a decrease in their thermal stability relative to the homologous baboon DNA hybrid. Therefore, the decrease in the final extent of nucleic acid homology is most likely due to an accumulation of base-pair mutations, reflecting an increasing phylogenetic distance from the baboon.

Table 2 shows the thermal stability of ape and human non-repetitive cellular DNA hybrids. Radioactively-labelled cellular DNA from diploid cultures of human, chimpanzee, and gorilla cells was hybridised to cellular DNA from cell cultures and tissues of several representatives of each species. Chimpanzee, gorilla and human cellular DNA all yield a $\Delta T_m R$ of approximately 2.3–2.6 °C when hybridised to each other. More distantly related to these three apes are the orang-utan (4.5 °C $\Delta T_m R$), the gibbon and siamang (6.3–6.5 °C $\Delta T_m R$), and the baboon (8.6–9.3 °C $\Delta T_m R$). The $\Delta T_m R$ values shown in Table 2 for ape–baboon DNA hybrids are the same as the values shown for the baboon–ape hybrids in Table 1. There is therefore a

Table 1 Nucleic acid homology and thermal stability between baboon cellular DNA and the DNA from various primate species

Species		Baboon cellular DNA	
	% hybrid	ΔT_m (°C)	$\Delta T_m R$ (°C)
Old World monkeys

The DNA of a baboon lung cell strain was labelled with ^{3}H-thymidine (120 μCi per ml of cell culture media) for 72 h and extracted[20]. "Non-repetitive" cellular DNA was isolated by removing the highly reiterated DNA sequences that anneal by a C_0t of 200 (40% of the total DNA) by fractionation on hydroxyapatite[1]. Cellular DNA was extracted from tissues and cell cultures, and sonically treated to a mean size of 6–8S as determined by centrifugation on alkaline sucrose gradients[20]. DNA–DNA hybridisations were incubated at 65 °C in reaction mixtures containing 0.01 M Tris, *p*H 7.4, 0.75 M NaCl, 2×10^{-3} M EDTA, 0.05% SDS, 40,000 c.p.m. of ^{3}H-thymidine-labelled baboon cellular DNA (0.2 μg) per ml and 2–4 mg of cellular DNA per ml. Hybridisations were started by heating the mixtures to 98 °C for 10 min, cooling on ice to 4 °C, and incubating at 65 °C. At various times, 0.025-ml portions were removed and frozen at −80 °C. The percentage hybrid is the saturating normalised value obtained after digestion of the hybrids with the single-strand specific nuclease S_1 (refs 36, 37). All hybridisations were carried out to a C_0t value[7,38] of 4×10^4. The actual final extent of *P. cynocephalus* cellular DNA hybridisation to its non-repetitive cellular ^{3}H-DNA was 76%. The temperature at which 50% of the hybrids are dissociated (T_m) was 86 °C for the homologous *P. cynocephalus–P. cynocephalus* hybrid. The ΔT_m is the difference in T_m between the other DNA–DNA hybrids and the T_m of the homologous hybrid. $\Delta T_m R$ is the thermal stability difference for all the non repeated DNA[4], and is the ΔT_m value corrected for the final percentage of hybridisation of the cellular DNA to the labelled baboon DNA. This correction is based on the assumption that the difference between the various primate DNAs is due to divergence from common ancestral nucleic acid sequences, and not to the addition or deletion of large amounts of DNA unrelated to that in the species being tested.

close agreement in $\Delta T_m R$ values for the various reciprocal hybrids tested. The siamang and gibbon cellular DNAs possess as much nucleic acid sequence homology (2.5 °C $\Delta T_m R$) as chimpanzee, gorilla and human DNA share with each other.

The thermal stabilities of the various non-repetitive cellular DNA hybrids were used to construct a phylogenetic tree of primate evolution (Fig. 1). Since there is an apparent effect of generation time on the rate of accumulation of base-pair mutations in DNA[4,9,10], divergence times for certain of the apes have been adjusted for the time needed to reach a fertile state, as explained in the legend. In addition, all the divergence times shown depend on the choice of 30 Myr as the time when Old World monkeys and apes initially diverged[11]. The data show the gelada closely related to the baboon and are consistent with a model in which the baboon, mangabey and macaque lineages have been derived from a common ancestor somewhat more recently (7–8 Myr ago) than the lineage leading to the *Cercopithecus* and *Erythrocebus* group (12 Myr). The subfamily Colobinae (langur and colobus) seems to have diverged from the other Old World monkey subfamily Cercopithecinae approximately 18 Myr ago. Hybrid animals have been obtained by breeding different species of *Papio* (*P. anubis* and *P. hamadryas*, for example) and different species of *Macaca* (*M. mulatta* and *M. nemestrina*), as well as *Papio* and *Theropithecus*, and *Papio* and *Macaca*[12]. The *Papio–Theropithecus* hybrids are apparently fertile, while the *Papio–Macaca* hybrids are reported to be sterile[12]. These data support the conclusion that the *Papio–Theropithecus* divergence is more recent than that of *Papio* and *Macaca*, and suggest that a $\Delta T_m R$ difference of 2 °C for the reassociation of DNA hybrids may represent the upper limit in anthropoid primates for genetic compatibility leading to the production of fertile offspring.

As is evident from Fig. 1, man is quite closely related to the chimpanzee and gorilla. The human–chimpanzee and human–gorilla "non-repeated" cellular DNA hybrids dissociate with a $\Delta T_m R$ of approximately 2.4 °C (ΔT_m 1.3 °C) lower than the dissociation temperature obtained for the reannealing of human DNA. The divergence between chimpanzee, gorilla and man emerges therefore as a trichotomy with a common ancestor 12 Myr ago (8 Myr if the data are not corrected for the longer generation time of this group). Our data do not reveal any two of these three species as being closer to each other than the third (see Table 2). Both African apes, then, are equally close to man; our next closest relatives, but clearly more distant than the African apes, are the orang-utan (diverging 18 Myr ago) and the gibbons (diverging 26 Myr ago). The gibbon and siamang are closely related to each other, having last had a common ancestor about 6–8 Myr ago.

The data obtained correlate closely with those of other investigators who used DNA reassociation techniques[4–6,9] or amino acid and immunological data[13–17] to classify the primates, as well as with some of the phylogenetic relationships established on the basis of anatomical considerations and the fossil record[2,3,11]. The nucleic acid sequence homology of ape cellular DNA supports the classification proposed on an immunological basis by Goodman and Moore[17] that places man, chimpanzee and gorilla in one subfamily (Homininae) since they clearly had a common ancestor more recently than any of these three species had with the orang-utan or with the gibbons. The genetic distance between man, chimpanzee and gorilla as measured by the decrease in thermal stability of nucleic acid hybrids ($\Delta T_m R$) is comparable, for example, with that found between gibbon and siamang, or between baboon, rhesus and mangabey (see Table 1).

The actual evolutionary dates for the divergence of the various primate species depend on the choice of 30 Myr for the ape–Old World monkey divergence. If this date is shown to be radically wrong (most likely as an underestimate) by future palaeontological discoveries, the relative relationships among the various primate species would nevertheless remain the same. For example, the extent of nucleic acid sequence divergence among chimpanzee, gorilla and man is three to four times less than that between any of these three Homininae and the Old World monkeys.

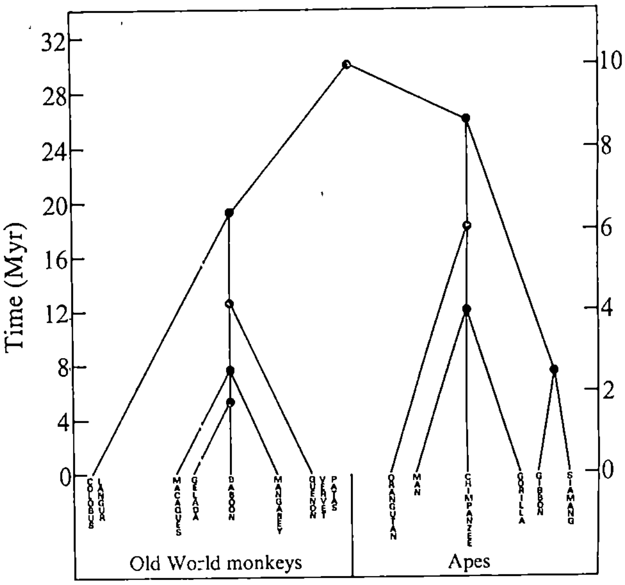

Fig. 1 Phylogenetic tree depicting relationships among the cellular DNAs of Old World monkeys and apes. The $\Delta T_m R$ (°C) of the various DNA–DNA hybrids shown in Tables 1 and 2 are plotted as a function of years of evolution. The points shown depend on the choice of 30 Myr for the time when Old World monkeys and apes diverged[11]. For the Old World monkeys (generation time 4–6 years[39]), a value of 1 °C $\Delta T_m R$ equal to 3 Myr of evolution was chosen based on the fact that the $\Delta T_m R$ between Old World monkey and ape DNA is approximately 9 °C. This relationship was also employed for the gibbon and siamang (generation time approximately 6 yr). For the longer lived higher apes, the values were adjusted as follows: orang-utan (1 °C $\Delta T_m R$ equal to 4 Myr) and chimpanzee, gorilla, and man (1 °C $\Delta T_m R$ equal to 5 Myr) (generation time of approximately 8–10 yr). The generation time is taken as the time needed to reach a fertile state; the present-day values are assumed to provide an estimate of the generation time of the ancestors of the species[40]. A more comprehensive discussion of the correction for differences in the generation times among present-day primates is in ref. 10.

Nucleic acid homologies among primate type C viral genes

All Old World monkeys and apes have previously been shown to contain endogenous primate type C virogenes as an integral component of their cellular DNA[1]. We therefore examined these primates for the extent of homology of their type C virogenes to the type C virus isolated from baboons. The baboon type C virus used in these studies was first isolated and subsequently propagated in non-primate cell lines (dog, bat, or mink)[18,19] to eliminate the possibility that the radioactively-labelled DNA probes prepared from the baboon viral RNA might contain other primate cellular sequences.

Figure 2 shows that there is a decrease in the final extent of hybridisation and in the thermal stability of hybrids formed between the baboon viral DNA probe and primate cellular DNA that is a function of phylogenetic distance from the baboon. The hybrid with the highest thermal stability is obtained with the cellular DNA of *P. cynocephalus*, the species from which the baboon type C virus was isolated. The DNA from three other species of baboons form hybrids with the baboon type C DNA probe that are slightly less stable (ΔT_m values range from 0.3 to 2.2 °C lower). The cellular DNAs from other species of Old World monkeys form hybrids that contain even more extensive base-pair mismatching. The reduced thermal stabilities obtained with the Old World monkey DNAs also indicate that the partial homologies detected between the baboon type C viral probe and the DNAs from these primates are a result of alteration by base-pair substitution or by rearrangements, of much, and perhaps all, of the viral genome, and not to the strict preservation of a large segment of the viral genome.

Table 2 Thermal stability of hybrids formed between ape non-repetitive cellular DNAs

Species	Cellular DNAs $\Delta T_m R$ (°C)			
	Chimpanzee	Gorilla	Man	Gibbon
Chimpanzee	—	2.4	2.3	6.3
Gorilla	2.6	—	2.4	6.5
Man	2.4	2.6	—	6.9
Orang-utan	NT	4.5	NT	NT
Gibbon	6.5	6.5	6.4	—
Siamang	6.3	NT	6.4	2.5
Baboon	9.3	8.6	9.0	9.1

Chimpanzee, gorilla, human and gibbon cell cultures were each labelled with ^{3}H-thymidine and the non-repetitive cellular DNA isolated and hybridised to the cellular DNA of the species listed as described in the legend to Table 1. The chimpanzee cell cultures (obtained from Dr C. J. Gibbs) were derived from brain cells. One line of chimpanzee liver cells obtained from a commercial source and used in our initial experiments characterising the baboon probe[20] has been identified as human in origin. The $\Delta T_m R$ values for the various DNA–DNA hybrids are listed. The ΔT_m values are approximately one-half the values shown; for example, the ΔT_m value for the human–chimpanzee hybrid was 1.4 °C. The temperature at which 50% of the hybrids are dissociated (T_m) ranged between 84 °C to 88 °C for the homologous DNA–DNA hybrids in various experiments. The T_m values were derived from six separate experiments in which hybrids were melted at 1 °C intervals over a range of ±7 °C from the T_m.

A striking finding, however, is that the decrease in nucleic acid homology and thermal stability for the type C virogene sequences does not always parallel the decrease in thermal stability of the non-repetitive cellular DNA. For example, even though the macaques and mangabeys are approximately equally distant phylogenetically from the baboon (2.6 °C $\Delta T_m R$; see Table 1 and Fig. 1), the virogene sequences of these animals are quite different, forming hybrids with baboon viral DNA that melt 8.2 °C and 5.0 °C lower, respectively. Even more striking are the data obtained with the Colobinae. Colobus and langur cellular DNA possess an equivalent

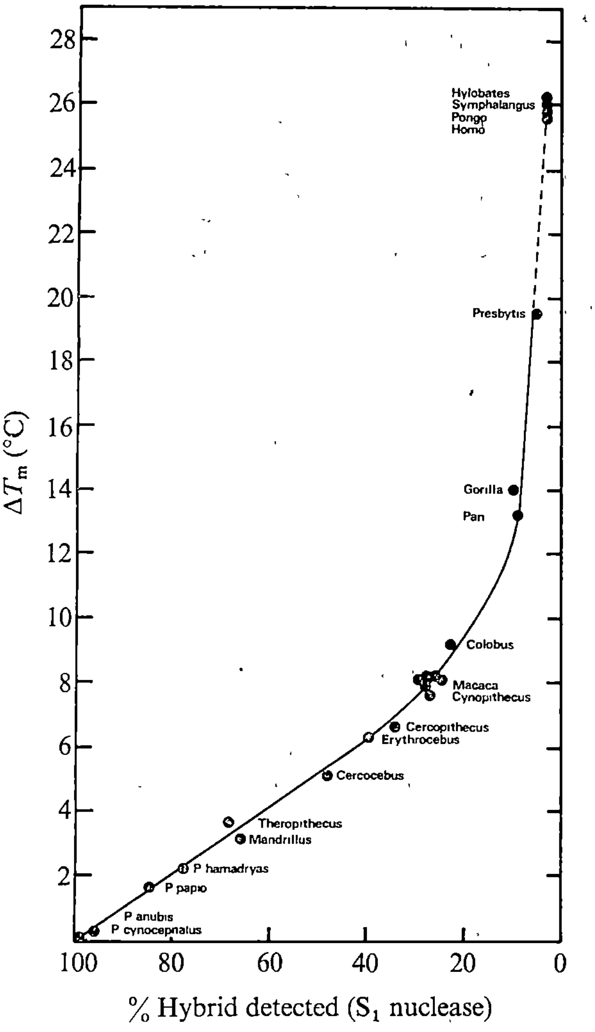

Fig. 2 Hybridisation of baboon type C viral DNA probe to primate cellular DNAs. ^{3}H-thymidine-labelled viral DNA probes were prepared as follows: the baboon viruses[18,19] were propagated in either a canine thymus (FCf2Th) or a bat lung (TblLu) cell line from which supernatant media was collected every 3 h for 1 d and stored at 2 °C. The supernatant was clarified of cellular debris and the virus banded on sucrose gradients, pelleted, and used immediately in an endogenous reverse transcriptase reaction. Reaction mixtures were incubated at 37 °C for 2 h and contained 0.04 M Tris, pH 7.8, 0.06 M KCl, 6×10^{-3} M magnesium acetate; 2×10^{-3} M dithiothreitol; 0.02% (v/v) Triton X-100; 30 μg ml^{-1} actinomycin D; 5×10^{-5} M ^{3}H-TTP (50 Ci mmol^{-1}), and 2×10^{-3} M each of dATP, dCTP, and dGTP. These conditions have been shown to result in the synthesis of long, representative DNA copies of the viral genome[41–43]. The ^{3}H-DNA baboon probe was deproteinised and purified as described previously[20]. The specific activity of the ^{3}H-DNA was 1.8×10^7 c.p.m. μg^{-1}. The ^{3}H-DNA probes contained 65–86% of their respective 70S viral RNA sequences at a ^{3}H-DNA: ^{32}P-viral RNA molar ratio of 1.0 (ref. 20), indicating that they contain most of the sequences present in viral RNA and that these sequences are in proportions similar to their content in 70S RNA. Several of these baboon probes were subsequently further purified by hybridising them to 70S or 35S viral RNA extracted from baboon virus grown in the cells of a non-primate species different from the one in which the virus had been grown. Probes prepared from the baboon virus grown in the bat lung cell line were cycled against RNA extracted from the virus grown in the canine thymus cell line. In some experiments the reciprocal cycling was performed: virus grown in the canine thymus cell line was cycled against RNA extracted from the virus grown in the bat cell line. The non-hybridised portion of the baboon ^{3}H-DNA probe was removed by digesting with S_1 nuclease. These probes were then treated with alkali to hydrolyse the RNA, and deproteinised, and purified as described[20]. Viral probes treated in this manner hybridised to 90–100% of baboon viral RNA. DNA–DNA hybridisations were incubated as described in the legend to Table 1, and the extent of hybridisation determined with the single-strand specific nuclease S_1. The normalised final percentage values obtained after hybridising the various primate cellular DNAs to the baboon viral probe are shown. The ΔT_m values obtained for the DNA–DNA hybrids relative to the homologous baboon viral ^{3}H-DNA–*Papio cynocephalus* cellular DNA hybrid are listed on the ordinate. The final percentage hybridisation values of the baboon viral probe to gibbon, siamang, orang-utan and human DNA are too low (3–4%) (see Table 3) for the ΔT_m to be determined experimentally; these values have been extrapolated from the curve as shown.

amount of nucleic acid sequence dissimilarity relative to baboon cellular DNA (6.4–6.5 °C ΔT_mR, Table 1), but the virogenes of these two species hybridise to 23% and 6% of the baboon viral probe, respectively (Fig. 1, Table 4). Finally, although the DNA of all six genera of apes are indistinguishable relative to baboon cellular DNA (8.9–9.5 °C ΔT_mR), two of the apes, chimpanzee and gorilla, contain virogene sequences that are much more closely related to baboon virogene DNA than are those of the other apes (gibbon, siamang, orang-utan) or man. In fact, chimpanzee and gorilla cellular DNA consistently hybridise more to the baboon virogene probe than does the DNA of the langur, an Old World monkey. The hybridisation values of gibbon, siamang, orang-utan and human DNA to baboon viral DNA as detected by S_1 nuclease are too low (3–5%) for the ΔT_m values to be determined experimentally; they are extrapolated from the curve as shown in Fig. 2.

Earlier studies on primate evolution using the baboon viral probe[1,20,21] focused on the observation that the baboon virus was, in fact, an endogenous primate virus and that related nucleic acid sequences could be detected in various other Old World monkey tissues. The final extents of hybridisation to ape DNAs were much lower than those obtained to Old World monkey DNAs but significantly higher than those obtained to New World monkey, prosimian, or other mammalian DNA. The differences in final extent between the various ape DNAs were difficult to determine based on only a few S_1 nuclease determinations[1]. In one previous study, the source of chimpanzee DNA was a tissue culture line (chimpanzee liver cells, obtained from Flow Laboratories, Rockville, Maryland) which provided an apparent discrepancy in the data[20]. Further analysis revealed the cell line DNA to be human, most probably HeLa, and not chimpanzee.

Since only a low degree of homology is obtained with the baboon viral probe to ape DNA using stringent hybridisation assay conditions (such as S_1 nuclease), a large number of experiments is needed to obtain statistically significant differences. The final extent of hybridisation (from several separate experiments) of the baboon viral probe to colobus and langur DNA and to chimpanzee, gorilla, gibbon, orang-utan and human DNA is shown in Table 3. Although the final hybridisation levels obtained with langur, gibbon, and human DNA are low, they are significant when compared with the hybridisation values obtained with four non-primate mammals (cow, hippopotamus, pig and rabbit) as well as with the non-mammalian salmon sperm DNA. The DNAs from a total of 36 human tissues have been separately examined. Most show a small increase in the final extent of hybridisation when compared with non-primate DNAs, some do not hybridise significantly above the levels found with the non-primate controls, while still others yield what seem to be unexpectedly high final hybridisation values to the baboon viral transcripts. The latter DNAs (3 of 36) have been obtained from tissues of individuals with tumours. The basis for the apparent occasional "higher reactors" among human DNA samples requires further study and will be the subject of a separate report. Nevertheless, the large differences in the final extent of hybridisation of colobus and langur DNA and of chimpanzee and human DNA to the baboon type C viral probe are clearly evident. With a DNA transcript prepared from an endogenous domestic cat virus (RD-114) that is partially related to the baboon virus, a higher final extent of homology has also been obtained to gorilla and chimpanzee DNA than to human or gibbon cellular DNA[22].

Hybrids with more extensive mismatching can be detected by lowering the stringency of the annealing conditions[23]; this permits the detection of partially homologous sequences in more distantly related species[4]. Table 3 shows data obtained with the baboon viral probe when the hybridisation conditions are modified by decreasing the temperature to 56 °C, the salt concentration to 0.50 M Na^+, and by using hydroxyapatite rather than S_1 nuclease, thus allowing partial hybrids to be detected as double-stranded molecules. Although the background values obtained with non-primate DNA increase, the higher final extent of hybridisation to chimpanzee and gorilla DNA compared with gibbon, orang-utan and human DNA are still evident.

A higher final extent of hybridisation to the various Old World monkey DNAs can also be obtained by changing the S_1 nuclease incubation conditions. For example, by decreasing the temperature of the S_1 nuclease incubation from 45 °C to 37 °C and by increasing the monovalent cation concentration from 0.15 M to 0.30 M, the final extent of hybridisation of the baboon viral probe to mangabey DNA increases from 50% to 85%, and the value to rhesus and other macaque DNAs increases from 25% to 60%. The relative relationships among the various primate virogene sequences remain the same.

Differences in African and Asian primate type C viral genes

The Old World monkeys and apes inhabit both Asia and Africa. All the genera of the Old World monkey subfamily Cercopithecinae inhabit Africa with the exception of various macaque species and the closely related celebes ape (*Cynopithecus*), which inhabit Asia. Table 4 lists representative species from the subfamily Cercopithecinae that have evolved in both areas and whose DNA has diverged to a comparable extent from baboon cellular DNA (as shown by their $\Delta T_m R$ values). The cellular DNA of those animals whose habitat is Africa hybridises to a much greater extent to the baboon viral DNA probe. The DNA extracted from two species of mangabeys, for example, hybridises 48% and 51% to the baboon type C viral DNA probe, whereas the DNA extracted from four different species of macaques hybridises only 25–28%. The use of hydroxyapatite to detect these hybrids raises the final extent of hybridisation to 65–70% for mangabey DNA and to 45–50% for rhesus DNA, but the clear differences between these primates remain. Two genera from the other Old World monkey subfamily, the Colobinae, were also examined. The cellular DNA from the African species, the colobus, hybridises to 23% of the baboon virogene probe, whereas the Asian langur cellular DNA hybridises to only 5% of the probe. Finally, among the apes, the cellular DNA of chimpanzee and gorilla (which inhabit Africa) hybridise 9% and 10%, respectively, to the baboon virogene probe. The gibbon, siamang and orang-utan, which inhabit Southeast Asia, hybridise to a much lower extent to the baboon viral probe, as does the human DNA.

Table 3 Detection of endogenous type C virogene sequences in various primate and human tissues

Species	No. of individuals tested	No. of tissues tested	No. of Expts	% Hybrid S_1 nuclease* Avg.†	s.d.	% Hybrid minus background‡
Colobus	2	3	18	27.8	±2.6	24.1
Langur	1	2	12	9.1	±1.5	5.4
Gorilla	2	5	15	14.0	±1.4	10.3
Chimpanzee	5	11	44	13.5	±3.1	9.8
Gibbon	8	14	28	6.8	±1.3	3.1
Man	36	36	68	7.0	±2.6	3.3

Rabbit	1	2	12	7.5	±2.0	0
Salmon	—	—	5	2.7	±0.7	0

*Cellular DNA was extracted from various tissues of the species listed[20]; salmon sperm DNA was obtained commercially. ^{3}H-DNA probes prepared from the baboon type C virus grown in a bat lung cell line (TblLu) or in a canine cell line (FCf2Th) were hybridised at 65 °C in 0.75 M NaCl to the various cellular DNAs as described in the legend to Table 1. The extent of hybridisation was determined by digestion of the hybrids with S_1 nuclease[36,37].

†The average hybridisation values from the number of determinations listed are normalised to the actual final extent of hybridisation obtained to baboon (*P. cynocephalus*) cellular DNA (86–100%). Cycled viral probes (see Fig. 2) and uncycled probes yielded comparable hybridisation values to the various species when normalised to the homologous system. Some baboon viral probes prepared using virus produced by human cells, however, gave artefactually high values with human cellular DNA. The standard deviation of all the data is shown in the next column.

‡The values obtained after hybridising the baboon viral probe to the primate cellular DNAs are shown; the average hybridisation value obtained with non-primate mammalian DNA has been subtracted. Non-mammalian DNA (salmon sperm) yields an even lower hybridisation value than that obtained for the non-primate mammals; this value has not been included in the average.

‖ The extent of hybridisation between the ^{3}H-DNA probe prepared from the baboon type C virus and the cellular DNAs was detected on hydroxyapatite[1]. The percentage hybridisation values shown are normalised values from four to seven experiments; the final extent of hybridisation to baboon cellular DNA varied between 74–88%. DNA–DNA hybridisations were performed at 56 °C in 0.025 ml reaction mixtures containing 0.01 M Tris, pH 7.4, 0.50 M NaCl, 2×10^{-3} M EDTA, 0.05% SDS, 2,000 c.p.m. of ^{3}H-baboon type C DNA probe, and 0.1 mg of cellular DNA.

Table 4 Differences in extent of genomic alteration between African and Asian Old World monkey and ape virogenes

	African origin				Asian origin		
Primate	$\Delta T_{\rm m}R$ (°C)* cellular DNA	No. of species	% Hybrid† virogene DNA	Primate	$\Delta T_{\rm m}R$ (°C)* cellular DNA	No. of species	% Hybrid† virogene DNA
				Old World monkeys			
				Cercopithecinae			
Mandrill	2.1	1	66	Celebes Ape	2.3	1	27
Mangabey	2.6	2	48, 51	Macaques	2.5–2.9	4	25–28
				Colobinae			
Colobus	6.5	1	24	Langur	6.4	1	5
				Apes			
				Gibbon	9.0	1	3

Chimpanzee	9.3	1	9	Orang-utan	8.9	1	3
Man	9.2	1	3	Man	9.2	1	3

*The $\Delta T_{\rm m}R$ (°C) of hybrids formed between the cellular DNA of the primate species and ^{3}H-non-repetitive baboon cellular DNA is shown. These values are from the data listed in Table 1.

†The normalised final percentage of hybridisation of primate cellular DNA to the baboon viral DNA probe is listed These values are from the data shown in Fig. 2 and Table 3. By varying the S_1 nuclease incubation conditions a higher final extent of hybridisation to the various primate DNAs can be obtained. For example, by increasing the monovalent cation concentration from 0.15 M to 0.30 M and by decreasing the temperature of the S_1 nuclease incubation from 45 °C to 37 °C, the final extent of hybridisation of the baboon viral probe to mangabey DNA increases from 50% to 85%, and the value to rhesus and other macaque cellular DNAs increases from 25% to approximately 60%. The substantial difference between the various African and Asian primate DNAs remains, however.

The hybridisation data obtained with non-repetitive cellular DNA group the primates in terms of their phylogenetic proximity to the baboon (Fig. 3). The data obtained with the endogenous type C virogene sequences show that the type C virogenes of the Asian primates hybridise less to the baboon probe than do the virogenes of their African counterparts. Thus, with the endogenous primate type C viral gene sequences (although not with the overall cellular DNA), we are able to discriminate quite clearly between Asian and African primates. Among the apes, the gibbon and orang-utan clearly stand out as Asian. Within the ape subfamily Homininae (man, chimpanzee and gorilla[17]), *Homo sapiens* stands out as the only non-African representative. We therefore propose an Asian origin for man, with a long history in that region before our species migrated all over the world.

An alternative interpretation of the data would be that man is unusual among primates in having a deletion (or series of deletions) in his virogene sequences that makes its properties coincide with those of the orang-utan, gibbon and siamang. A partial deletion hypothesis in man, however, does not account for the marked differences in the extent of genomic alteration between the Asian and the African Cercopithecinae or Colobinae virogenes when tested with baboon viral DNA transcripts.

The results presented here show that the extent of nucleic acid dissimilarity between the primate virogenes depends on two factors: (1) the taxonomic distance of the species from *Papio*, and (2) the geographical habitat of the species. A comparison of baboon and mangabey type C virogenes, which have evolved together in Africa, and of baboon and macaque virogenes, where the species have been physically separated from each other for several million years, reveals that the differences in their virogene sequences result from the effect of one environment as opposed to another. Thus the differences in thermal stability and final extent of hybridisation in this particular set of mammalian genes is influenced by environmental factors. The ubiquitous presence of endogenous type C virogenes among anthropoid primates and their evolutionary persistence for at least 30–40 Myr suggest that such genes provide functions with a selective advantage to the species possessing them. Thus, some functions of the type C virogenes are acted on by the environment in such a way as to select for certain genetic sequences and against others.

Type C viruses can be isolated readily from four different species of baboons (*P. cynocephalus*, *P. anubis*, *P. papio*, and *P. hamadryas*) and from the closely related genus, *Theropithecus*[18,19,24,25], all of which inhabit Africa. Extensive attempts to isolate infectious type C viruses from other anthropoid primates using the same techniques that have led to the isolation of the baboon and gelada viruses, have so far been unsuccessful[25]. The action of selective environmental pressure presupposes that the virogenes are expressed during the lifetime of the animal and, further, that they affect the survival or the reproductive capacity of individuals of the species. The primate species from which infectious viruses have not yet been isolated must therefore express at least some virogene products on which the environment may act. Resistance to infection by exogenous type C viruses might be a critical selective factor; baboons range throughout Africa and release a virus that might be potentially damaging to recipient species. The endogenous domestic cat virus RD-114 has been postulated to have originated from an endogenous Old World monkey type C virus horizontally transmitted to an ancestor of the domestic cat[22]. This suggests the possibility that ancestors of the baboon may have been releasing infectious virus particles for several million years. The selective pressure on the other primates to maintain their related virogenes and so protect themselves against viral infection would be continuous and strong. Endogenous type C virogenes have previously been shown to restrict the replication of highly related viruses in the same cells[26]. The African primates may well have had to conserve a greater degree of nucleic acid sequence homology relative to the baboon type C virus in order to restrict the replication of this virus in their cells. Those portions of the virogene most directly involved in controlling virus spread from animal to animal would be expected to show the most extreme environmental effect.

Asian primates, which would not be exposed to the baboon endogenous virus, would be under less selective pressure to maintain cellular nucleic acid sequences similar to those present in the baboon type C viruses; their virogenes, then, would be free to accumulate genomic alterations at an apparently faster rate relative to baboon virogene sequences. Rhesus monkey cells, for example, are extremely permissive for the replication of baboon type C viruses, whereas baboon, gelada and mangabey cells restrict baboon virus replication. Man, postulated here to be an Asian primate that has only recently migrated into Africa, would, therefore, be expected to be susceptible to infection by baboon type C virus. Human cell

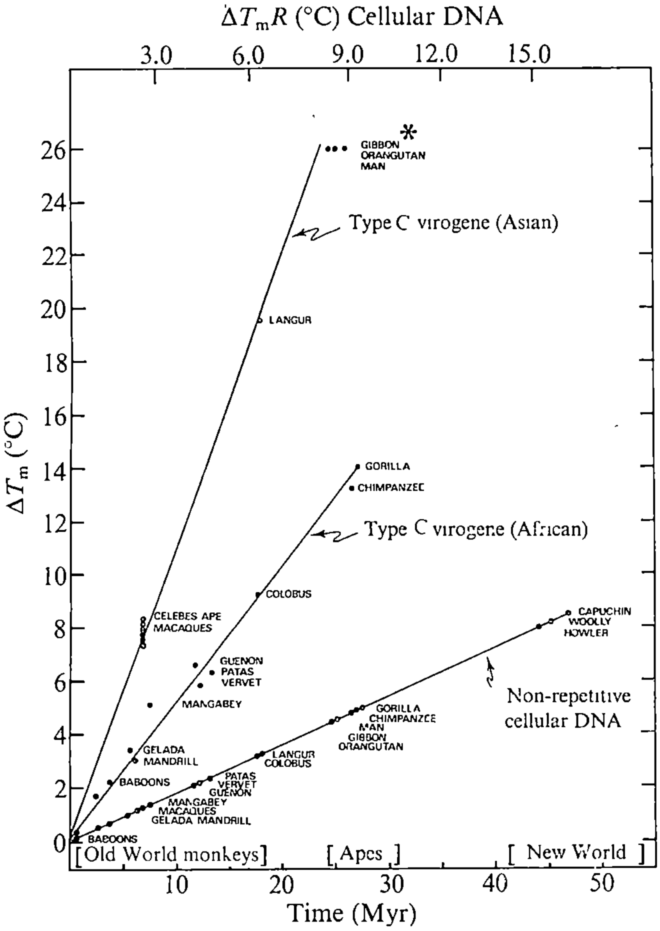

Fig. 3 Relationship among primate cellular DNAs as determined by the extent of their homology to baboon non-repetitive cellular DNA and to the baboon type C viral DNA probe. The genetic distance from the baboon (*P. cynocephalus*) of various primate species as determined by the thermal stability (ΔT_mR) of hybrids formed between their cellular DNA and non-repetitive baboon DNA is shown in the lower curve. The thermal stabilities of the virogene sequences of all the African primates tested fall on the middle curve and those of all the Asian primates and also of man fall on the upper curve. No direct comparison can be made between the rate of base-pair changes in the cellular and viral nucleic acid sequences since the latter are present in 10–20 copies per haploid genome[44] whereas the cellular gene sequences are predominantly present in only one copy[7].

*Accurate T_m values for the hybridisation of gibbon, orangutan and human cellular DNA to the baboon viral probe have not been determined experimentally; they are extrapolated from the data shown in Fig. 2. Nevertheless, these T_m values are lower than those obtained to gorilla and chimpanzee DNA.

cultures, in fact, have been shown to be highly susceptible to infection by various isolates of the baboon type C virus[18,19,25].

The rhesus monkey produces endogenous type C viruses that can be seen by electron microscopy[27], and expresses type C viral p30 antigen and reverse transcriptase[28,29], but so far, no infectious virus has been isolated. Such a virus would allow us to study Asian primate virogenes and perhaps determine whether they too are more closely related to one another than they are to the virogenes of African primates.

Possible implications for the origin of man

Because of man's close morphological and anatomical resemblance to the African apes, and because most of the recent palaeontological discoveries have been made in Africa, many investigators have proposed an African origin for our species. The results presented here lead to a conclusion that is not consistent with the palaeontological studies which place the major developmental changes that have led to modern man as occurring in Africa; rather, they suggest to us that man has originated outside Africa.

The time of divergence of the hominid stock from the apes has variously been estimated at between 4 and 20 Myr; our data indicate a divergence time of approximately 12 Myr. *Ramapithecus* and *Kenyapithecus*, which have been dated by potassium–argon at 12–14 Myr were found in India and in East Africa[30–32]. They seem, according to our data, to precede or perhaps to be contemporary with the man–chimpanzee–gorilla ancestor. There then follows a period of about 10 Myr, virtually all of the Pliocene, where fossil finds have been few and have not been extensively characterised. Between 1 and 3 Myr, fossils that appear to be hominids have again been found both in Africa and Asia. Our data suggest that man's direct ancestors probably spent most if not all of the Pliocene in Asia. The older Australopithecines found in Africa, though clearly hominids, were probably, therefore, not in the main lineage to man, but rather, unsuccessful offshoots whose progeny have not endured to the present[33]. The data do not preclude a more recent migration, perhaps in the last 2–3 Myr, of hominids into Africa. The nucleic acid sequence changes we are measuring are the result of millions of years of evolution. The relatively recent migration, or return, of man's ancestors to Africa does not seem to have reversed the long evolutionary history of man's type C virogenes while in Asia. The much more recent migrations by modern man all over the world and his divergence in the last hundred thousand years into the various races are also events which are too recent to be detected with these techniques[34,35].

Of all the primates, the hominids have been the most successful at adapting to a terrestrial life and have migrated all over the world; their geographical origin, therefore, is more obscure than that of the other primates. The major selective pressures that influence the evolutionary history of a species are recorded and retained in its genetic material. The baboon viral gene sequences have allowed us to distinguish clearly between Asian and African primates and to study the imprint of this environmental selective pressure on primate cellular DNA. The data obtained with the primate virogenes suggest that, during the Pliocene, man's ancestors were developing in Asia.

We thank Drs Leonard Radinsky and Richard Thorington, Jr for their helpful discussions, and R. Heinemann, J. Koci, and G. L. Wilson for assistance with these experiments. This research was supported in part by the Virus Cancer Programme of the National Cancer Institute.

Rare earths, Fe and Ti concentrations in basalts dredged along the Galapagos spreading centre reveal that a juvenile mantle plume is welling up beneath the Galapagos Islands and mixing with the depleted asthenosphere to the north-east and north-west beneath the ridge. Unusually extensive shallow-depth, crystal fractionation is also apparent on the ridge between 85 and 87° W. The 'magnetic telechemistry' hypothesis is further clarified.

THE plate tectonic theory provides a simple and unified explanation for surface geological features such as mountain ranges, trenches, island arcs and mid-ocean ridges, and describes their kinematic relationships. The theory does not, however, adequately explain shallow oceanic platforms such as those found around the Azores, Hawaii, Iceland, and the Galapagos Islands.

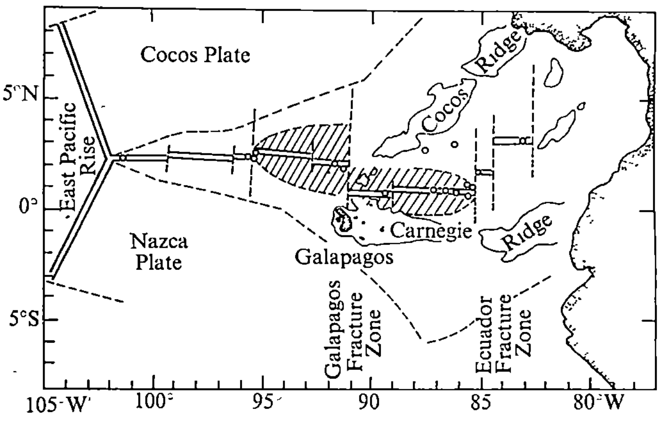
These unusually extensive outpourings of lava have been attributed to fixed hot spots[1] and mantle plumes[2]. Vogt has suggested[3] that flows of asthenospheric partial melts associated with mantle plumes could be monitored for hot spots located near the mid-ocean ridge, and that the flow is probably concentrated in a pipe-like region below the spreading axis; transform faults would tend to dam such sub-axial flow[4,5].

Schilling[4,6] has mapped large-scale chemical gradients from basalts dredged from the axis of the Mid-Atlantic Ridge away from Iceland or the Azores, and attributed the gradients to binary mixing, at shallow depth beneath the ridge, of two geochemically distinct mantle slush components: namely a mantle plume enriched in light rare earths (RE) and radiogenic Sr and Pb isotopes, and a widespread asthenosphere depleted in light RE and low Sr and Pb isotopic ratios[4,6–10] (subsequently referred to as depleted low velocity layer—DLVL).

We report here new geochemical data for the Galapagos spreading centre and its associated platform (Fig. 1). The area contains most of the typical elements of the Iceland type of 'hot spot'[11]. The Galapagos Archipelago is mainly built of tholeiitic lava of 'plume'-derived or 'blob'-derived composition, judging from their RE patterns[12–14]. The Cocos and Carnegie aseismic ridges branch from the platform, and the Galapagos spreading centre shoals where it passes north of the platform (Figs 1 and 2). No regional free-air gravity high, relative to the figure of hydrostatic equilibrium, has been observed over the region, however. Unusually high magnetic anomaly amplitudes have also been noted over the crest of the Galapagos spreading centre within 5° of the platform (Fig. 1).

Vogt and Johnson[16] have attributed the large magnetic anomaly to an oceanic crust rich in Fe and Ti derived from a mantle plume welling up beneath the Galapagos Islands and flowing outwards at shallow depth; Anderson, *et al.*[17] also suggested Fe and Ti enrichment, but suggested

Fig. 1 Location of the dredge hauls studied (circles) along the Galapagos spreading centre (double lines), and their relationships to the high magnetic amplitude region (hatched area) and major tectonic elements, namely: the Cocos and Carnegie aseismic ridges; the Galapagos Islands (blackened); fracture zones (heavier vertical dashed lines); the Galapagos Gore (light dashed line)[11,32].



that it is caused by a large 'melting anomaly' centred about the Galapagos Archipelago, with exceptionally intense, shallow-depth, fractional crystallisation of plagioclase feldspar and olivine from a normal, light RE-depleted mid-ocean ridge basaltic melt. Relative RE patterns of the Fe-rich residual liquids produced by the latter mechanism, although enriched as a whole, would remain depleted in light RE elements, and should develop an anomalous Eu depletion (proportional to the extent of plagioclase removal and anorthite content)[13,18], whereas mantle plume basalts are commonly enriched in light RE elements, and generally show no Eu anomaly. The RE distinction can thus serve as a simple test of the two mechanisms and origins proposed for the region of high magnetic amplitude over the Galapagos spreading centre.

Results from this pilot study show the effect of local Fe enrichment caused by the shallow plagioclase–clinopyroxene and olivine crystal fractionation of DLVL-derived basalts. They also indicate mantle-plume mixing along the ridge segment nearest to the Galapagos Archipelago. Extensive shallow crystal fractionation seems to be limited to 85–87°W along a segment of the ridge apparently not affected by the Galapagos mantle plume.

Results

Locations of the dredged rocks are shown in Fig. 1. The RE, FeO* and TiO_2 concentrations, and FeO*/FeO*+MgO ratios of these rocks are given in Table 1. Major element analyses and magnetic properties of rocks from stations T6, HFD-1, D-7 and D-17 have already been reported by Anderson, *et al.*[17]. The complete major element analyses of rocks from USNS De Steiguer dredge hauls are presented in Table 2. These samples were obtained on either side of the boundary delineating the high magnetic anomaly province, to define the sharpness of the transition. Cocotow dredged rocks were obtained with R. V. Melville, and their major element chemistry will be reported elsewhere (J. W. Hawkins, unpublished). The chemistry of basalt RC-10-56 has already been reported[19]. Highly differentiated and atypical oceanic volcanic rocks were also dredged north of

Fig. 2 *a*, La/Sm concentration ratio (normalised to chondrites); *b*, TiO_2 weight percentages; *c*, FeO*; in basalt erupted along the Galapagos spreading centre (data from Table 1); *d*, variations along the ridge axis of the central magnetic anomaly; *e*, water depth. Later data from Anderson, *et al.*[17]. For comparison, dotted-dashed lines are averages of 13 dredged basalts from the East Pacific Rise between 0 and 19°S (ref. 22), (FeO* = 9.2±0.5 weight %; TiO_2 = 1.41±0.22 weight %; and [La/Sm] = 0.60±0.12). The averages exclude the three ferrobasalts also reported for this normal EPR segment. The error bars attached to the averages are for 1 s d. Open symbols, dredge stations off the ridge axis; solid symbols, stations on the axis.

the axis near 95°W and on the 85°W fracture zone, but are not considered here.

Petrographically, the basalts studied for RE show quenched textures typical of pillow basalts, and range from aphyric to plagioclase or, more rarely, olivine, porphyritic basalts. The new De Steiguer samples are classified as tholeiitic basalts according to Yoder and Tilley's[20] normative scheme (Fig. 3). They range from olivine normative to mildly quartz normative; and follow a Skaergaard trend on the AFM diagram (Fig. 3), with extreme iron enrichment reaching 18% FeO* for station D1, near 85°30′W. Cocotow rocks (J. W. Hawkins, unpublished), Southtow basalts[17] and RC10-56[19] fall on the same iron fractionation trend.

Basalts from stations Southtow D-17 and Batlett T6 tend to be alkali rich relative to common mid-ocean ridge basalts[21]. Since Fe_2O_3/FeO proportions were not determined by Anderson, *et al.*[17], Southtow D-7 and HFD-1 are not directly comparable with the De Steiguer samples. Anderson, *et al.*'s basalts[17] are, however, close to the Di normative join if Fe_2O_3 is assumed to be 1.5% (ref. 18). It is possible that the high alkali content of station T6 is attributable to alteration by sea water, and is not an intrinsic characteristic of melts erupted near the Hess Depression. On the other hand, the rare earth patterns of station T6 samples are depleted in light RE, and are typical of other tholeiitic basalts erupted along normal ridge segments (Fig. 4).

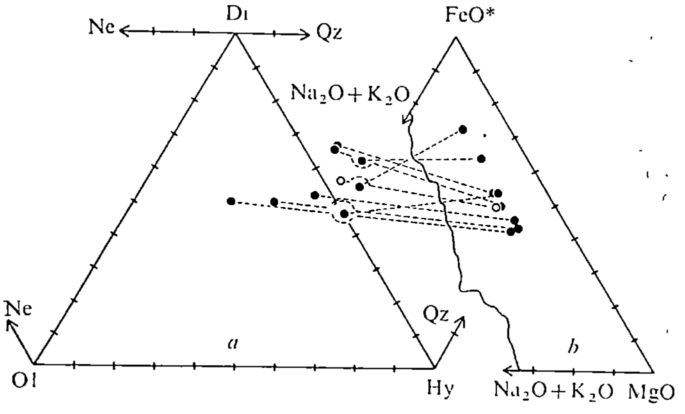

Fig. 3 *a*, Quartz – diopside – hypersthene – olivine – nepheline normative diagram of De Steiguer-dredged basalts: solid circles, light RE-depleted; open circles, RC-10-56 light RE-enriched basalt. No relationship is apparent between RE patterns and normative mineralogy. *b*, FeO* (total iron as FeO), Na_2O+K_2O, MgO diagram for the same samples Bulk chemistry data for De Steiguer samples are given in Table 2, and for RC-10-56 in ref. 19. Relationship between Fe/Mg variation and normative mineralogy is indicated by tie lines between the two diagrams.

RE variations along the ridge

Figures 2 and 4 show that all basalts located beyond 450 km west of east of the Galapagos Fracture Zone are depleted in light RE elements, including those from station T6 near the triple junction. Judging from such evidence[10], these basalts seem to have been derived from the light RE-depleted asthenosphere source, whether they were erupted within or outside the high magnetic amplitude region.

In contrast, ridge basalts enriched in light RE elements are found only near and just north of the Galapagos Archipelago (Figs 1 and 4). Some 190 km east of 91°W, an intermediate flat RE pattern is found. Yet, normatively, basalts from these later three stations are indistinguishable from the light RE-depleted basalts found further out from the Galapagos Islands (Fig. 3). Tholeiitic basalts with such light RE enrichment suggest mantle plume derivation[4,6]. The degree of light RE enrichment in these three stations is, however, too low relative to tholeiitic basalts from the Galapagos Archipelago to be 100% derived from the mantle plume[12,13].

It seems that the distribution of RE patterns along the ridge show no simple relationship with magnetic anomaly amplitudes. Basalts with both light RE-enriched and light RE-depleted patterns occur within the high magnetic amplitude region; and light RE-depleted patterns occur both within and outside the high magnetic zone as well. Judging from the RE patterns so far available, mantle plume mixing with DLVL material seems to be limited to a radius of approximately 450 km from the centre of the Galapagos Archipelago, and not to the entire length of the high magnetic amplitude zone.

Chemical correlations along the ridge axis

The variations of iron, titanium and light RE fractionation in basalts erupted along the Galapagos spreading centre are shown in Fig. 2 in relation to variations of the magnetic anomaly intensity, and ridge elevation. The chemical variations are compared with averages obtained along the East Pacific Rise (EPR) between 0 and 20°S. This part of the EPR seems geochemically typical of normal mid-ocean ridge segments[10,22], and it is regionally close to the Galapagos region. Figure 2 shows that outside the high magnetic anomaly region of the Galapagos spreading centre, the Fe content of the basalts closely straddles the average value found for the EPR; with the exception of somewhat lower values near 83°W. On the other hand, within the magnetic anomaly zone, there is a tendency for the Fe content to be somewhat higher than the EPR average; whereas the TiO_2 content is not greatly different from that in samples from outside the zone, and is generally close to that of the EPR. Finally, between 85 and 87°W unusually large FeO* and TiO_2 enrichments occur corresponding to the area of highest magnetic anomaly intensities. A relationship between magnetic intensity and Fe enrichment thus seems valid; but so far no obvious relationship is apparent with Ti outside the 85–87°W region. Further, it needs to be noted that low FeO* and TiO_2 values occur together with the high values in the area between 85 and 87°W. There also seems to be no systematic variation in Fe and Ti enrichment with distance or age across the ridge in the 85–87°W area.

Basalts from De Steiguer station D1 located on the ridge axis (~0 Myr), are the most Fe enriched (18% FeO*). Basalts from station 3D, dredged between magnetic anomalies 1 and 2 (~ 1.3 Myr), are close to the EPR average (9.2% ± 0.5 FeO*), and are thus normal. Basalts from station 4D, the northernmost station (~1.7 Myr), have intermediate FeO* contents (~15% FeO*). Both stations 4D and 3D were near the edge of the high amplitude zone. These observations suggest that the correlation between magnetic intensity and Fe–Ti content is not simple, as pointed out by Watkins (and Vogt and Johnson)[23]. Among other things, one would also have to know the relative volumes of iron-rich to normal lavas, to establish further a telechemical relationship between Fe (and perhaps Ti) enrichments and magnetic anomaly intensity.

The variation of the La/Sm ratio along the ridge shows a progressive decrease with distance (or depth) from the Galapagos platform; however, the ratio does not correlate directly with FeO* or TiO_2 content (Fig. 2). Thus, Vogt and Johnson's[16] idea of correlating Fe and Ti enrichments with $[La/Sm]_{EF}$ for the Galapagos spreading centre (and the Iceland–Reykjanes Ridge as well; J.-G. S., unpublished), seems to be invalid. The reason is that FeO*, TiO_2 and large ionic lithophile (LIL) element concentrations and their ratios in basalts, are not only functions of the type of mineral fractionation involved during partial melting in the mantle, fractional crystallisation during magma ascent, or stagnation in magma chambers, but also of the content of the mantle source(s) from which basalts are derived. No simple relationship can theoretically be predicted which would be of general application and independent of the geological processes and mantle sources involved. That should not, however, detract from the fact that the La/Sm ratio remains a reliable source indicator when dealing with tholeiitic basalts. Schilling[10] has shown that the La/Sm ratio of a tholeiitic basalt produced by some 20% or greater degree of partial melting, is practically identical to that of its mantle source, to within 20% or less. The ratio varies by more than a factor of two along the Galapagos spreading centre, and is independent of the Fe or Ti contents. The apparent decrease in the La/Sm ratio outwards from the Galapagos, suggests mantle plume mixing with DLVL material within a radius of approximately 450 km from the centre of the Archipelago. Even extensive shallow-depth fractional crystallisation of the olivine-gabbro type[24] cannot produce the light RE enrichment found in tholeiites occurring near the Galapagos Islands.

Fe enrichments of DLVL-derived basalts between 85 and 87°W

Figure 4 shows that the extent of RE enrichment and Eu depletion in basalts erupted between 85 and 87°W correlate closely with the Fe content of Galapagos lavas, although the degree of light RE fractionation (that is, the La/Sm ratio) remains rather insensitive to the Fe enrichment mechanism. We have modelled quantitatively such Fe and RE enrichments by fractional crystallisation. First, we have tried to satisfy the major element chemistry of the basalts using Wright and Doherty's[25] linear programming technique which allows determination of the type and extent of mineral extract. We then tested such mineral extracts against RE patterns of these rocks using the Doerner–Hoskin's logarithmic law for describing the change of the RE concentrations during fractional crystallisation[26]. In this process we found, as did Kay, *et al.*[18], that the Fe enrichment trend is accompanied by a decrease in the MgO, CaO and Al_2O_3 contents, and an increase in the TiO_2, P_2O_5 and, to a lesser extent, Na_2O contents; whereas the SiO_2 content stays practically constant, or decreases slightly. Contrary to the findings of Kay, *et al.*, however, we were not able to minimise SiO_2 residuals by extracting only olivine and plagioclase, but had also to extract a significant amount of clinopyroxene. Table 3 illustrates our point for an extreme case. This model shows that the most differentiated Fe-rich basalt, De Steiguer-D1, can be derived from a melt of the composition averaging Southtow D-7 by 75% fractional

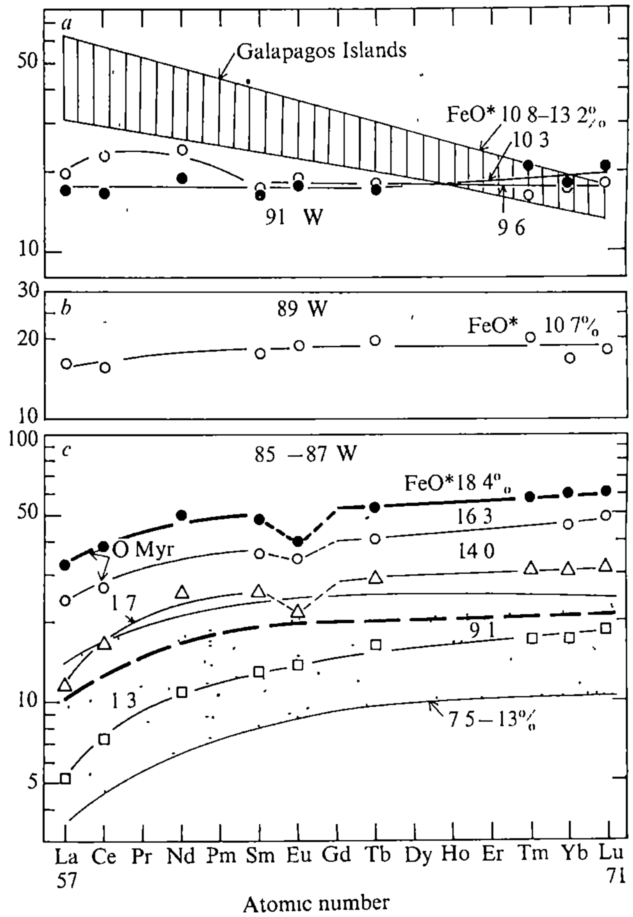

Fig. 4 Chondrite normalised rare earth patterns of dredged basalts from the Galapagos spreading centre. *a* and *b*, Basalts located within a radius of 450 km from the archipelego Hatched area, the field occupied by four Galapagos Island tholeiites studies petrochemically by McBirney and Williams[12]. Isabela (E-132), Baltra (E-28), Marchena (E-15) and the north-westernmost island of the archipelago, Darwin Island (E-35); $[La/Sm]_{EF}$ ratios are 1.67, 1.45, 1.15 and 1.49; and FeO*, 12.7, 13.2, 11.4 and 10.8 w%, respectively). Rare earth data from this laboratory (unpublished). *c*, Shaded area shows range obtained for basalts located outside a 450-km radius, east of 87°30'W and west of 95°W; all light RE depleted (see data in Table 1). De Steiguer stations located near the eastern end of the high magnetic amplitude region shown separately in relation to their FeO* content and their estimated magnetic age: D-1A (solid circle); D-1B (open circle); D-4 (triangle); average of D-3A and B (square). Note good correlation between total RE content and FeO*. Heavy dashed line is calculated model RE pattern of original melt discussed in text. RE and FeO* data taken from Table 1.

crystallisation of a mixture composed of plagioclase (An 62), clinopyroxene (En 48.5, Fs 10, Wo 41.5) and olivine (Fo 55), in proportions 0.54, 0.37 and 0.09, respectively. The proportions are reasonably close to the ternary eutectic (0.435 An, 0.49 Di and 0.075 Fo) experimentally determined for the simplified basalt system diopside–forsterite–anorthite[27]; thus adding some credibility to the model.

By inverting the problem, the RE pattern of the 'original melt' was calculated from the DS-D-1 residual melt RE pattern, using the crystallisation model, and the average crystal-melt RE partition coefficients listed in Table 3. The calculated RE pattern of the 'original melt' is shown in Fig. 4. It is light RE depleted and no longer shows any Eu anomaly, as expected The level of overall RE pattern enrichment satisfactorily falls within the range occupied by other 'normal ridge basalts' so far studied along the Galapagos spreading centre.

*Minimum residuals were obtained by arbitrarily disregarding Fe_2O_3 contents and recalculating the analyses to 100% on a water free basis
†K is defined as trace element concentration in crystal relative to the melt.

We conclude that the shallow-depth fractional crystallisation model satisfactorily explains the Fe-rich basalts and associated RE patterns occurring near 86°W. The shallow-depth crystallisation process seems to be dominated by extractions of plagioclase, and to a lesser extent of pyroxene and olivine, from melts originally derived from the DLVL source. The model is thus consistent with Anderson, *et al.*'s[17] suggestion, but seems to be limited to the 85–87°W area.

Finally, we emphasise that even in the extreme case of some 18% FeO* enrichment apparently requiring some 70–80% extent of crystallisation, the RE patterns of such residual liquids have retained the light RE-depleted patterns of the original melt, characteristic of normal ridge segments, although they develop a noticeable Eu depletion relative to RE neighbours, and a higher overall level of enrichment. In contrast to the 85–87°W area, ferrobasalts[12] from James Island (FeO* = 12 4%) and Jervis Island (FeO* = 13.4%) are light RE enriched (La/Sm_{EF} = 1 53 and 2.03, respectively) and are comparable with other subaerial tholeiites from the archipelago (Fig. 4). Those considerations suggest that the light RE-enriched patterns found in the two basalts erupted along the Galapagos spreading centre just north of the archipelago, can hardly be the product of shallow-depth fractional crystallisation. The two basalts show no Eu depletion or overall enrichment of the relative RE patterns, nor do they show any FeO* enrichments. More likely, these later basalts were derived from a mantle source significantly enriched in light RE elements relative to the DLVL-source feeding normal segments of the Galapagos spreading centre.

Conclusions

Several points need to be emphasised on the basis of this pilot study.

- Both light RE-enriched and depleted types of RE patterns occur within the region of high magnetic anomaly amplitudes. Light RE-depleted patterns also occur both within and outside the zone of high magnetic anomaly amplitudes. Thus, no simple relationship is readily apparent between types of RE pattern and the intensity of magnetic anomaly amplitudes.
- The highest Fe and Ti enrichments occur where the magnetic anomaly amplitudes are also largest (between 85 and 87°W) The RE and major elements in these basalts suggest unusually extensive, shallow-depth fractional crystallisation of the olivine gabbro type occasionally found along normal ridge segments[10,18,22]. The crystallisation model based on the new De Steiguer samples is thus consistent with Anderson, *et al* 's[17] explanation for the high magnetic anomaly amplitude near 86°W.
- On the other hand, our preliminary data suggest that a shallow-depth olivine gabbro crystallisation mechanism, such as that found between 85 and 87°W, is apparently not the mechanism responsible for the high magnetic anomaly across the whole region, contrary to the suggestion of Anderson, *et al.*[17] (see Fig. 2). That is evident from the fact that no overall RE enrichments and relative Eu depletions are found within this zone, nor is the Fe content of the basalts markedly and systematically higher, except between 85 and 87°W. Additional sampling is required to resolve the question of the high magnetic amplitude region. Mild Fe enrichments in the area cannot be ruled out as an explanation.
- The telechemical idea[16] of correlating magnetic anomaly amplitudes directly to Fe and Ti content of basalts, remains a complex and open question. Similarly, the idea[16] of using the intensity of magnetic amplitudes to infer Fe and Ti contents, and in turn an array of LIL elements (and by inference their ratios as well) and Pb and Sr radiogenic isotopes, has no general validity, since Fe and Ti enrichment may have several causes. For example, Fe and Ti enrich-

ments can be obtained from either a mantle depleted in light RE along normal ridge segments (for example, as at the Galapagos spreading centre near 86°W), or from a mantle with light RE-enriched patterns and relatively richer in Sr and Pb radiogenic isotopes (for example, in the mantle beneath Iceland and the northern part of the Reykjanes Ridge[4,7,9], and the Galapagos Islands[12]). Thus, the idea[16] of using magnetic amplitudes to infer Fe and Ti contents to identify plume-derived oceanic crust, is ambiguous on this basis alone, and could be misleading.

- Basalts with light RE-depleted RE patterns, characterising 'normal ridge segments' are confined to east of 87°W, and west of 95°W. On this basis, the two segments of the Galapagos spreading centre situated between 95°W and 101°W (including the triple junction with the East Pacific Rise) and 87° to at least 83°W, are considered 'normal ridge segments'. Basalts erupted along these two segments seem to have been derived from the DLVL mantle source.
- So far, ridge basalts with RE patterns similar to those of light RE-enriched mantle plumes are confined to a radius 450 km from the centre of the Galapagos Archipelago. Maximum $[\text{La/Sm}]_{\text{EF}}$ values (1.1) are found just north of the main islands, but these values seem to be diminished already by mixing with DLVL material, relative to tholeiitic basalts from the Galapagos Islands[12,13]. The data are consistent with the presence of a mantle plume rising beneath the Galapagos platform. The sampling along the Galapagos spreading centre, however, is so far insufficient to decide whether the mantle plume flow in the asthenosphere occurs radially about the Galapagos platform; or preferentially along certain directions, such as generally northward towards the Galapagos spreading centre, or perhaps channelled along the major Galapagos Fracture Zone. Our data are also insufficient to infer whether the Galapagos mantle plume is, or is not, richer in Fe and Ti contents relative to the surrounding DLVL mantle source.
- Finally, the cause of unusually extensive shallow-depth fractional crystallisation of DLVL-derived basalts near 86°W, remains puzzling. Unusually extensive hydrothermal activity has been reported in the area[29,30] compared with elsewhere on the Galapagos spreading centre[31]. It is conceivable that unusually intense hydrothermal circulation might have been removing heat more efficiently from a magma chamber generated by spreading, thus enhancing locally fractional crystallisation before lava eruption on the sea floor. The model remains to be quantified in terms of the various rates involved.

We thank R. Kingsley and P. Aldrich for help and F. DiMeglio and his staff for neutron irradiations and facilities at the Rhode Island Nuclear Science Center R Hekinian provided sample RC-10-56. This work was supported by the National Science Foundation and the Office of Naval Research.

Transient X-ray source A0620–00 observed at 408 MHz

THE transient X-ray source A0620–00 reported by Elvis, *et al.*[1] was also detected as a transient radio source at a number of observatories[2-5] at frequencies from 962 to 5,000 MHz. We report here the detection of the source at 408 MHz using the Molonglo radio telescope on August 20, 1975. Since the result is based on a single observation we shall discuss the steps taken to ensure that the detection is real.

The Molonglo telescope is a transit instrument with 11 simultaneous beams in declination covering a strip of sky 15′ wide. Because of the large uncertainty in the position of the source available to us at the time, several nights were required to map the area. By the time we became aware of a reliable position for the source it was no longer detectable above the noise level.

A source of 0.3 Jy was observed on August 20, very close to the accurate position of the object identified with the X-ray source[6]. No such source was detected on a previous survey record nor on records taken subsequent to the decay of the X-ray source. As the r.m.s. noise for a single observation is 0.04 Jy, the detection level of ~7 s.d. is well above the possibility of a random noise fluctuation. The 408-MHz position compared with that for the optical source is

optical	06 h 20 min 11.2 s	−00°19′10″
408 MHz	06 h 20 min 11.6±0.6 s	−00°18′18±20″

The right ascension agrees extremely well but the declination differs by 2.6 s.d. The probability of a radial discrepancy of this order is ~3%, so it is not highly significant on the assumption of noise errors alone.

Table 1 Flux density

Date	Flux density at the optical position (Jy)
December 29, 1973	−0.08
August 20, 1975	+0.28
September 6, 1975	+0.02
September 7, 1975	0.00
September 17, 1975	−0.03
December 28, 1975	−0.08

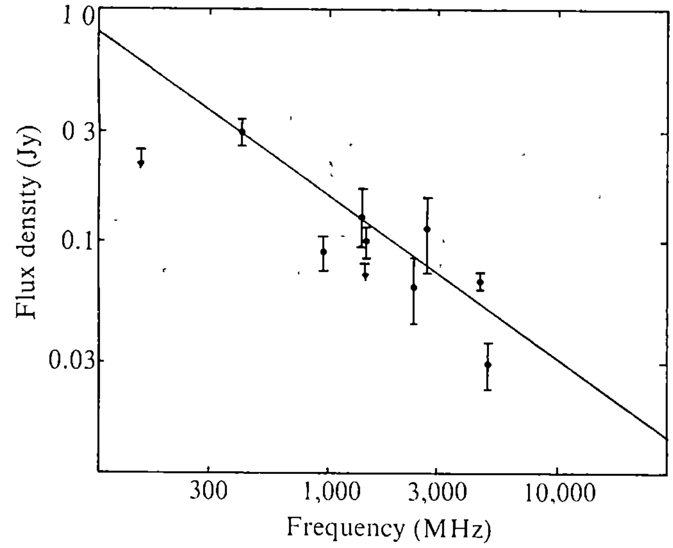

Fig. 1 The flux density of the radio source associated with the X-ray object A0620-00 plotted as a function of frequency. All points have been reduced to the common date of August 19.9, 1975 (UT). A line corresponding to a non-thermal spectrum (see text) is shown for comparison.

There remains the possibility of confusion with a weaker source or with a weak side lobe which may be either positive or negative, These effects are normally very small but in the galactic plane cannot be entirely ignored. We have therefore calculated the flux density at the optical position for all days on which this region of sky was observed (Table 1).

The estimated r.m.s. noise error on each of the above measurements is 0.04 Jy. The mean of all days other than August 20, 1975 is −0.03±0.02 Jy. The relative flux density on August 20 is 0.31±0.05 Jy which is highly significant and free of confusion. Based on the rate of decay of the source at higher frequencies the expected flux density at 408 MHz on September 6–7 would be <0.01 Jy and these have been considered as background points.

The flux density at 408 MHz is much larger than the higher frequency values. The available data are plotted in Fig. 1. The points have been reduced to the common epoch of August 19.9 UT using decay rates where available and using a time constant of 4.5 d for all other data.

The high flux density at 408 MHz is consistent with the suggestion of Owen *et al.*[7] that the spectrum could be non-thermal. In fact a spectral index α ($S = S_0\nu^{\alpha}$) of ~ -0.7 as shown in Fig. 1 fits the data quite well except that the points obtained with 3″ resolution tend to fall somewhat below the line.

The Molonglo radio telescope is operated with the support of grants from the Australian Research Grants Committee, the University of Sydney Research Grants Committee and the Science Foundation for Physics within the University of Sydney.

Explanation for the very low Ga and Ge concentrations in some iron meteorite groups

THE Ge/Ni ratios in iron meteorites range from 10^{-2} to 10^{-7} atoms/atom (ref. 1). Gallium is strongly correlated with Ge, but the total range in Ga/Ni ratio is only about 2,000. Iron meteorites tend to have Ga and Ge concentrations within various restricted ranges—thus their usefulness for the classification of iron meteorites. No other element correlates strongly with Ga and Ge. Here we point out parallels between the abundance patterns of moderately volatile elements in iron meteorites and ordinary chondrites, and discuss how these can be related to condensation processes in the solar nebula.

Most (83%) of the irons have Ge/Ni ratios in the range $(0.2–6.3)\times10^{-3}$ atoms/atom, in the same range as ratios in primitive, volatile-rich CI chondrites, 2.6×10^{-3} atoms/atom and in other groups of chondritic meteorites[1,2]. Two iron meteorite groups show much lower Ge/Ni ratios. $(1.0–1.2)\times10^{-6}$ atoms/atom in Group IVA and $(1.6–2.9)\times10^{-7}$ in Group IVB. The processes responsible for these very low Ge concentrations were clearly much more effective than those that affected the chondritic meteorites.

Concentrations of Ga and Ge in iron meteorites were probably established either during condensation[3] at the nebular location where that parent body formed and/or during processes occurring within each parent body.

Wai *et al.*[4,5] showed that core formation in a planetary body does not result in fractionation of Ge from Ni. By default, it seems that the fractionation of Ge and Ga from Ni must have occurred during the condensation and agglomeration of the solar nebula

Gallium and germanium belong to a group of moderately volatile elements having abundances 1.2–10 times lower in ordinary chondrites than in CI chondrites, which are generally believed to be most representative of mean Solar System abundances[6]. It is instructive to compare Ga and Ge with two other moderately volatile elements, As and Cu. In Fig. 1 data for Group IVA and IVB irons are compared with IIIAB irons and H-group ordinary chondrites; element/Ni ratios are normalised to CI chondrites

The H/CI ratios in Fig 1 show a steady decrease from As to Ge; Wasson and Chou[6] suggested that nebular condensation temperatures decrease similarly, and that a nebular mechanism existed which resulted in increasing loss of gas with decreasing condensation temperature. Wasson and Chou discussed several nebular processes which could result in such loss patterns.

Figure 2 shows equilibrium condensation activities of the most stable compounds of Cu, Ga and Ge at nebular pressures of 10^{-4} and 10^{-6} atm. No calculations are reported for As, since data could not be found for a number of potentially important compounds. Equilibrium between gases and solids and ideal solution was assumed. Mean Solar System abundances of C, H and O were taken from Cameron[7], and for Cu, Ga and Ge from Wasson and Chou[6]. Free energy data were taken from the JANAF (1971) tables for CO, H_2O and Cu compounds[8], and from other recent sources for Ga (refs 9 and 10) and Ge (refs 11–14).

In a departure from earlier calculations regarding trace element condensation[15,16], the ordinate does not show the fraction of the element removed from the gas phase, but rather the equilibrium activity in each phase divided by that expected if the element condensed entirely in this phase. This representation allows more insight into the siting of each element during equilibrium processes in the nebula. For the six phases of importance these normalising CI ratios were· Cu metal, $Cu/(Fe+Ni)=6.1\times10^{-4}$; $CuS_{0.5}$,

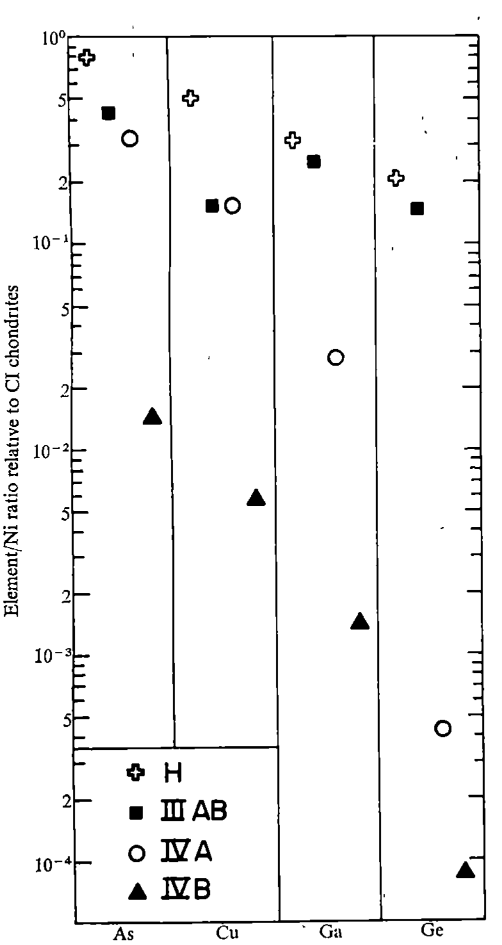

Fig. 1 CI chondrite normalised element/Ni ratios of four moderately volatile elements are generally similar in H-group chondrites and IIIAB irons. The IVB irons have very low ratios of each volatile, whereas the IVA irons have normal amounts of two volatiles (As and Cu) and very low amounts of two others (Ga and Ge).

unity above 680 K, Cu/S=5.4×10^{-3} below 680 K; Ga metal, Ga/(Fe+Ni)=4.3×10^{-5}; $GaO_{1.5}$, Ga/Al=4.8×10^{-4}; Ge metal, Ge/(Fe+Ni)=1.3×10^{-4}; Mg_2GeO_4, Ge/Si=1.2×10^{-4}. An implicit assumption of this treatment is that unit activity of a trace element results from complete substitution for the element in the denominator (the exception is Cu for Fe in FeS).

Scott[17] noted that the IVB irons are enriched in refractories (Re, Os, Ir) and depleted in volatiles and concluded that they represent high temperature nebular condensates. The data in Fig. 1 cannot be explained by equilibrium condensation processes, however. This conclusion is independent of pressure, but can be conveniently demonstrated by consideration of the condensation curves at a pressure of 10^{-4} atm (Fig. 2*a*). In order that only 0.6% Cu condenses, equilibration with nebular gases must cease at a temperature of about 1,350 K. At this temperature, however, the equilibrium Ga and Ge activity ratios are 2.2×10^{-4} and 5.3×10^{-5}, substantially lower than IVB values. Kelly and Larimer[3] reached a similar conclusion.

The moderately volatile element pattern in IVB is in fact quite similar to that in ordinary chondrites (Fig. 1) The difference is one of degree, implying that the same loss mechanisms were responsible but that the IVB process was much more efficient.

A plausible picture is the following. Condensation at the Group IVB location occurred during a period when the temperature decreased rapidly. Diffusion was too slow to allow trace metals to reach the centres of Fe–Ni grains, and solution occurred only in the outermost atomic layers. As temperatures continued to fall, trace metals condensed as a fine aerosol that was later blown away by a T-Tauri solar storm. The IVB irons have high Ni contents suggesting that an appreciable amount of Ni-poor metal was lost, possibly by the same mechanism. Condensation at the H-group location was more complete because the temperature decreased less rapidly, and trace metals could diffuse deeper into Fe–Ni grains.

As noted by Scott[17] the abundances of As and Cu in Group IVA irons are nearly identical to those in Group IIIAB, whereas Ga and Ge are lower in IVA by factors of about 10 and 300, respectively. The IIIAB abundances are nearly identical to those in the H group, and it is likely that the same process was responsible for the loss of moderately volatile elements at both nebula locations.

At the IVA location conditions were also similar as the nebula cooled to the condensation temperature of Cu, but below this temperature condensation was much less complete. We can think of two ways in which IVA conditions may have differed from IIIAB or H conditions: either (1) the rate of temperature decrease increased abruptly below the Cu condensation temperature, and incomplete condensation and loss of Ga and Ge occurred in conditions similar to those proposed for the loss of volatiles at the IVB location; or (2) early condensation occurred in equilibrium conditions, but below some limiting temperature the gas and solids became physically separated and no further condensation was possible[3]. If the second mechanism is viable, we should find temperatures in Fig. 2 which account for the Ga and Ge depletions in IVA relative to those in Group IIIAB. At a pressure of 10^{-4} atm 1,060 K could provide the correct factors. At 10^{-6} atm no temperature exactly matches the IVA/IIIAB depletions; the best fits are obtained at about 820 and 900 K. This double value results from the tendency of Ga preferentially to enter the silicates below 860 K. The temperature of equilibration with nebular gases cannot have been less than 820 K, since lower temperatures result in sharp increases in the Ge/Ga ratio in Fe–Ni. This lower temperature is implausible, however, since the Ga concentration in the silicates is high, and this Ga should re-enter the metal at the high temperatures needed to bring about gravitational separation of metal from silicate in order to form a core

Determination of a siderophilic element (that is, one tending to remain in the metallic state) more volatile than Ge offers a means for choosing among the two IVA models. The model involving a change in cooling rate should result in higher concentrations of such an element than that incorporating a minimum equilibration temperature. Unfortunately, the same atomic forces that cause some elements to show siderophilic properties tend to produce moderately high nebular condensation temperatures. We know of no siderophilic element more volatile than Ge. The most siderophilic of the more volatile elements is Zn, which has a condensation temperature close to 680 K. Published data on Zn show considerable scatter, but it seems that metal/sulphide concentration ratios can be as high as 0.1. Smales *et al.*[18] reported Zn concentrations less than their detection limit of 1 μg g^{-1} in IVA irons. We are initiating a neutron activation study of Zn in these meteorites which will allow detection down to ng g^{-1} levels.

Although S has a pressure-independent condensation temperature (680 K, Fig. 2) lower than that of Ge at 10^{-4} atm, and the same as Ge at 10^{-6} atm, CI normalised S/Ni ratios in IVA and IVB irons are ~ 1×10^{-2} and 7×10^{-4}, respectively—factors of 8 and 20 higher than those of Ge. This difference may result in part from the differences in condensation reactions. Whereas Ge and Ga can condense as pure metals, S must form FeS by reaction with the surfaces of metal grains. The latter reaction should proceed rapidly until all grains are coated with

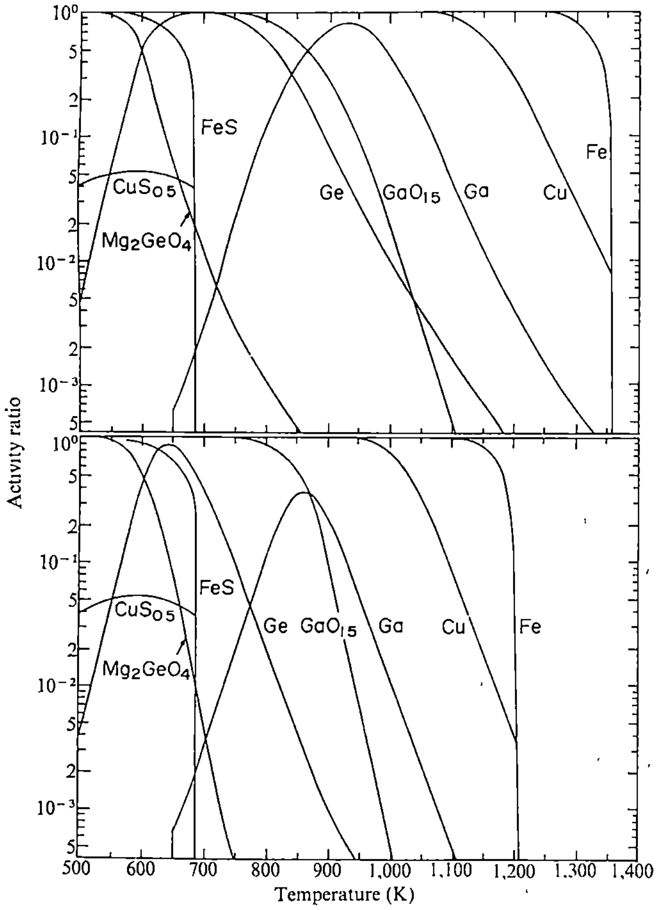

Fig. 2 Nebular condensation of Cu, Ga and Ge at pressures of 10^{-4} atm (*a*) and 10^{-6} atm (*b*); the ordinate gives the equilibrium activity of the substance divided by that expected from full condensation of the trace element in this chemical form. At high temperatures Ga and Ge condense as the metal but at low temperatures the oxide form becomes dominant. Some Cu enters FeS when the latter becomes a stable phase at 685 K.

FeS. At moderate temperatures (>500 K) there is no other reaction by which an appreciable fraction of the S can condense, thus it cannot undergo homogeneous condensation as a fine aerosol capable of being blown away by a T-Tauri wind.

We thank W. V. Boynton and E. R. D. Scott for fruitful discussions, and R. Hutchison for a stimulating review. This research was supported by a grant from NASA.

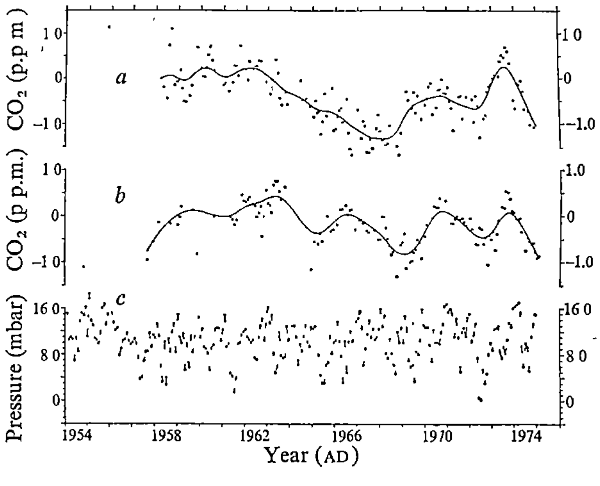
Modulation of atmospheric carbon dioxide by the Southern Oscillation

ATMOSPHERIC CO_2 records for the South Pole and Mauna Loa Observatory, Hawaii, show a seasonal variation, presumably arising from the uptake and release of CO_2 by vegetation, and a long term increase, almost certainly caused by combustion of fossil fuel. The increase is much greater in some years than in others[1,2]. Changes in the rate of fossil fuel combustion are not likely to be the cause of the variation in yearly increase, as combustion has increased very steadily[3]. I present here evidence that the variation is connected to the Southern Oscillation, a large scale atmospheric and hydrospheric fluctuation with an irregular period of 1–5 yr (ref. 4). The connection, if present, indicates that a principal cause of the variation may be a change in the rate of removal of CO_2 by the oceans.

The CO_2 records, approximately as they would appear if there were no seasonal effect and no long term increase, are shown in Fig. 1. These 'anomaly curves' were obtained by an iterative procedure in which the data were first fitted to a long term increase and a seasonal effect, represented, respectively, by a spline function[5] (with stiffness set by eye) and by an average over identical months, for each year, of the difference between the data and the spline. A constant airborne fraction multiplied by an integral of the fossil fuel consumption rate was then subtracted from the spline (long term increase) to remove the effect of fossil fuel combustion. The analysis will be discussed in more detail elsewhere.

The difference in average monthly barometric pressures between Easter Island and Darwin, Australia, is a suitable indicator[6] of the Southern Oscillation, and will be called the Southern Oscillation Index (SOI). Easter Island is near the centre of a subtropical high pressure cell, and Darwin is representative of the equatorial low pressure zone. The SOI is directly related to the strength of the easterly trade winds that blow along the Equator. When the SOI is high, the trade winds are stronger than average. The middle latitude westerlies along the southern flank of the subtropical

Fig. 1 Atmospheric CO_2 records at *a*, Mauna Loa, Hawaii and *b*, South Pole, with seasonal effect and fossil fuel increase removed by a procedure described in the text. *c*, Southern Oscillation Index. Data assembled by W. H. Quinn, Oregon State University.



anticyclone belt also tend to blow more strongly. The Humboldt Current and equatorial currents are accelerated, thereby increasing upwelling along the coast of South America and along the Equator. The equatorial countercurrent, which flows against the trade winds, is decelerated. Low SOI brings reduced trade winds and reduced middle-latitude westerlies. The equatorial countercurrent flows more strongly and carries warmer water to the eastern Pacific[7]. Low SOI is often accompanied by El Niño, an invasion of warm water off the west coast of northern South America, which brings disaster to the fishing industry and torrential rain to a normally arid region.

Correlation maxima[8] for the South Pole anomaly with the smoothed SOI (12-month moving average) near zero lag are 0.40 with a positive SOI lag of 3 months and −0.45 with a negative SOI lag of 17 months (Fig. 2). If these two time series were uncorrelated, the cross-correlation function would be expected to be zero, with a standard deviation, near zero lag, of approximately 0.29. The statistical confidence level for the existence of a connection is thus about 83%. The correlation maxima with positive SOI lag of three months would not seem to meet the requirement of a causal relationship, since one would expect the Southern Oscillation to be the cause of change in atmospheric CO_2 level, and not the reverse. (The possibility exists that the anomaly in CO_2 level drives the Southern Oscillation, but it seems unlikely because the CO_2 changes are only 1 part per million (p.p.m.) in a total of about 330 p.p.m.) The negative, 17-month SOI lag is physically possible, but rather long. Corresponding correlation maxima for the Mauna Loa anomaly are smaller: 0.14 with an SOI lag of 6 months, and −0.28 with a negative SOI lag of 10 months. The standard deviation, if the series were unconnected, would be 0.18 near zero lag. Consequently, none of these correlation maxima is entirely satisfactory.

An atmosphere and hydrospheric circulation phenomenon should directly affect the rate of change of the CO_2 level instead of the level itself. For example, the transfer of CO_2 across the air–sea interface is governed approximately by an equation of the form

$$-(\mathrm{d}p/\mathrm{d}t) = k(p-P) \qquad (1)$$

where p is the CO_2 partial pressure in the atmosphere, P is the CO_2 partial pressure in the ocean beneath a thin boundary layer, and k is a rate factor which depends strongly on the boundary layer thickness, and consequently on wind shear[9]. It is therefore reasonable to correlate the derivatives of the anomaly curves with the smoothed SOI (Fig. 3).

Correlation maxima are then −0.64 with a negative SOI lag of 6 months for the South Pole, and −0.55 with a negative SOI lag of 2.5 months for Mauna Loa. Standard deviations near zero lag would be 0.34 and 0.28, respectively, if the series were uncorrelated. Not only are the derivative anomaly correlations higher, relative to the standard deviations, but the time lags are more reasonable.

The nominal confidence level for the existence of a connection between the time derivatives of the anomalies and the Southern Oscillation is about 95%. The true confidence level, however, is probably smaller because of the extensive data manipulation and smoothing. Longer CO_2 records should resolve whether a connection exists.

The influence of the Southern Oscillation on the atmospheric CO_2 level seems to be felt 3.5 months earlier at Mauna Loa than at the South Pole. The reason for this may be that the South Pole is in a relatively fixed high pressure zone, isolated from the lower latitudes by circumpolar winds[10].

Increased loss of CO_2 from the atmosphere during periods of high SOI must be attributable to increased uptake by one of the two natural reservoirs with which atmospheric CO_2 principally exchanges: the oceans and the biota. If a high SOI were associated with increased rainfall over arid but otherwise fertile land, increased vegetative uptake could explain the correlations. Data to test this hypothesis are probably available, but have not been examined in the course of this study. The large areas of land that would have to be involved make this explanation seem unlikely, however.

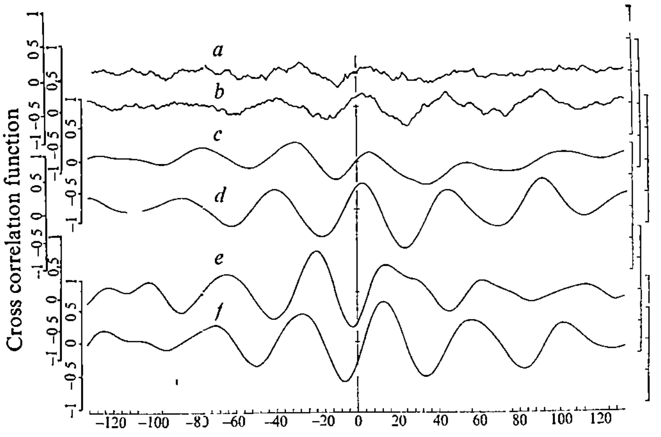


Fig. 2 Cross correlation functions for Mauna Loa and South Pole CO_2 records and the SOI: *a*, unsmoothed Mauna Loa anomaly data (with missing data filled in by interpolation) and unsmoothed SOI; *b*, unsmoothed South Pole anomaly data (with missing data filled in by interpolation), and unsmoothed SOI; *c*, Mauna Loa anomaly curve and smoothed (12-month moving average) SOI; *d*, South Pole anomaly curve and smoothed SOI; *e*, derivative Mauna Loa anomaly curve and smoothed SOI; *f*, derivative South Pole anomaly curve and smoothed SOI. All correlation functions are plotted against the lag of the SOI. Standard deviations, if each pair of curves were uncorrelated, would be (*a*–*f*): 0.09, 0.12, 0.18, 0.29, 0.28, and 0.34.

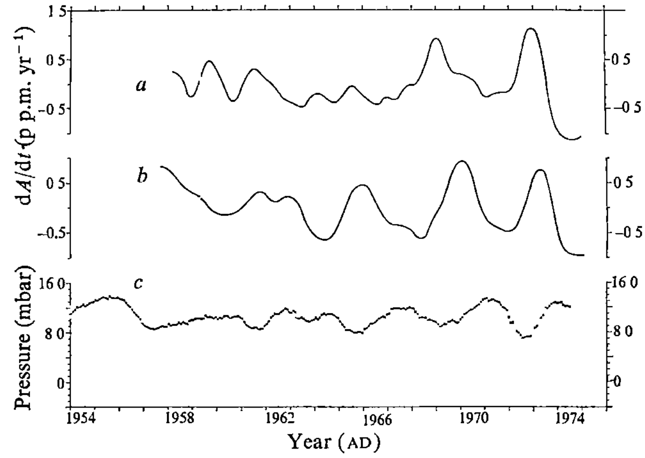
The oceans transfer CO_2 to the atmosphere in regions where there is upwelling: along the Equator and along the western margins of continents, and absorb CO_2 from the atmosphere in many other regions where the CO_2 partial pressure exerted by the oceans is less than that of the atmosphere[11].

The Southern Oscillation has global influence[12], and indeed may be a fluctuation in the intensity of the general atmospheric circulation. Kanwisher has shown that the CO_2 exchange rate (essentially the coefficient k in equation (1)) varies as the square of the wind speed[9], so a small increase

Fig. 3 Time derivative CO_2 records at *a*, Mauna Loa and *b*, South Pole, obtained by differentiating corresponding curves in Fig. 1. *c*, SOI, smoothed by a 12-month moving average, shown for comparison.



in average wind speed at high SOI could cause increased uptake by the oceans.

If the Southern Oscillation is mainly localised in the South Pacific, the explanation may be that increased ocean uptake occurs in the zone of westerly winds from ~ 40–50° S. This region should have a very high exchange rate for CO_2 because of the strong winds and large ocean area[9], and the westerly winds in this zone correlate with the easterly trade winds to the north[10], and thus with the SOI.

On the other hand, a high SOI should also bring increased upwelling, at least along the western coast of South America and along the equatorial Pacific. The observed correlations seem to indicate that the stronger absorption by the oceans dominates the effect of the increased upwelling.

I thank C. D. Keeling, C. S. Cox, and J. Namias for critical comments, R. A. Haubrich for statistical consultation, and L. Gamble for assistance in preparing the manuscript. This work was supported by grants from the Atmospheric Sciences division of the NSF.

D-region rocket measurements in winter anomaly absorption conditions

The winter anomaly in ionospheric absorption was first identified by Appleton[1], and although extensively studied over the past 40 yr it still remains for the most part a major unsolved problem. Its principal feature is that at latitudes above ~35°, on most winter days, h.f. ionospheric absorption is large (often larger than on summer days at 1200). Furthermore, there is considerably greater variability in the day-to-day absorption in winter than in summer, and the magnitude of the anomaly seems to increase with latitude, although at high latitudes the phenomenon is largely masked by other disturbances characteristic of the auroral zone. Rocket measurements have shown that on winter anomaly days there is a considerable enhancement of the electron density of the lower ionosphere particularly in the height range 80–90 km (refs 2–4). Calculations indicate that these enhanced electron densities would be sufficient to account for the winter anomaly absorption without involving any changes in other parameters which determine the magnitude of h.f. absorption such as the collisional frequency ν.

On a recent coordinated firing of three Petrel payloads from South Uist (57.4° N, 7.4° W) at approximately 1200 on November 29, 1974 we measured ion and electron concentrations on a day of very marked winter anomaly absorption. The first rocket was instrumented by the Max-Planck-Institut, Heidelberg and carried a quadrupole mass spectrometer to measure positive ions and neutral constituents. The second rocket was instrumented by the Appleton Laboratory to measure atomic oxygen and also carried a Langmuir probe to measure relative values of the electron concentration. The third rocket was instrumented by the University College of Wales, Aberystwyth and carried a Faraday rotation radio experiment on two frequencies (which provided absolute measurements of the electron concentration) and also carried a Langmuir probe identical to that flown on the second rocket. Mass spectrometer measurements of positive ion composition were obtained over a height range of 70–115 km and it was observed that above 72 km NO^+ was by far the most abundant species. This is in contrast to the normal situation in which O_2^+ ions reach abundances comparable with NO^+ above about 85 km, and water cluster ions are dominant below that height[5]. Relative measures of electron density by the Langmuir probes were obtained from 60 to 130 km and absolute values by the Faraday rotation technique were obtained from 70 to 90 km. These various results are shown in Fig. 1. For comparison purposes Fig. 1 also shows electron density curves for about the same solar zenith angle but measured (1) on a winter day of below average absorption and (2) on a summer day.

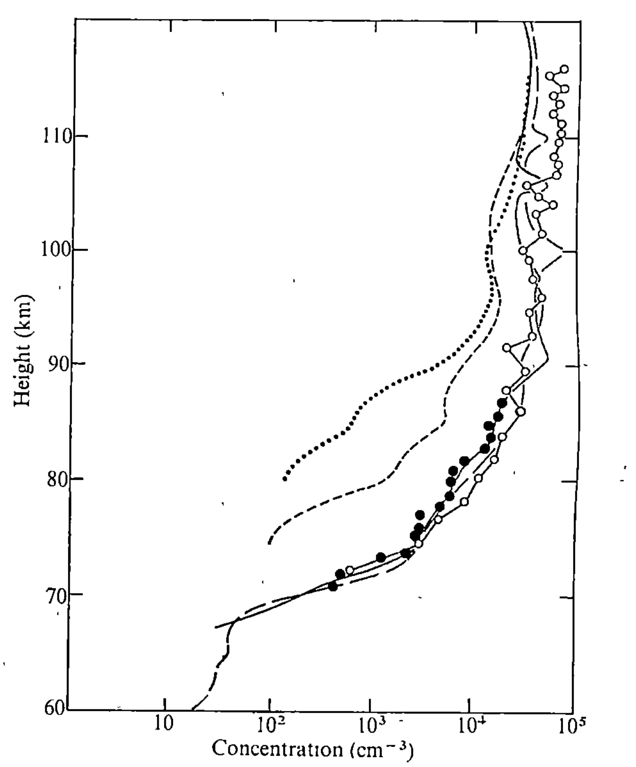

Fig. 1 Comparison of NO^+ ion and electron concentrations (Ne) during severe winter anomaly absorption at South Uist, Scotland (57.20° N, 7.14° W). Also shown are electron concentrations for normal winter and summer conditions at similar solar zenith angles χ. November 29, 1974—winter anomaly day, $\chi \approx 80°$: o—o—o, NO^+ flight, P182H, 1117 UT; ————, Ne (probe), P175H, 1153 UT; ————, Ne (probe), P179H, 1309 UT; • • •, Ne (Faraday rotation) P179H. December 6, 1971, normal winter day, $\chi \approx 83°$: – – – – – –, Ne (Faraday rotation + probe), P83H, 1402 UT. June 26, 1971, summer day, $\chi \approx 80°$. ······, Ne (Faraday rotation + probe), P120H, 1944 UT.

It can be seen that throughout the height range 70–115 km the profile of enhanced electron density on the winter anomaly day is practically coincident with the profile of NO^+ concentration, a result which points strongly to the conclusion that winter anomaly absorption occurs as a result of a greatly enhanced concentration of NO particularly at D-region heights.

Earlier work on the spatial and temporal morphology of the winter anomaly absorption phenomenon has indicated that its incidence may well be associated with the occurrence of some fairly large scale atmospheric movements in the lower ionosphere. If further experimental results support the conclusion indicated by the present rocket results concerning the role of NO, and if further progress with the problem is to be made, an explanation will be needed for the enhanced production of NO and/or its transport to the locations concerned during the winter months.

A fuller account of this work and of other results obtained in these rocket flights will be published elsewhere.

Recent activity of Stromboli

DURING a recent extensive phase[1] on Stromboli (November 5–24, 1975; Fig. 1), which was accompanied by an increase of explosive activity, I noticed an interesting inverse relationship between seismic and eruptive activity.

The recent extensive phase was the first since 1971. In October 1972 the crater terrace was an oval shaped basin with five vents, aligned along a NE–SW fissure (Fig. 2*a*); four of the vents were active. In December 1972 two strong explosions occurred, and large fragments of old lava fell near San Bartolo. In April 1974 a fissure appeared in the central part of the 'Fossa'; three cones were built by the explosive activity along this fissure between May and August (Fig. 2*c*). On September 19, 1974 at 0010 GMT two big explosions occurred; after the explosions I observed that the cinder cones had been destroyed and that an irregular elongated crater with three vents had taken their place (Fig. 2*d*).

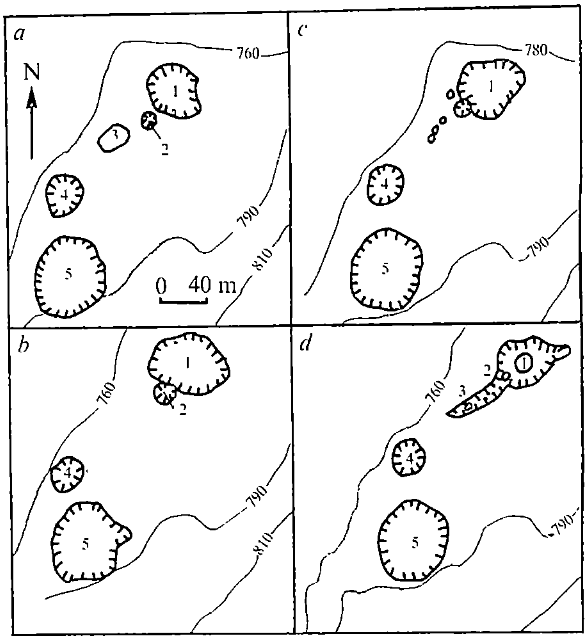

Fig. 2 Evolution of the crater plain (Fossa): *a*, October 1972; *b*, May 1973; *c*, May 1974; *d*, December 1974. Since the explosions of September 1974 vents 1, 2, 3 are all inside an elongated crater (*d*).

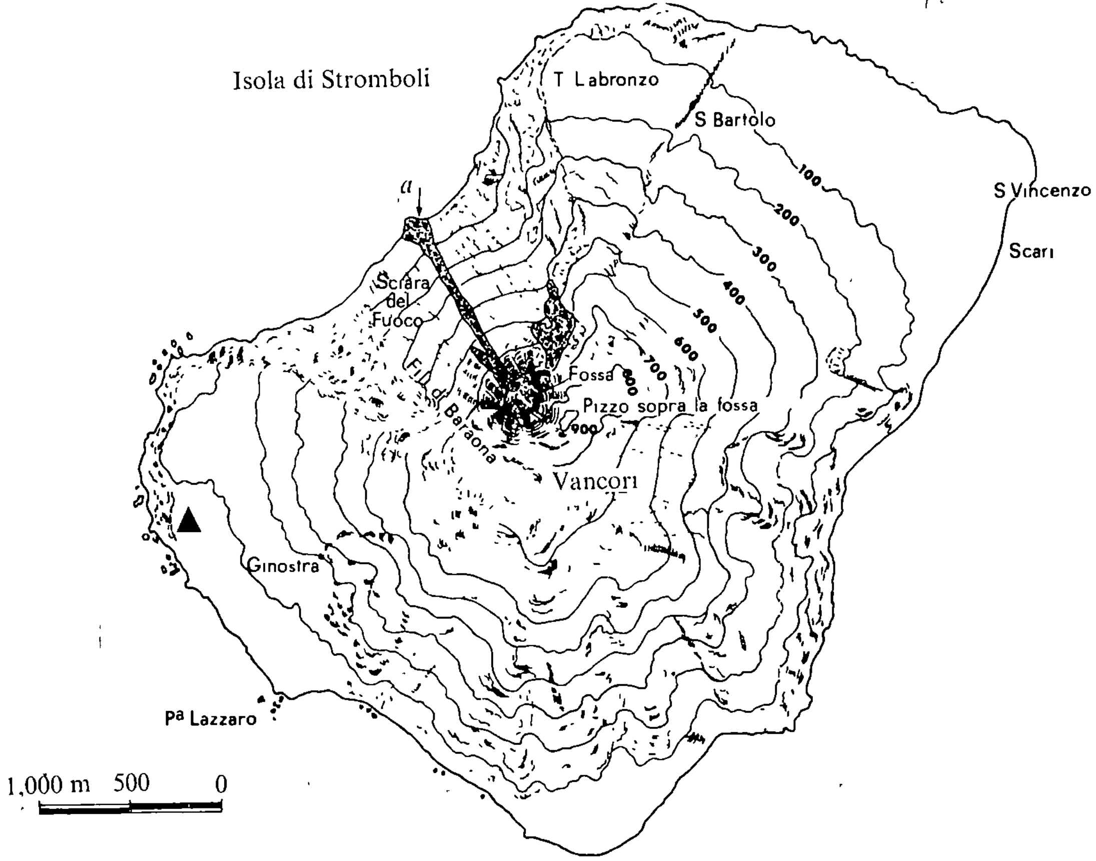
Fig. 1 Sketch map of Stromboli: the two most recent lava flows, the seismic station of Ginostra (▲), and 1975 lava flow.



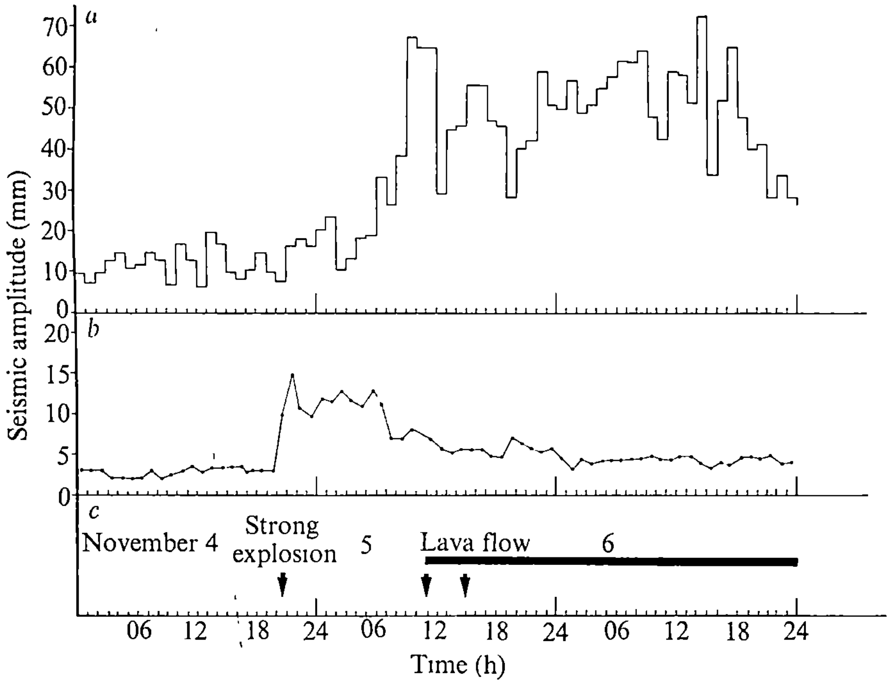


Fig. 3 *a*, Hourly frequencies of seismic events; *b*, relative amplitude of tremors; *c*, eruptive activity.

The earliest lavas produced were observed on November 5, 1975 at 1500. At that time the two flow fronts were at 400 m OD and 500 m OD on the Sciara del Fuoco, respectively. The first flow originated from a new bocca at 700 m OD on the Sciara del Fuoco; the second flowed from a collapse of the crater rim originating from a vent within the main crater close to the lip (Fig. 1). This flow stopped on November 6. The flow from the bocca on the Sciara del Fuoco reached the sea on November 5 at 1800.

The lava flow down the Sciara was 10 m wide, but at the Sciara base where the lava flowed into the sea, the flow formed a delta-like body with a front about 100 m wide. Only a small part of this material was molten lava, flanked with fragments of lava pushed aside during flow along the Sciara. The effusive activity stopped on November 24.

The explosive activity reached its peak between November 5 and November 7 (when more than one explosion occurred every second). Two of the vents inside the elongated crater (Crater 1, Fig. 2*d*) were very active. Also active were vents 4 and 5. Crater 1 was characterised by fire fountaining and explosions. The explosions threw lava fragments and scoriae to a maximum height of 700 m and there was rumbling within the crater. Vent 5 was also characterised by explosions with maximum projectile heights of about 400 m. The explosions from Vent 4 ejected ash to about 800 m above the crater lip. During this period of activity 65% of the explosions were from Crater 1 and 21% and 12%, respectively, from Vents 4 and 5. On November 10 and 11 the ejection of ash had replaced the ejection of molten fragmenta and scoriae. Only two craters were active, Crater 1, in which 52% of the explosions occurred, and Crater 5, in which 22% of the explosions occurred; the other 26% was represented by weak explosions (or very shallow earthquakes?) recorded only on the seismograph at Ginostra. On November 13 only the ejection of ash occurred from Craters 1 and 5.

The seismic activity of Stromboli Volcano is recorded at a station at Ginostra, located about 2 km west of the crater plain. The station includes a 1-Hz vertical geophone, and the amplified signal is sent by telemetry to the Osservatorio Geofisico di Lipari. There, the signal is recorded on magnetic tape and monitored. Generally, the seismic activity of Stromboli comprises single seismic events superimposed on a continuous microtremor. On the evening of November 4, 1975, the amplitude of volcanic tremor increased sharply from 2000, and suddenly decreased at 0700 on November 5 (Fig. 3*b*). At that time the hourly frequencies of the seismic events increased (Fig. 3*a*). Figure 3 shows that the increase of the volcanic tremor began 11 h before the beginning of eruptive paroxysm. On the morning of November 7, in order to determine the nature of the single events recorded, observations were conducted for 1 h at the crater plain. Around 99% of the events recorded were related to observed explosions. During later observations (November 10, 11, and 13) the proportions of seismic events related to explosions were 65%, 42% and 35%, respectively. This change must be related to the fact that the level of the magmatic column became progressively lower. In fact, after November 10 the products of explosion appeared on the crater lip more than 10 s after the seismic event was recorded.

The seismic record during this recent activity of Stromboli confirms that the source of the seismic energy is located within the volcanic superstructure, that an inverse relationship between the amplitude of microtremors and number of events per unit time exists (Fig. 3), and that the seismic events can be clearly related to events in the crater. Such a clear relationship between events in the crater, and seismic activity recorded, suggests that major changes of crater activity can be detected by the existing seismic network.

Sulphate–light scattering ratio as an index of the role of sulphur in tropospheric optics

THE optical properties of the non-cloudy atmosphere are determined by a fixed component, the molecular gases, and a variable component, the aerosol particles. The optical effects of these two components have been subject to speculation and scientific investigation for many years. The major features of molecular and particle optics are reasonably well understood[1–3] and instrumental techniques have been developed to measure extinction of light[4], scattering phase function[5,6] and the scattering component of extinction[7]. Few data or analyses have, however, been presented which consider the chemical nature of the aerosol in terms of its effects on radiative properties, although a few exceptions can be cited[8–12]. Experimental evidence quantitatively linking the chemical composition of aerosol particles with the macroscopic optical consequences is sparse, but here we mention one approach relating chemical and optical measurements on regional scale air masses and present preliminary data.

Measurements[13,14] have shown that the aerosol particle volume distribution is usually bimodal, and that the two modes are approximately log normal, are of mass mean diameters 0.4–0.8 μm and 8–20 μm and geometric standard deviations of about 2. Mie calculations show that the small particle mode usually dominates the optical scattering. Further, the measured particle volume concentration in the range 0.1–1.0 μm is often highly correlated to the extinction due to scattering by particles as measured with an integrating nephelometer with a correlation coefficient as high as 0.95 (ref. 14). Chemical analyses have shown that the small particle mode is often dominated by few substances notably non-maritime sulphates, nitrates, ammonium and condensed organic material[8,15,16]. Measurements in and near St Louis, Missouri[17] showed that sulphates often accounted for $\geq 50\%$ of the mass of material in the diameter range $0.1 \geq D_p \geq 1$ μm.

Dry particle light scattering and the possibly dominant chemical quantity (sulphate compounds) seem the most useful parameters to measure. These measurements may be compared with other atmospheric data, with laboratory values for simulated systems and with Mie theory to provide insight into the fraction of optical effect attributable to sulphate components. The key ratio is that of sulphate concentration to light scattering extinction coefficient due to dry particles, $[SO_4^{2-}]/b_{sp}$, g m^{-2}.

Table 1 provides a summary of various schemes which can be used for this evaluation of the mass concentration/b_{sp} and/or $[SO_4^{2-}]/b_{sp}$ ratio. It should be noted, of course, that "sulphate" is not a compound itself and must have a cation. The lightest cation is H^+ and it is found in atmospheric particles some of the time. One of the heavier ions is NH_4^+ as in $(NH_4)_2SO_4$, which in also frequently found as an optically dominant component (that is, 50 mol %)[17]. Since the ratio of molecular weight of $(NH_4)_2SO_4$ to that of SO_4^{2-} is only about 1.5, and that of H_2SO_4 is almost 1, the use of SO_4^{2-} mass concentration alone for an index is warranted at the outset. This simplification, which is due, in many cases, to a lack of knowledge, of the cation associated with sulphate, must be kept in mind as it produces an inherent uncertainty of about ±25% in the ratio.

The data pairs for the ratio were obtained from aircraft flights, mainly over southern Sweden. An integrating nephelometer[23] was used to measure the extinction coefficient due to dry particles at a given wavelength (in most cases 450 nm) and a filter was used to obtain samples for postanalysis of the SO_4^{2-} content by the thorin method. Incoming air was heated to ~20 °C, providing relative humidities below 50%. Some flight paths and altitudes were selected beforehand to provide air from populated areas of continental Europe as part of the study by the Organization for Economic Cooperation and Development of sulphur transport across national boundaries *vis-à-vis* the problem of acidic rain (Long Range Transport of Air Pollutants project), whereas others were deliberately made at random. Most flights were at altitudes above 300–1,000 m and well inland (250 km) so that large particle ($D_p > 1$ μm) maritime sulphate concentrations should be small or nonexistent. The average sulphate concentrations ranged up to 35 μg m^{-3}, significantly higher than the maritime SO_4^{2-} in this area (typically less than 3–10 μg m^{-3} based on Cl^- analysis) and provided an adequate dynamic range for correlation calculations.

Table 2 includes all ratios of the $[SO_4^{2-}]$ and b_{sp}, and summarises the correlation calculations.

(1) The $[SO_4^{2-}]/b_{sp}$ ratio from the overall regression is 0.2 g m^{-2} which is comparable with the measured and predicted ratios in Table 1 for the ratio of submicrometre mass concentration to b_{sp}.

(2) The correlation between $[SO_4^{2-}]$ and b_{sp} for all data is 0.73, indicating that a large fraction of the variance of b_{sp} can be associated with $[SO_4^{2-}]$.

(3) The correlation between $[SO_4^{2-}]$ and b_{sp} for individual days (that is, flights) ranges from $r=0.99$ to $r=0.24$. Five of nine cases with three or more data points had $r > 0.86$, whereas the rest had $r < 0.60$. Trajectory calculations showed that the

¶Trajectory from north-west, north, north-east, east.

high correlation cases occurred with flow from the south-east, south and south-west whereas the low correlation cases were from the north-west, north and north-east.

(4) The $[SO_4^{2-}]/b_{sp}$ ratio is comparable with that found in St Louis, Missouri.

(5) If the size distribution were known, more definite conclusions could be made regarding the fraction of b_{sp} due to $[SO_4^{2-}]$. Such measurements need to be made in the future, especially resolving $[SO_4^{2-}]$ as a function of size.

(6) The cases in which the correlation coefficient was low, and the cases where $[SO_4^{2-}]/b_{sp} \leqslant 0.2$ g m^{-2} do not fit the simple model of $[SO_4^{2-}]$ dominance of b_{sp}. In the case of a ratio greater than 0.2 g m^{-2}, it seems possible that large particle SO_4^{2-} was present. Further sampling and chemical analyses are needed to explain these cases. There were very few cases of $[SO_4^{2-}]/b_{sp} < 0.1$ g m^{-2}, so that there was nearly always sufficient SO_4^{2-} to account for the observed b_{sp}. When the SO_4^{2-}/b_{sp} was 0.2 g m^{-2}, assuming a particle size distribution similar to that found by Whitby[16] (log normal, geometric standard deviation = 2, mass mean radius = 0.3 μm) leads to the conclusion that much, and perhaps most, of the light scattering was due to SO_4^{2-}. If the measured ratio was ~0.1 g m^{-2}, then perhaps half of the optical effect can be attributed to SO_4^{2-} (assuming constant size distribution, and so on). Further, the two separate analyses (regression analysis and comparison of measured ratios with those from theory and other experiments) are consistent with this same conclusion.

Since the SO_4^{2-} in southern Scandinavia in the selected meteorological conditions probably arises from the oxidation of man-made SO_2 (ref. 24), these measurements tend to indicate that SO_4^{2-} is not only involved in rain chemistry but also in the aerosol and its optical consequences.

Using this approach, it is interesting to consider the $[SO_4^{2-}]/b_{sp}$ ratio as an index of the role of sulphur in tropospheric optics and (since man is rapidly changing the sulphur cycle) also as an index of the effects of human activity on atmospheric optics. Before we can be certain, however, more data will be needed, especially with regard to the non-human, natural sources of submicrometre SO_4^{2-} aerosol. Until such time as these data exist, we feel that the study of the $[SO_4^{2-}]/b_{sp}$ ratio and its variations is warranted to explore and test these hypotheses.

This work is part of a cooperative project between our various institutions, with funding from the NSF, the National Swedish Environment Protection Board, the Swedish Natural Science Research Council, and from NORDFORSK.

Prevailing winds in lower thermosphere

WINDS in the upper atmosphere have been measured at Adelaide, South Australia (35°S) by radio observations of drifting meteor trails, using a combined continuous wave and pulse technique[1]. The systematic features of the winds can be described in terms of a prevailing component and 24-, 12- and 8-h periodic components. Here we are concerned primarily with the behaviour of the prevailing component in the height range 75–105 km for the six years from June 1966 to June 1972.

The observations were usually carried out on four successive days near the middle of each month. Each quarter the observing interval was extended to 7 d, and on a few occasions to 20 d. An average of 250 usable echoes giving drift measurements were recorded each day. The analysis was carried out using a least squares fitting method developed by Groves[2]. For each day this gives the most probable height profiles of the prevailing and periodic wind components. The precision in height is ±2 km.

Figure 1 shows isotachs of the zonal and meridional winds. The zonal wind has a very regular annual pattern and exhibits two distinct circulation regimes. Below 85 km eastward winds occur in winter and westward winds in early summer, corresponding to the monsoonal type circulation that dominates the air motion in the mesosphere and upper stratosphere. Above 90 km the main features of the circulation are a strong eastward flow in summer, a westward flow in winter and early spring, and relatively large gradients at the solstices. A rapid build-up of eastward flow occurs at upper levels during October and November reaching speeds as high as 80 m s^{-1} at 100 km in December. In some years a second but weaker maximum in the upper circulation pattern occurs about March. The superposition of the two zonal circulation systems produces a complex behaviour near 90 km where the flow is predominantly eastward, and lacks any marked annual variation as illustrated in Table 1.

The reversals of zonal flow that occur at the lower levels are of short duration, typically ~ 1 month. The times of reversals show a phase retardation with height of 0.3–1 d km^{-1}. On three occasions, during the months of November, 1966, 1969 and 1970 the reversals extended up to 100 km and on two occasions merged with the westward flow of the upper pattern just before its changeover to the strong summer circulation.

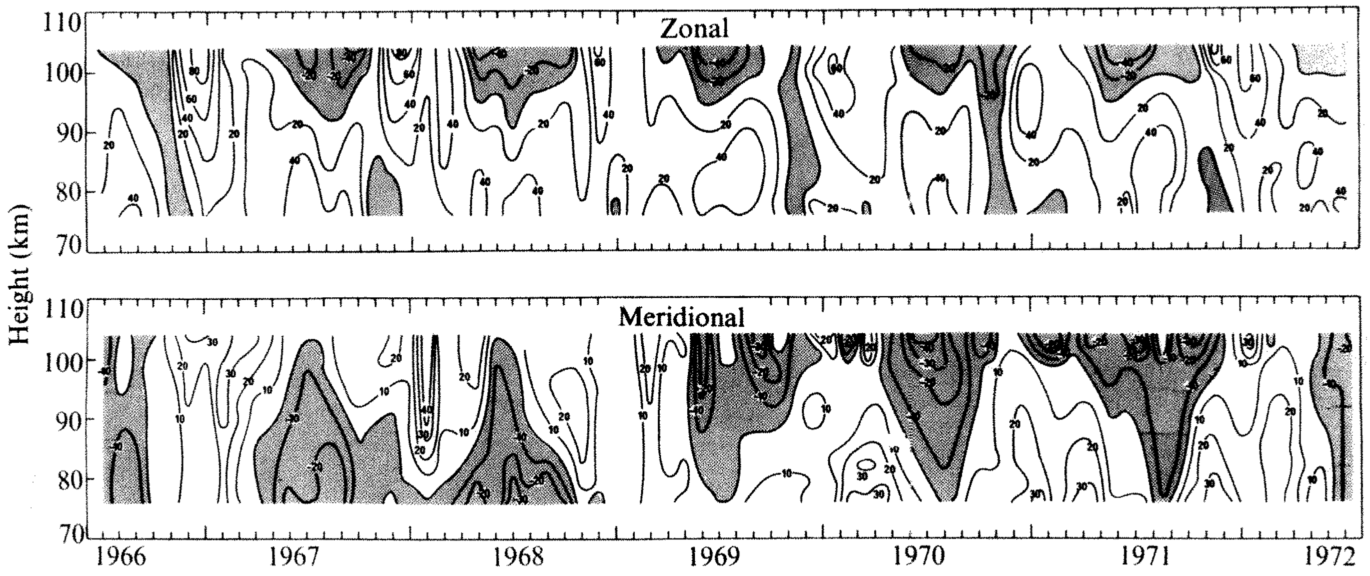
Table 1 Amplitudes and phases of the annual and semi-annual waves

Height	Annual		Semi-annual	
	Zonal wind			
(km)	Amplitude (m s^{-1})	Phase (date)	Amplitude (m s^{-1})	Phase (date)
82	16	May 25	7	January 10
90	6	February 21	6	December 26
98	25	December 28	9	December 15
	Meridional wind			
(km)	Amplitude (m s^{-1})	Phase (date)	Amplitude (m s^{-1})	Phase (date)
82	14	January 4	4	March 15
90	13	December 28	4	March 6
98	12	December 28	3	February 24

The meridional prevailing winds exhibit annual reversals that are symmetrical in time with respect to the solstices, although the time of a reversal can change with height as rapidly as 7 d km^{-1}. The maximum southward flow occurs about the time of the winter solstice at all heights while the northward flow usually exhibits two maxima close to midsummer. Extreme meridional speeds rarely exceed 30 m s^{-1}. The pattern of the meridional flow changed in early 1969 so that the predominantly northward flow that had occurred at the upper levels since mid-1966 became a southward flow of almost equal strength. This change is reflected in the gradient of the meridional wind as shown in Fig. 2. The gradient values have been calculated at the 90-km level but are generally typical of the whole height range under investigation. The changeover commenced about October 1968 and was completed by April 1969. Early in 1973 a return to positive meridional gradients occurred. There is no evidence of any substantial complementary changes in the zonal flow at these times.

The variability in the meridional gradient during the years 1969–72 is of the order of the mean value of the gradient so that the extremes range between 0 and −2 m s^{-1} km^{-1}. The times of occurrence of the maxima and minima do not show any seasonal dependence. In general the gradients that occur in the meridional flow are much smaller than those in the zonal flow. At 90 km the zonal gradients range from a mean value of 2.2 m s^{-1} km^{-1} in summer to −3.7 s^{-1} km^{-1} in winter. An extreme value of −5.5 m s^{-1} km^{-1} occurred during the winter of 1969. Even higher values occur near 100 km.

Fig. 1 Height–time cross sections of the zonal and meridional prevailing winds for the period June 1966–June 1972. The shaded areas represent winds toward the west and toward the south. Speeds in m s^{-1}.



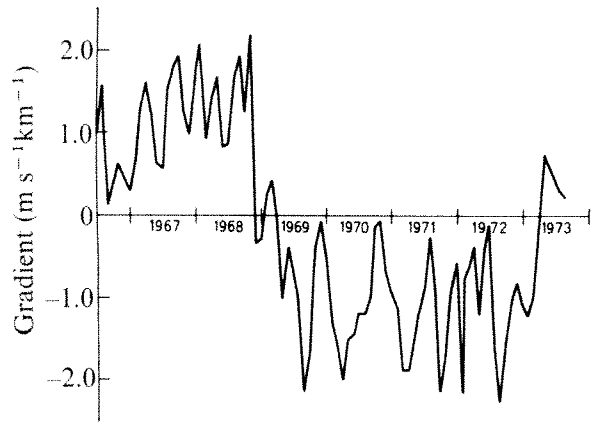


Fig. 2 Vertical gradient of the meridional prevailing wind measured at 90 km showing a sudden change in early 1969.

The annual and semi-annual variation in the prevailing winds have been determined for the period June 1966–June 1972, and the amplitudes and phases (times of maximum eastward or northward flow) at the heights 82, 90 and 98 km, are given in Table 1.

The phase of the annual oscillation in the zonal winds at 82 km is consistent with the phase of this oscillation in the lower mesosphere determined from rocketsonde data[3]. These results show that at 35°S and at a height of 65 km, maximum eastward flow occurs in late June and tends to be earlier with increasing height. The amplitude of the annual wave deduced from the rocketsonde data is 60–70 m s^{-1} at 65 km, whereas the meteor drift observations indicate an amplitude of 16 m s^{-1} at 82 km. In spite of this rapid fall off in amplitude above 70 km, the consistency of the phase between the heights of 60 and 80 km supports the earlier comment that the mesospheric circumpolar vortex extends to a height of ~ 85 km.

The zonal semi-annual oscillation at 82 km has its maximum eastward flow on January 10; this is about three months earlier than the time of occurrence of maximum eastward flow at 65 km, determined from the rocketsonde data. Such a rapid phase shift with height is not consistent with the relatively slow change in phase below 65 km and requires further investigation.

At a height of 98 km the annual oscillation in the zonal wind has an amplitude of 25 m s^{-1} and its strength increases with height. The time of maximum eastward flow occurs close to mid-summer. This value of phase is maintained up to the limit of the data at 104 km and is probably typical of this oscillation in the lower thermosphere.

In addition to the annual and semi-annual waves in the zonal winds, oscillations with periods of four months and three months occur with significant amplitudes. These reflect the rapid increase of the zonal wind strength during the months October to December. The meridional prevailing winds are dominated by the annual oscillation whose maximum northward flow occurs almost simultaneously at all levels, a few days after the summer solstice. It is of interest to note that this annual oscillation was essentially unaffected by the major change in the mean meridional flow that occurred in 1969.

Table 2 Standard deviations of the zonal and meridional prevailing winds (speeds in m s^{-1})

Height (km)	Zonal Summer	Zonal Autumn	Zonal Winter	Zonal Spring
82	16	15	14	14
90	12	13	15	18
98	13	17	17	18

Height (km)	Meridional Summer 1966–69	Summer 1969–72	Autumn 1966–69	Autumn 1969–72	Winter 1966–72	Spring 1966–72
82	27	10	16	11	11	11
90	28	12	17	12	10	10
98	25	14	18	15	16	12

The significance of the mean meridional flow, its long term variations and annual oscillation is open to conjecture. One possibility is that the flow arises from a circumpolar standing wave with a phase variation with height. An annual variation in the phase constant of the wave would account for the annual variation in the merdional winds at any level. Further, a long term change in the phase constant of the whole wave system could reverse the gradient of the winds as is observed. It has been shown[4] that such a standing wave can transport significant quantities of heat towards or away from the polar regions.

An alternative possibility is that the observed meridional flow is typical of the mean meridional flow across a circle of latitude. This situation has been considered by Ebel[5] who has shown that such flows imply meridional cells with vertical velocities of the order of a few cm s^{-1}, and momentum sources and sinks of ~ 100 ms^{-1} d^{-1} per unit mass. The strength and direction of flow in the cells would undergo annual changes, while long term changes in the observed meridional winds could be produced by changes in the latitude of the cell boundaries. If the latitudinal distribution of the zonal and meridional winds are known, it is also possible to calculate the strengths of the heat and momentum sources required to drive this meridional circulation[6]. The actual situation is likely to be a combination of both mean meridional flow and circumpolar standing waves. The contribution which each makes to the observed north–south winds must await simultaneous observations at several sites around a circle of latitude.

On a limited number of occasions when observations extended continuously for ten days or more, slow and regular changes in the strength of the zonal and meridional winds have been observed. The magnitude of the variation is comparable to the speed of the mean flow and the quasi-period is ~ 10–15 d. This transient motion occurs at all times of the year and is interpreted as planetary waves. The intensity of the variability produced by this long wave activity has been determined by calculating, for each season, the s.d. of the observed daily values of zonal and meridional flow from the mean monthly values. The results are given in Table 2. The strength of the zonal variability is independent of the season at 82 km, although above 90 km it is marginally smaller in summer. The pattern of meridional variability showed a marked change in 1969. For the period 1969–72, its magnitude is essentially independent of season and shows only a marginal increase with height: for the period 1966–69 the variability is two to three times larger in summer than in winter. Although the mechanism for this change in the strength of the variability is not known, it is clearly associated with the reversal of the gradient of the mean meridional flow which occurred in early 1969.

Mercury in Mersey estuary sediments, and the analytical procedure for total mercury

THE Mersey estuary consists of a wide, shallow upper region, separated from the sea by deeper 'narrows'. The upper estuary (Fig. 1) is an area of continuous accretion of sediment, observed since the mid-nineteenth century with occasional short periods of depletion. The main freshwater inflows are the River Mersey itself, flowing over Howley Weir, and the Manchester Ship Canal, entering the estuary at Eastham Locks. The River Weaver flows into the Manchester Ship Canal at Weston[1]. The area is industrialised and heavily populated and the estuary receives both domestic sewage from surrounding towns and industrial effluent[1,2]. We are aware of no published data for mercury concentrations in the sediments of the estuary, and have undertaken such measurements. Samples were obtained from the places shown in Fig. 1. We analysed 136 samples for total mercury and the results presented in Fig. 1 and in Table 1 are compared with other data. The levels found are, in general, somewhat higher than in other, more limited, surveys.

The samples were obtained as follows: the top 5 cm of the sediment were sampled, and 10–20 g were taken at each point. The samples were stored frozen, in glass bottles, until analysis. Total mercury was determined by cold vapour atomic absorption spectrophotometry following digestion in aqua regia, and oxidation with a mixture of potassium dichromate and potassium persulphate[3,4]. This was found to be superior to the potassium permanganate mixture suggested previously[3,5], as this has a tendency to deposit oxides of manganese on the vessel walls, trapping a proportion of the mercury. Replicate analyses of 10 identical test samples gave a mean value of 2.46 μg g^{-1}, and a r.s.d. of 3.3%. The detection limit (the mean of the blank, plus twice the s.d. of the blank) was ~0.01 μg g^{-1} in the sediment. Portions of the samples were dried to determine the water content, and all results are quoted as μg per g of dry sediment.

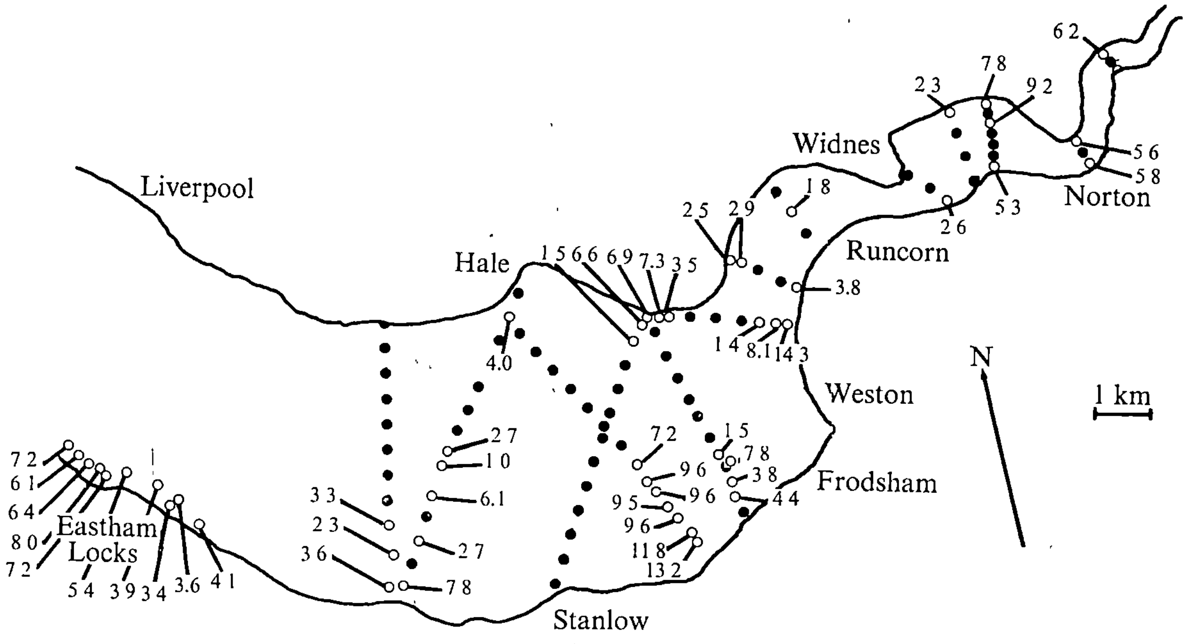
*Mean value including two 10-cm core samples = 1.60 p.p.m.

Fig. 1 Total mercury levels in the upper Mersey estuary. ● indicates < 1µg g^{-1}.



The mean value in the 136 samples was 2.23 μg g^{-1}. The maximum value recorded was 14.3 μg g^{-1}, and 23 samples were below the detection limit. High values occurred in those sediments consisting of fine silt, with a large amount of organic material present. This type of sediment is found along the edges of the water course. Lowest values were found in the relatively clean sandy material from the fast running tidal channels of the centre of the estuary. Figure 1 shows Hg concentrations from sampling points with levels >1 μg g^{-1}. Sampling points with levels <1 μg g^{-1} are shown as dots. These results indicate three main areas with significantly elevated total mercury concentrations; at Norton, Weston, and Stanlow. Distribution of mercury in the sediments reflects the position and movement of the fine silt in the estuary, and a high mercury level is not necessarily indicative of a mercury input at that point.

Several studies of total mercury concentrations in sediments, but mainly relating to North America, have been carried out and comparison with our work is made in Table 1.

It was not possible to analyse all samples immediately and a report that if a sample of a river sediment containing mercury is taken and stored at −15 °C, 50% of the total mercury present originally is lost after 7 d (ref. 6), was therefore relevant to our work. We investigated this alleged loss of mercury from frozen sediments to determine the effect of storage in various conditions on the levels of total mercury found when analysis was carried out.

We found that total mercury does not seem to be lost in significant quantities from samples stored at −20 °C, −6 °C and even at room temperature (allowing for natural temperature variations). This does not agree with previous work, but a possible explanation is that in Daughdrill's samples[6] the mercury was present in the form of methyl mercury or that mercuric sulphide was being formed. The form of the sampling was as follows: a bulk sample was taken initially and immediately homogenised and divided into a number of smaller samples. These were frozen with solid carbon dioxide and taken to the laboratory where the first analysis was made the next day (day 0, corresponding to the true environmental level). The data presented in Fig. 2 are of importance for analytical work since they indicate that sediments containing mercury may be stored even at room temperature for at least 9 weeks and still give reliable values for total mercury content.

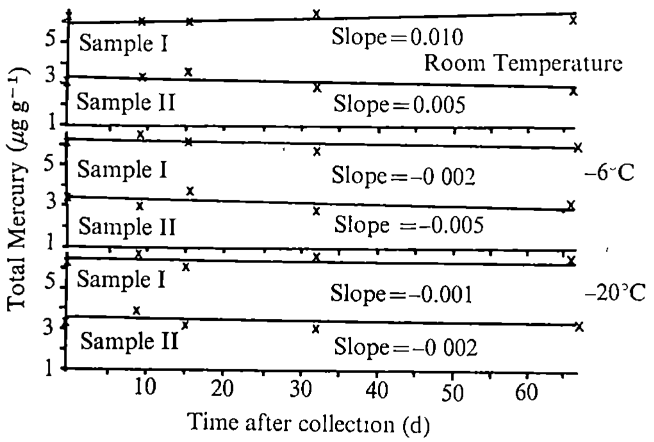


Fig. 2 Repeated analysis of sediment for total mercury

Aliphatic amines in the Murchison meteorite

ANALYSES of the organic compounds found in the Murchison meteorite, a C2 chondrite that fell in Australia in 1969, have provided much new information about extraterrestrial organic chemical evolution. The soluble fraction of this meteorite has been shown to contain aromatic and aliphatic hydrocarbons[1–4], mono-[5] and dicarboxylic acids[6] and various nitrogen-containing organic compounds. The latter include both amino acids[2,3,7–9] and nitrogen-heterocyclic compounds[10–11]. The presence of amines, ureas and amides has been suggested[11], although no individual compounds from these classes have been identified. Here we report the determination of aliphatic amines in water extracts of the Murchison meteorite.

The Murchison samples used in this work were clean interior specimens obtained from the Center for Meteorite Studies, Arizona State University. All glassware was acid-washed and heated in an oven at the annealing temperature of glass before use. Water for extraction was distilled in an all-glass distilling apparatus from alkaline potassium permanganate. The Murchison fragments were crushed in a clean mortar and transferred to the extraction vessel. One set of samples was extracted in a round bottomed flask under reflux conditions as described previously[7]. These samples were subsequently hydrolysed in 6 N HCl. Another set of Murchison samples was extracted in sealed ampoules at 120 °C for 4 d.

The amines of the aqueous extracts were analysed by gas chromatography both as the free amines (Fig. 1*a*) and as 2,4-dinitrophenyl (DNP) derivatives (Fig. 1*b*). Methylamine, ethylamine, diethylamine, isopropylamine, *n*-butylamine, *sec*-butylamine, isobutylamine, and *tert*-butylamine were identified as the free amines. Diethylamine and *n*-propylamine could not be identified unambiguously by this method because of incomplete resolution. Peaks appear on the chromatogram at retention times that do not correspond to those of any of the known amines. This is not surprising since the amines were not separated from other organic material in the meteorite extract before chromatography. But most of the interfering low molecular weight compounds would be expected to have been volatilised during reduction in volume of the solution, and other compounds known to be present in the extracts such as fatty acids and dicarboxylic acids should have been trapped as salts in the injection port. Injection of an 18-component amino acid standard solution (Bio Rad Laboratories) did not cause elution of any peaks corresponding to known amines although a few peaks were apparent that matched unidentified peaks in the Murchison extract.

In order to strengthen the evidence for amines, gas chromatographic separation of the DNP derivatives was carried out[14]. In Fig. 1*b* peaks are seen corresponding to the DNP derivatives of ethylamine, dimethylamine and diethylamine, as well as at the positions of the unresolved pairs, isopropylamine–*tert*-butylamine, methylamine–*sec*-butylamine, and *n*-propylamine–isobutylamine. A large dinitroaniline (DNA) peak is observed in addition to several unknowns.

Primary amines can be readily determined with an amino acid analyser by extending the final elution step (J.R.C. and P. E. Hare, unpublished). This method was used for analysis of the Murchison amines and the chromatogram is shown in Fig. 2. Well resolved peaks are seen corresponding to methylamine, ethylamine, isopropylamine, *tert*-butylamine, *n*-propylamine and *n*-butylamine. An unresolved peak is seen corresponding to *sec*-butylamine and/or isobutylamine. Secondary amines are not detected with this system as a result of their lack of reactivity with the detection reagent. An aqueous extract of the meteorite that had not been subjected to acid hydrolysis was also chromatographed. The amounts of each amine found, both before and after acid hydrolysis, are given in Table 1.

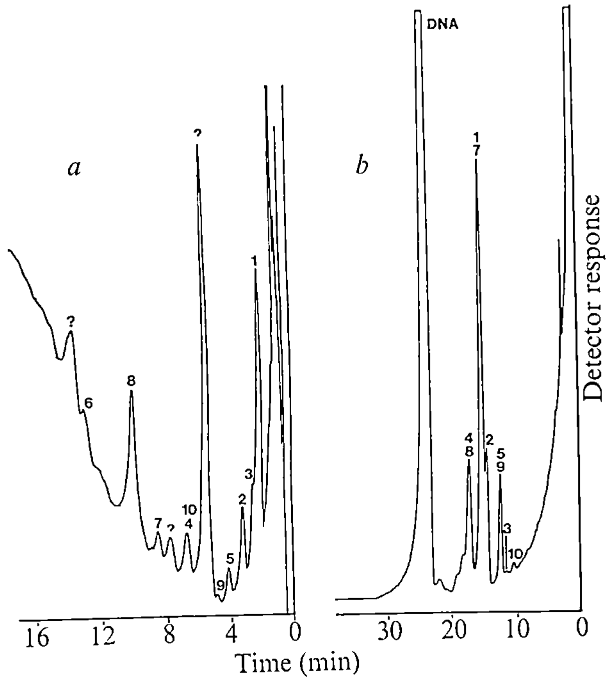

Fig. 1 Gas chromatographic analysis of meteorite amines. The peaks corresponding to known amines or DNP amines are identified by number as in Table 1. *a*, Gas chromatography of the free amines. An extract derived from approximately 0.5 g of the Murchison meteorite was acidified and evaporated to near dryness with gentle heating under a stream of purified nitrogen. The resulting solution was injected directly into the injection port of a Perkin-Elmer 3920 gas chromatograph. The injection port was packed with 25% potassium hydroxide on 80/100 mesh Chromosorb W in order to liberate the free amines from the hydrochloride salts[12]. The gas chromatograph contained a 12 foot×1/8 inch stainless steel column packed with 20% UCON LB 550-X plus 10% KOH on 120/140 mesh Chromosorb W and was temperature programmed from 60 °C to 110 °C at 4 °C min^{-1} with a helium flow rate of 50 ml min^{-1}. *b*, Gas chromatography of the DNP amines. The amine DNP derivatives were prepared from 2 ml of meteorite extract (0.8 g meteorite) by reaction with sodium dinitrobenzenesulphonate[13]. The reaction time was lengthened to enhance the formation of DNP derivatives of the secondary amines. The DNP amines were extracted into benzene and washed with a saturated borax solution. The volume of the benzene layer was reduced to a few μl and analysed on a 6 foot×1/8 inch stainless steel column packed with 7% XE-60 on 110/120 Anakrom ABS.

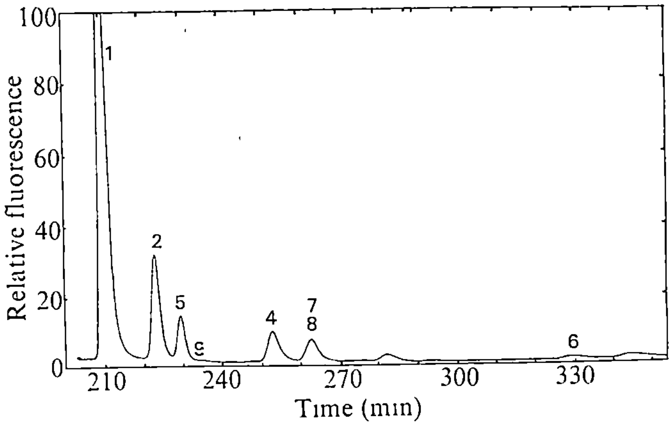

Fig. 2 Ion exchange chromatographic analysis of meteorite amines. The peaks corresponding to known amines are identified by number as in Table 1. An acid-hydrolysed water extract from 0.09 g Murchison meteorite was applied to a 0.20×25 cm DC4A resin (Durrum Chemical Co., Palo Alto) column. Separation of amino acids in the sample was achieved by sequential elution of the column with citrate buffers (0.2 M sodium ion) of increasing *p*H. Basic amino acids, followed by amines, were brought off the column by continuing the elution with a 0.032 M borate buffer, *p*H 10.7, which had been brought to 0.23 M in sodium ion by the addition of NaCl. Amino acids and amines were detected fluorometrically after reaction with *o*-phthalaldehyde[15]. Only the latter part of the overall chromatogram is reproduced above.

The results summarised in Table 1 give evidence for the presence in water extracts of the Murchison meteorite of all of the possible primary aliphatic monoamines (eight) with fewer than five carbon atoms. Five of these amines could be identified unambiguously in at least two of the three chromatographic systems used. Two of the seven possible secondary or tertiary aliphatic monoamines were identified. Chromatographic standards were lacking for the remaining five amines of this type and they went unrecognised, if present.

The primary amines that could be identified in the aqueous extract total 80 nmol per g meteorite. It is interesting to note that these compounds, some of which are quite volatile, have not been lost during the travel of the meteorite in space. They thus seem to be chemically or physically trapped in the meteorite.

Two similarities are apparent between the water-extractable amines and amino acids of the Murchison meteorite: (1) The level at which amines are present declines sharply with increasing carbon number in the homologous series, methylamine, ethylamine, *n*-propylamine, *n*-butylamine. Although the decline in content is not as sharp, the same is true within the amino acid series,

Table 1 Chromatographic identification of amines

Amine	Gas chromatography		Ion exchange chromatography (nmol per g meteorite)	
	Free amine	DNP amine	Extract	Hydrolysed extract
1 Methylamine	+	+*	49	143
2 Ethylamine	+	+	14	30
3 Dimethylamine	+	+	†	†
4 *n*-Propylamine	+*	+*	5	10
5 Isopropylamine	+	+*	9	13
6 *n*-Butylamine	+		0	3
7 *sec*-Butylamine	+	+*	+*	+*
8 Isobutylamine	+	+*	+*	+*
9 *tert*-Butylamine	+	+*	3	3
10 Diethylamine	+*	+	†	†

*Unambiguous identification not possible because of incomplete resolution.

†Secondary amines not detectable with *o*-phthalaldehyde

glycine, alanine, α-amino-*n*-butyric acid, norvaline, norleucine. These quantitative relationships are consistent with a chemical synthesis in which a simple carbon compound, methane, for example, is the precursor of meteorite amines and amino acids. (2) The amine content of the aqueous meteorite extract increases by over 100% on acid hydrolysis. A similar observation has been made with respect to the amino acids in aqueous extracts of both the Murchison and Murray meteorites[7]. Thus both amines and amino acids are extracted from the meteorite as such, as well as in the form of acid-hydrolysable derivative or precursor species.

This research was supported by grants from NASA and the Earth Sciences Section, National Science Foundation. We thank Dr P. E. Hare for help with the liquid chromatographic amine analysis. One of us (J.R.C.) thanks the Geophysical Laboratory of the Carnegie Institution of Washington for support during the course of this work.

Antiquity of man in America indicated by radiometric dates on the Yuha burial site

MUCH evidence suggests that man was present in the Western Hemisphere before 12,000 yr ago, but the case has remained less than conclusive[1]. In some situations, the geological age of the site is reasonably well established but the association or nature of the artefacts is questionable[2,3]. In other cases, museum specimens of human bones dated by radiocarbon analysis of collagen lack desirable information concerning site location, geology, and stratigraphy even though the accuracy of their absolute ages seems valid[4–6]. We report here the results of radiometric dates of the Yuha burial site from Imperial County, California, for which the geology and stratigraphy have been documented and reported in detail[7].

Claims of great antiquity on human bones based on amino acid racemisation[8] also suffer from shortcomings. The applicability of this technique by itself to bones where burial history is unknown is doubtful, and successful application of this technique requires a known temperature history of the bone, or, alternatively, a radiocarbon calibration point[9–13].

The Yuha site was discovered and excavated in 1971 and consisted of a partially preserved skeleton buried 35 cm below the surface. The burial was located on a dissected alluvial fan at the edge of a now dry pluvial lake, and was covered by a cairn of local cobbles and boulders. Flaked stone artefacts of a unifacial lower lithic industry were associated with the skeleton[7]. Subsequent to the time of burial, soil caliche precipitated, cementing the upper 15–60 cm of the entire alluvial deposit, coating the bones, the buried cairn boulders, and the underside of the exposed boulders.

A sample of the caliche coating the underside of one of the exposed cairn boulders (sample 103) and a sample of caliche coating one of the bone fragments (sample 104) were chosen for radiocarbon analysis. The results indicate ages of 22,125 ± 400 yr BP for sample 103 (R.P., UCLA2600) and 21,500 ± 1,000 yr BP for 104 (Geochron Laboratories, Cambridge, Massachusetts, GX2674). A modified ^{230}Th dating technique for application to soil caliches has been developed (T. L. Ku, W. B. Bull and K. G. Knauss, unpublished), but the technique can be successful only when corrections can be made for the detrital impurities. This was possible only for sample 103, which yielded an absolute age of 19,000 ± 3,000 yr BP, in good agreement with the radiocarbon results. In as much as the details of the ^{230}Th technique are yet to be published, however, the case for the antiquity of the Yuha skeleton must rest heavily on the radiocarbon results.

In proper conditions and with careful sample selection radiocarbon dates on soil caliches from arid zone palaeosols can indicate the true age of soil formation[14,15]. The Mungo burial in Australia represents essentially the same arid zone setting, environment, and time frame as the Yuha burial. Radiocarbon dates of soil caliche associated with this burial reflect the true age of local caliche pedogenesis[16].

A lone radiocarbon date on soil caliche, however, is always suspect because of possible contamination by younger organic matter in the soil or by older or 'dead' carbon from detrital limestone. Random or scattered apparent ages would result from such contamination, however, if more than one sample were analysed from a small area, since contamination is unlikely to be homogeneous over any distance. The close agreement among our samples with respect to age strongly suggests they are free from such contamination and represent the true age of the caliche precipitation. The ^{230}Th date supports this conclusion.

These results compare favourably with a date of $2{,}4000\pm^{2{,}000}_{1{,}000}$ yr BP (sample 401, ref. 7 and Geochron GX2722) obtained on soil caliche at the same elevation on the alluvial fan (134 m above sea level, but at a distance of 2 km from the burial). Similar caliches taken at successive distances up the slope from the burial and at higher elevations in the fan (250–300 m) yield successively older ages of 27,000–30,000 yr BP (ref. 7), indicating that caliche pedogenesis was progressive, beginning at the head of the fan and progressing down slope as the water table receded in response to desiccation of the pluvial lake. The original base level of the fan itself was apparently the high stand of the pluvial lake, at 45 m elevation, dated by lake shore tufa and freshwater snails at 37,400 yr BP (ref. 7).

In as much as the time of burial predates the precipitation of local caliche, our results yield a minimum age for the Yuha burial. Absolute dating of the skeleton itself by the collagen–radiocarbon technique will be carried out, but will require destruction of most of the skeletal material, since preliminary microanalytical analyses yielded a nitrogen content of only 0.68%. Consequently, such dating must await the completion of physical anthropological studies and construction of casts of each bone. With two A_2 dates the absolute chronological position of the Yuha hominid around 22,000 yr BP or older seems to be positively affirmed[17].

We thank K. Knauss, University of Southern California for carrying out the ^{230}Th age determination. Financial support from the NSF and the Deutsche Forschungsgemeinschaft is acknowledged.

Estimates of speeds of dinosaurs

THE faster an animal walks or runs the longer, in general, are its strides. Many dinosaur tracks have been found from which stride lengths can be measured[1]. I have now obtained a relationship between speed, stride length and body size from observations of living animals and applied this to dinosaurs to achieve estimates of their speeds. The estimated speeds are rather low—between 1.0 and 3.6 m s^{-1}.

Estimates of the speeds of large dinosaurs must depend on data from smaller animals. A means of allowing for differences in size is offered by the theory of physical similarity[2].

If meaningful comparisons are to be made between animals of different sizes, an appropriate non-dimensional parameter is needed to serve as a criterion for physical similarity. The most familiar parameter of this type is the Reynolds number which applies in situations where inertia and viscous forces interact and is very important in aerodynamics. Less familiar to biologists is the Froude number, which applies to any situation where inertia and gravity interact, and is important in nautical engineering. The Froude number is u^2/gl where u is the velocity, g the acceleration of free fall and l a characteristic length (in nautical engineering, the hull length) which, in this application to terrestrial locomotion, is the height h of the hip from the ground. The Froude number then becomes u^2/gh.

Considerations of physical similarity predict that the movements of animals of geometrically similar form but of different sizes will be geometrically similar only when they move with the same Froude number u^2/gh (that is, when the squares of their speeds are proportional to their linear dimensions). Geometrically similar movements require equal values of λ/h (that is, their stride lengths also must be proportional to their linear dimensions). The theory of physical similarity further predicts that, even when the Froude numbers are not the same, λ/h will be a function of the Froude number, although this function is not defined; we are obliged to obtain this relationship by empirical methods. It should be noted that stride length λ in this paper means the distance between corresponding points on successive prints of the same foot[3]; the term is used to mean half this distance in some accounts of dinosaur tracks.

Animals of different sizes are not geometrically similar; there seems, however, to be a rather widespread relationship between λ/h and u^2/gh (ref. 4). Figure 1*a* shows that for mammals as diverse as jirds, men and horses

$$\lambda/h \simeq 2.3(u^2/gh)^{0.3} \qquad (1)$$

Figure 1*b* shows that for man, and presumably for other animals, the relationship between stride length and speed is not appreciably different for firm ground and soft mud. Equation (1) can be written

$$u \simeq 0.25 g^{0.5} \lambda^{1.67} h^{-1.17} \qquad (2)$$

so that u can be estimated from known values of λ and h. λ can be measured accurately from tracks but h can only be estimated from the size of the footprints (see below). Equation 2 shows that if h is overestimated by 10%, u will be underestimated by 11%.

The tracks to be considered were made by unidentified bipedal dinosaurs and sauropods. It is assumed in each case that the metatarsophalangeal joint rested on the ground, but the tarsometatarsal joint did not. If this is correct, the length of the hind footprint is 0.23–0.28h for many bipedal dinosaurs of a wide range of sizes, both Theropoda and Ornithopoda, and about 0.25h for *Apatosaurus* (Sauropoda) (see for instance the photographs of skeletons in refs 5 and 6). It will therefore be assumed that hind footprint length is 0.25h in all cases.

All the data in Table 1 refer to trails of fairly evenly spaced footprints, indicating progression at fairly constant speed. The plan in ref. 7 from which some of the data are taken has

Fig. 1 Graphs on logarithmic coordinates of relative stride length (λ/h) against Froude number (u^2/gh). *a*, Data from travelling on firm ground or treadmills for men[10,11] walking and running, horses[12], jirds (*Meriones unguiculatus*, unpublished observations of S. N. G. Frodsham and R. McN. A.), elephant[12] (*Elephas maximus*) (●) and ostrich[12] (*Struthio camelus*) (○). *b*, New data for man walking and running on hard ground (○), sandy mud (⊙) and soft mud (●) at Snettisham beach, Norfolk. The subjects were an adult man and, two children (aged 11 and 13), each of whom made 4–8 walks or runs at various speeds (in random order) over a 25 m course on each substrate. They made moderate footprints in the sandy mud and very deep ones in the soft mud, on which it was very difficult to run. The broken line on each graph is

$$\lambda/h = 2.3(u^2/gh)^{0.3}.$$

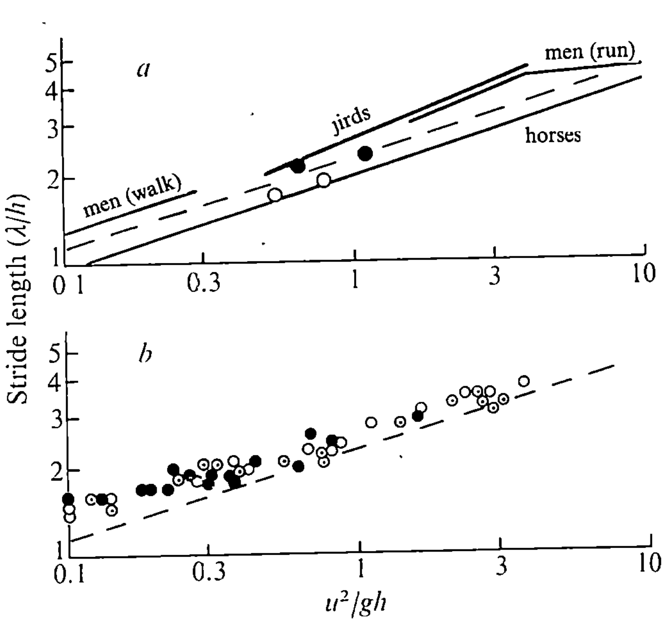

Table 1 Dimensions of dinosaur tracks and data estimated from them

	Bipedal dinosaurs						Sauropods	
Reference	13	7	7	14	1	1	7	7
Stride length, λ (m)	3.0	3.0	2.4	1.3	1.8 –2.5	1.5 –1.8	2.5	1.6

Relative stride length, λ/h	1.4	1.5	2.5	1.2	1.7	2.4	0.8	1.1
Speed, u (m s^{-1})	2.0	2.2	3.6	1.2	2.2	2.9	1.0	1.1

*Footprint length taken from measurements at the British Museum (Natural History). Other dimensions are taken from the published descriptions.

no scale but the paper includes a photograph of part of the same area marked out in yard squares, from which the scale has been determined. The speeds are rather low, especially those of the sauropods. Large and small sauropods seem to have been walking at the same speed, consistent with the suggestion that they were travelling as a herd[1,7].

Mammals generally change from a walk to a run or trot when the Froude number reaches about 0.6 and λ/h reaches 2.0 (ref. 4). Of the tracks recorded in Table 1, only the two fastest seem to show running, and both were made by fairly small dinosaurs. This does not necessarily mean that large dinosaurs never ran, but it seems to conform better with the traditional image of lumbering dinosaurs than with that of the lively runners shown in some recent restorations[8,9].

This research was supported by a grant from SRC. Jane and Gordon Alexander helped with the experiment recorded in Fig. 1*b*.

Stereoscopic vision within the schizochroal eye of trilobites

Most trilobites had holochroal eyes which were probably analogous with the compound eyes of most living arthropods[1]. Trilobites of the suborder Phacopina had schizochroal eyes, in which comparatively few large separate lenses are distributed over the eye surface. Clarkson and Levi-Setti[2] showed that the schizochroal eye is unique in structure, in that each lens is biconvex and is made of two calcitic elements of different refractive indices, separated by an aspherical surface with a configuration such that the lens was corrected for spherical aberration. A modified interpretation by Campbell[3] suggests that the e and o rays were transmitted through the calcite lens to focus in the same plane. Since chromatic aberration is not important in seawater more than a few metres deep, either interpretation implies that each lens of the schizochroal eye was capable of forming an accurate image of its field of vision[2,3].

We suggest that the schizochroal eye was adapted to give stereoscopic vision by the comparison and integration of optically accurate images from lenses within the same eye. Stereoscopic vision depends on the simultaneous perception of the same field of view through two lenses set at some distance apart. The images produced by the lenses should be of sufficient optical quality to define objects at useful resolution, the images should overlap considerably and there should be appropriate neural structures to interpret the information provided by the overlapping images. Towe[4], Clarkson and Levi-Setti[2] and Campbell[3] have already established the optical quality of the lenses. It remains to be shown that there would have been useful overlap between the images produced by adjacent lenses, and that it is reasonable to infer the existence of a suitable neural network behind the eye.

Clarkson[5,6] has measured the angular separation between the axes of the lens on many schizochroal eyes. The vertical spacing between lens axes is typically 2–10°, whereas the horizontal spacing is typically 7–20°. Since no part of the visual field is left unscanned, the cone of useful vision of a typical schizochroal lens would have been about 15–20° (for comparison, the ommatidia of *Limulus* have a useful range within 10–20° of their optic axes[7]).

The approximate hexagonal packing of lenses on the schizochroal eye usually included files of lenses arranged dorso-ventrally Coupled with the astigmatism of the eye surface, this meant that the dorso–ventral files of lens axes formed "visual strips"[5]—files of lens axes with low angular separation, running nearly vertically across the visual field, each file of lenses separated by a significant angle from the next file. If each lens had an effective visual field of 15–20°, the visual fields of neighbouring lenses on each visual strip would have overlapped greatly, whereas the visual field of any given lens would only have overlapped marginally with its nearest neighbour on the next visual strip. Thus, given appropriate neural integration, the potential for stereoscopic vision was very great within each visual strip, but must have been marginal between strips.

We suggest that the large horizontal spacing between visual strips was such as to ensure that the whole visual field of the eye was scanned adequately, while the close vertical separation between lens axes along the visual strips allowed stereoscopic scrutiny over the whole visual field. Some phacopids had eyes in which the angular separation between lenses on visual strips approached the separation between strips. The arguments developed here would comfortably include these species, since the angles involved are never more than 6–7° (ref. 6), and would have permitted stereoscopic integration between lenses on the strips.

Rudwick and Clarkson[5] have shown how a trilobite might have detected an approaching object as it appeared successively on images produced by different lenses. In the ideal case, any array of closely spaced lens axes—as in a holochroal eye—would have been able to detect approaching objects with equal sensitivity. But in the real world of the trilobite, stereoscopic scrutiny by cooperating lenses arranged in files would more accurately have detected the existence, size, speed and character of objects in the field of view.

Stockton and Cowen (unpublished) have constructed a simple neurophysiological model of the integration of visual images within a linear array of lenses. According to this model, it is reasonable to suppose that a trilobite with schizochroal eyes could have had the neural apparatus to perceive objects stereoscopically. The model includes predictions of features of morphology found among phacopid trilobites, and it is amenable for testing by further study of the optics of phacopid lenses.

Phacopid trilobites had visual fields that usually extended through 360° in the horizontal plane, but only from 0 to 40° at most above the horizontal. If our suggestion is correct, they would have had stereoscopic vision throughout that field. In fact, they would have had a wider range of stereoscopic vision than any organism that has ever lived.

The system was essentially a defensive one. Hunting predators have stereoscopy which is best developed in a limited anterior field. Prey species often have all-round vision, but usually have limited stereoscopic capability. Phacopid trilobites can thus be interpreted as benthic animals with special adaptations for detecting moving enemies on the sea floor in the photic zone. Cephalopods, arthropods and (in the Devonian) fish would have been likely predators on phacopids.

The Phacopina became extinct at the end of the Devonian period, long before trilobites as a class became extinct. Although less than 10% of Ordovician trilobite genera were Phacopina, however, their representation rose to 10–20% during the Silurian and reached 20–40% during the Devonian[8]. Trilobites with schizochroal eyes were relatively successful for 150 Myr. Nothing like the schizochroal eye has ever re-evolved among the hundreds of thousands of species of later arthropods.

Parent–offspring resemblance for specific cognitive abilities in two ethnic groups

A LARGE scale study of familial factors in mental ability is in progress in Hawaii and data are being obtained on 15 cognitive variables (Table 1), various environmental indices, and blood group and enzyme systems. After three years of testing, there are now sufficient data (1,490 families; 5,077 individuals) for preliminary genetic analyses. Measures of parent–offspring resemblance for members of the two largest ethnic groups in our sample, Americans of European ancestry (AEA; 739 families) and Americans of Japanese ancestry (AJA; 244 families), are presented here. These measures provide upper-bound estimates for the heritability of performance on the individual tests and factor scores[1,2], in addition to a test of the hypothesis[3,4] that spatial visualisation ability is influenced by a sex-linked major gene. Relatively small scale studies of parent–offspring resemblance for specific cognitive abilities have been reported for a Caucasian sample[5] and a Korean sample[6]; however, to the best of our knowledge, this is the first comparative study of parent–offspring resemblance for measures of cognitive abilities in two ethnic groups.

A 'family', for our purposes, consists of both biological parents, 60 yr of age or younger, and one or more of their offspring, 13 yr of age or older. Because of the presence of marked age effects[2], age correction was deemed necessary; such correction was accomplished by using a z-score banding technique. Age bands consisted of yearly intervals for the ages 15–20 and 34–55, and of 2–6-yr intervals for other ages (depending on sample size).

In the absence of an environmental correlation between relatives, the regression of offspring's score on mid-parental score provides a direct estimate of heritability in its "narrow sense", that is, the proportion of the observed phenotypic variance due to the average effects of the genes[7]. This method for estimating heritability has several advantages over other methods, including its insensitivity to the effects of non-random mating. (Assortative marriage for specific cognitive abilities in this study has been discussed elsewhere[8].) For at least some measures of human mental ability, however, environmental correlations between family members are likely to be non-zero and positive. The regressions of offspring on mid-parental values presented here should, therefore, be regarded as measures of phenotypic (genetic and/or environmental) similarity and only upper-bound estimates of heritability.

The regression coefficients for each cognitive test and for five factor scores are presented in Table 2. Two sets of coefficients are given, one uncorrected and one corrected for test reliability. It is important to be clear about when and when not to adjust for lack of perfect test reliability[9]: when estimates are to be used in prediction equations with individual scores (for example, to predict response to selection), uncorrected estimates must be used, but when estimates obtained from tests with different reliabilities are to be compared, correction is appropriate. Since considerable variation can be seen among the reliabilities presented in Table 1, only the corrected regression coefficients will be examined for evidence of differential heritability.

Standard errors for the corrected regression coefficients in Table 2 are sufficiently small, especially for AEA, to indicate that at least some of the variability among estimates is real. An indication of the reliability of the differential estimates among tests is the marked congruence between ethnic groups. The correlation between AEA and AJA coefficients across the 15 individual tests is highly significant (Spearman rank correlation = 0.77, $P < 0.01$). With regard to the four varimax rotated factor scores, the regressions are moderately high for verbal and spatial ability, but somewhat lower for visual memory and perceptual speed in both ethnic groups. These results are highly consistent with previous evidence[10] for the differential heritability of specific cognitive abilities (especially for verbal ability and memory) and afford an opportunity for identification of those environmental factors that differentially affect cognitive abilities.

Our tests also provide a measure of 'general intelligence'. The progressive matrices test is a modified form of the well known test of abstract reasoning developed by Raven[11], a "culture-fair" test which is regarded by many as being one of the best single measures of general intelligence. Our modified form is reduced in length to 30 items (20-min time limit in group administration), but retains a relatively high reliability (see Table 1). Regression of offspring on mid-parental value (uncorrected) for this test is 0.51 for AEA subjects and 0.27 for AJA. These results are consistent with those of Guttman[12], who found the correlation between child and mid-parent in a sample of 100 families in Israel to be 0.41 for the complete test.

The unrotated first-principal component score may also be used as a measure of general intelligence. The regressions of offspring on mid-parental values (uncorrected) for this measure

†From Wilson *et al.*[2] Details concerning the testing procedure and factor analyses are available in this source.

are 0.61 and 0.42 for AEA and AJA, respectively. These values are comparable with those obtained by Williams[5], who reported that the regression of offspring on mid-parent was 0.46 for total IQ as measured by the Wechsler Intelligence Scales. Since the regression of offspring on mid-parent may only be regarded as an upper-bound estimate of heritability, these results suggest that the narrow-sense heritability for tests of general intelligence may be lower than the value of 0.71 reported by Jinks and Fulker[13] in their re-analysis of previously published data.

Scarr-Salapatek[14] concluded from twin data that the heritability of scholastic aptitudes may differ in different racial groups as a function of socioeconomic status. Although her conclusions have been criticised[15] on the basis of statistical considerations, she has recently[16] reported additional evidence for such a difference. Even though the educational and occupational levels of the two ethnic groups included in the present study are roughly comparable, differences in parent–offspring resemblance may exist between groups. From Table 2 it can be seen that 14 of the 15 regression coefficients for the individual tests are higher for AEA subjects. Only two of these differences however, are significant. When these data were examined for differences in parent–offspring resemblance as a function of socioeconomic status within ethnic groups, no significant differences were observed.

Single-parent, single-child correlations were also estimated for the individual tests and factor scores in order to explore the possibility of sex-linked inheritance. Stafford[3] first reported a pattern of parent–offspring correlations which suggested that spatial visualisation ability may be influenced by a sex-linked major gene. The expected pattern of correlations (r) for such a character is as follows

$$r_{\mathrm{FS}} < r_{\mathrm{MD}} < r_{\mathrm{MS}} = r_{\mathrm{FD}}$$

where F, M, S and D are father, mother, son and daughter, respectively. Stafford's original finding has been given considerable support by the more recent report of Bock and

Kolakowski[4]. Single-parent, single-child correlations obtained from the data of the present study are presented in Table 3. Of the correlations involving individual tests of spatial ability (mental rotations, "lines and dots", card rotations, hidden patterns, paper form board, progressive matrices), only the set for progressive matrices for AJA subjects conforms to the order expected of a character influenced by a sex-linked major gene. An hypothesis of homogeneity among the four correlations in this set could not be rejected ($\chi^2 = 2.06$, $P \geqslant 0.50$, d.f. $= 3$); thus, results of this analysis do not support the hypothesis that spatial ability is influenced by a sex-linked major gene. Nor is sex linkage indicated by the pattern of correlations for the spatial factor scores. In fact, the highest correlation for AEA families is between mother and daughter and that for AJA families is between father and son. These results suggest that alternatives to the sex-linked, major-gene hypothesis (for example, the sex-modified threshold model[17]) for the inheritance of spatial ability should also be considered.

Relative role of environmental and genetic factors in respiratory adaptation to high altitude

A VARIETY of adaptive mechanisms which aid in the physiological adjustment to the hypoxic environment of altitude have been reported in man[1]. Although visitors to high altitudes increase ventilation in response to environmental hypoxia, natives in the Andes and Himalayas show a blunted or absent ventilatory response to acute hypoxia both at rest and during exercise[2–5]. Adult high altitude natives in the Andes have larger lungs with a greater gas exchange surface, as judged by physiological tests of lung volume and diffusing capacity, than sea level natives or short term visitors at altitude[6–9]. Whether these respiratory adaptations in man are determined solely by environment or relate to genetic traits is uncertain. The age at which these pulmonary adaptations to hypoxia occur is not known, neither is it certain whether migrants to and from high altitude reversibly acquire these physiological changes. To investigate further the mechanism of pulmonary adaptations to chronic hypoxia and to clarify the position of genetic factors in this process, we undertook an expedition to Peru from April to August 1975. Control of ventilation and lung volumes were studied in different age groups, from neonatal period to adulthood, both at high altitude and sea level. It was found that the blunted ventilatory response to hypoxia and large lung volumes developed gradually after birth over a period of many years, and that the phenomena were at least partly reversible at sea level. The results showed that the adaptive response in respiratory physiology were determined by environmental rather than genetic factors.

The high altitude station was in Puno, a town on Lake Titicaca in the Altiplano (3,850 m; barometric pressure = 484 torr; $P_{\mathrm{IO}_2} = 91$ torr) and the laboratory at low altitude was established in Tacna (800 m; barometric pressure = 715 torr; $P_{\mathrm{IO}_2} = 139$ torr). Subjects were selected from the indigenous population of the two areas and from individuals who had migrated to or from high altitude. They were categorised by genetic background, birth place and parents' birth place, and by length of residence at high altitude. Most of the indigenous population of high altitude and migrants from high altitude were Peruvian Indians and those from sea level were mestizos (mixed extraction). Subjects ranged in age from several hours after birth to 50 yr.

The following measurements were made and recorded continuously using a Honeywell ultraviolet polygraph: inspired ventilation by a Fleisch pneumotachograph with integrating circuit; arterial O_2 saturation by Waters Oximeter; end-tidal P_{O_2} with a Beckman O_2 analyser; and P_{CO_2} with Godart capnograph. Neonates and infants were tested using a tight-fitting face mask with minimal dead space while the subjects were asleep in a thermoneutral condition. Children and adults were tested using a mouthpiece and nose clip while they were awake and seated in a chair. Ventilatory sensitivity to hypoxia was measured by both transient and quasi-steady-state techniques[10]. The sensitivity was expressed as the ratio between percentage increase in ventilation and percentage decrease in arterial O_2 saturation. A ratio < 1 indicated blunted hypoxic sensitivity; a ratio of up to 5 indicated intermediate response and > 5 a normal response. Ventilatory response to hypercapnia was studied by the conventional rebreathing technique. Lung volumes were measured by recording the largest of three vital capacity manoeuvres in children and adults, and crying vital capacity was measured in neonates and infants[11].

In 20 full-term highlander neonates < 5 d old, raising the inspired oxygen concentration from ambient (20.9%) to > 60% produced two types of response; an immediate response which was a small decrease in ventilation, followed by a sustained increase during prolonged oxygen breathing. Lowering the inspired oxygen concentration to 12–15% caused a small transient increase in ventilation and then a depression, which was promptly reversed by raising P_{IO_2}. The pattern of responses to alterations in inspired oxygen was similar in 35 full-term neonates studied at a low altitude. All the subjects, however, showed increased ventilation during rebreathing CO_2 in O_2. In infants up to the age of 6 months studied at both high and low altitude, lowering the inspired oxygen concentration produced a sustained increase in minute ventilation which promptly decreased on increasing P_{IO_2}. Thus, hypoxic ventilatory drive matures after birth at high altitude as it does at sea level[12].

Except for one 6-yr-old girl and a boy all 43 children up to the age of 12 yr showed an increase in ventilation with acute hypoxia and a decrease with hyperoxia at high altitude. These responses were similar to those of children studied at low altitude, excluding the two exceptions.

Of the 58 high altitude natives between 13 and 20 yr, ~ 30 showed a normal response, 16 an intermediate response, and 10 a blunted response to hypoxia. Acute hyperoxia depressed ventilation in those subjects who responded well to hypoxia. All 40 adult high altitude natives over the age of 22 demonstrated a blunted ventilatory response to hypoxia. Blunted responses occurred independent of the individual's parentage and genetic background. These results showed that a normal hypoxic ventilatory drive was developed in the natives of high altitude before it was substantially lost during adult life. The hypercapnic response in the adults was near normal.

Table 1 Respiratory adaptation to high altitude

Duration of hypoxia	Ventilatory response to acute hypoxia	Increased vital capacity from predicted sea level values
Birth to 1 week	±	0
2–6 months	+++	0
5–8 yr	++++	+
8–12 yr	+++	++
12–20 yr	++	+++
20–25 yr	+	+++

None of the migrants to high altitude demonstrated a diminished ventilatory response to hypoxia, although the longest period of residence at high altitude in migrants was 6 yr. All but one of the 28 migrants from high altitude to sea level who were less than 12 yr old showed normal ventilatory response to acute hypoxia. Recent migrants more than 15 yr old showed a diminished ventilatory response to hypoxia. These results conform with the findings at high altitude. Adult migrants who had been at sea level for long periods, however, usually showed a normal response to hypoxia, suggesting that the acquired blunted hypoxic response was a reversible phenomenon. Loss and reversal occurred over a prolonged period.

Vital capacity expressed in absolute terms or as ml per kg body weight was similar in 12 high altitude native neonates and in 20 sea level neonates, and was generally within the range of normal predicted values for crying vital capacity data[11]. Crying vital capacity tended to be similar in low and high altitude infants less than 1 yr old. High altitude children between 9 and 13 yr old had vital capacities that averaged 2.87±0.62 l, or 121±13.7% of predicted values based on age and height. The accelerated lung growth curve persisted throughout the teenage years, so that native young adults 18–21 yr old had vital capacities which were 5.05±0.67 l, or 145±16.7% of predicted, whereas vital capacity of sea level controls was 3.73±0.31 l, or 104±8.2% of predicted. The increase above predicted values of vital capacity in highlanders occurred independently of genetic background and place of birth of the parents. Thus, the normal vital capacity that occurs with age was greater at high altitude than at sea level.

In general, individuals of any age who had migrated to high altitude tended to have normal or near normal vital capacities if their stay at altitude was < 3 yr. Those migrants (ages 7, 9, 10 and 18 yr) who had lived at high altitude for more than 4 yr had vital capacities considerably above predicted values.

Thus the ventilatory response to hypoxia and vital capacity are similar in neonates and infants at sea level and at high altitude. Vital capacity tends to increase in the postnatal period and continues to do so throughout the teenage period. The blunted hypoxic response, however, only begins to manifest itself in teenage life, becoming universal in adults.

Our results, which are summarised in Table 1, suggest that the characteristic diminished ventilatory response to hypoxia and large lung volumes found in adult high altitude natives are determined environmentally, rather than genetically. A genetic trait tends to be excluded on the grounds that offspring of lowlanders born and bred at high altitude showed the same phenomena as native highlanders. A similar developmental adaptation of improved physical performance capacity in response to hypoxia has been reported[13].

The similarity in the lack of a sustained hypoxic ventilatory drive in sleeping neonates at sea level and high altitude suggests that the normal hypoxic control of ventilation develops fully only after birth. A reflex hypoxic drive is thus of limited value for survival in newborns at high altitude. In addition, newborns at low and high altitude have similar ventilatory control mechanisms and lung volumes, suggesting that no genetic or intrauterine adaptive changes occur in these parameters in preparation for life at high altitude. Appropriately, however, an increase in placental surface area relative to the body weight of the foetus occurs at high altitude[14]. It is presumably only after birth that high altitude neonates are exposed to a greater hypoxic stimuli than at sea level. The adult pattern of responses and adaptations to hypoxia begins to develop shortly after birth. In teenage life a variety of effective gas transport adaptations develop, such as the increased area for gas exchange provided by large lungs, and ventilatory hypoxic drive assumes a less important role.

The expedition was supported in part by a grant from the US Public Health Service. S.L. acknowledges advice and encouragement from Dr Alfred P. Fishman.

Elimination of aziridine residues from chemosterilised mosquitoes

CRITICISM[1–4] of the use of the alkylating agent thiotepa (triethylene thiophosphoramide) to sterilise mosquitoes, as part of an eradication programme in India, focused on its toxicity and the possibility that it or its breakdown products would harm other animal components of the food chain. For example, a Canadian team found reduced fertility in spiders fed on mosquitoes sterilised with thiotepa[5]. Some means was needed to ensure that no aziridine residues—breakdown products of thiotepa—remain in the insects after release into the environment. We have now achieved this, essentially by dipping the chemosterilised insects into acid and then alkaline solutions.

Complete breakdown of 3.1% thiotepa solution has been reported to occur in 90 min at *p*H 4, but aziridine activity persists for 24 h. This is due to the production of ethyleneimine which is stable in acid medium and tends to accumulate. Ethyleneimine is cytotoxic and mutagenic and may in some cases be carcinogenic[6] and therefore potentially hazardous. It breaks down to non-aziridine compounds at *p*H 9 (ref. 7).

The decomposition of thiotepa in acid medium was monitored by bioassay. A 0.6% solution was prepared in 0.01 N H_2SO_4, *p*H 1.8–2.0, and *p*H 3 was maintained by addition of small increments of N H_2SO_4 for 90 min. A hundred mosquito pupae (*Culex pipiens fatigans*) were placed in this solution for 3 h, washed twice in tap water and held in cages at 28–29 °C and 75% relative humidity until emergence. An equal number of virgin females was introduced into the cages and egg rafts were collected for routine bioassay. Fifty rafts, scored for percentage hatch, gave 92.7% fertility, whereas the controls dipped in water and in 0.6% thiotepa (*p*H 8) showed 94.9% and 0.01% fertility, respectively. Breakdown of thiotepa was complete in acid solution and the main decomposition product, ethyleneimine, proved inactive as a sterilant for *C. p. fatigans*. Therefore dipping sterilised pupae in acid solution (0.0025 N H_2SO_4, *p*H 2.6–2.8) for 90 min would ensure complete decomposition of thiotepa to ethyleneimine. Although no appreciable accumulation of ethyleneimine is likely, traces present as the intermediate decomposition product in sterile males may contaminate the environment. Ethyleneimine is hydrolysed to deuteriophosphoric acid and D_2NCH_2-CH_2OD, and this conversion can be accelerated by dipping acidified pupae in alkaline solution, *p*H 9 (ref. 7), thus making the mosquitoes free of any traces of aziridine compounds.

We tested the biological fitness of sterile male *C. p. fatigans* produced when pupae were dipped in 0.6% thiotepa, *p*H 8, for 3 h, washed twice in tap water, dipped in 0.0025 N H_2SO_4 for 90 min, washed in tap water, dipped in alkaline solution, *p*H 9.1–9.4, for 90 min, washed and transferred to tap water for emergence. No pupae died after this treatment. To assess survival, 100 sterile and 100 normal males were held in cages (ten replicates) and offered water-soaked raisins daily. The number of mosquitoes found dead in each cage was recorded at 24-h intervals. Weekly (%) mortality of sterile males averaged 1.9, 12.7 and 17.4 (cumulative total 32.2 in 3 weeks) and controls averaged 3.6, 13.2 and 20.3 (cumulative total 37.1 in 3 weeks). Thus the treatment had no effect on the longevity of the mosquitoes.

Sterile males were also tested for mating competitiveness. In ten laboratory cages, 100 sterile and 100 normal, 1-2-d-old males and 100 virgin, 2-d-old females were fed on raisins and allowed to mate for 4 d. They were offered pigeons for a blood meal. A total of 622 egg rafts was collected, of which 327 were sterile. As sterility averaged 52.57%, sterile males proved competitive.

Thus residues of thiotepa, and other aziridine compounds can be eliminated from sterile mosquitoes by dipping them in acid and alkaline solutions. Residue-free emergent adults survive well for at least 3 weeks. As sterile males compete favourably with normal males in the insemination of females, mass release of these sterile males for population control would not be hazardous to the food chain and would not contaminate the environment directly or indirectly.

Augmentation of human monocyte chemotactic response by levamisole

THE antihelminthic drug, levamisole ((−)-tetramisole) has been shown to possess potent immunostimulatory properties as demonstrated by its ability to enhance delayed hypersensitivity responses in aged individuals and in patients with cancer[1,2]. In addition, animals treated with (−)-tetramisole have heightened activity of their reticuloendothelial systems as measured by clearance of carbon particles and phagocytosis of sensitised sheep erythrocytes[3,4]. Although the mechanism of action of levamisole remains obscure, its pharmacological properties suggest that it may affect macrophage function and as such could be a useful tool to probe the pathophysiology of this cell. This report describes the effect of (−)-tetramisole and its isomers on monocyte chemotaxis *in vitro*, and demonstrates a potential mechanism of action for these drugs as well as their usefulness for delineating mechanisms of leukocyte chemotactic responsiveness.

Human monocyte chemotaxis was assayed *in vitro* by a minor modification of a previously described technique[5]. Briefly, peripheral blood monocytes were isolated on Ficoll–Hypaque gradients, washed extensively, and resuspended to contain 1.5×10^6 monocytes ml^{-1} in medium RPMI 1640 (Grand Island Biological Company, Grand Island, New York). Cell suspension (0.4 ml) was placed in the upper compartment of a modified Boyden chamber and separated from the chemotactic or control stimulant in the lower compartment by a 5.0-μm polycarbonate (Nuclepore) filter. After incubation for various times at 37 °C in humidified air, the chambers were emptied, the filters removed, fixed in ethanol and stained with haematoxylin. Chemotactic response was assessed by counting and averaging the number of cells which migrated completely through the filter per microscopic field in 20 oil immersion fields (×1,540). All assays were carried out in triplicate, each experiment repeated at least twice with cells from different donors and a single representative experiment presented.

Human polymorphonuclear leukocyte (PMN) chemotaxis was quantified similarly[6]. PMNs were isolated from whole blood by sedimentation with 3% Dextran in saline, washed extensively, and resuspended to 2.2×10^6 PMN ml^{-1} in Gey's balanced salt solution (BSS) containing 2% bovalbumin (Flow Laboratories, Rockville, Maryland), *p*H 7.2. A 5.0-μm nitrocellulose filter (Millipore) was used to separate the upper and lower compartments of the chemotaxis chambers. After incubation for 3 h at 37 °C, the filters were processed as described previously[6]. Chemotactic response was expressed as the average number of PMNs migrating completely through the filter per field in 20 high power fields (×780).

To determine the effect of (−)-tetramisole, its stereoisomer, (+)-tetramisole, and *p*-Br-(−)-tetramisole (Janssen, Beerse, Belgium) on monocyte chemotaxis, the isolated cells were incubated with various doses of the drugs contained in RPMI 1640 or with medium alone, and tested for chemotactic response to lymphocyte-derived chemotactic factor (LDCF), endotoxin-activated human serum (AHS) or to the chemotactically active peptide, *N*-formyl-methionyl-phenylalanine (f-met-phe)[7]. Table 1 illustrates that doses of (−)-tetramisole ranging from 10^{-5}–10^{-3} M enhanced the chemotactic response of monocytes to the three chemotactic factors by 20–148%. Similar doses of (+)-tetramisole had no significant ($P > 0.2$) effect on monocyte chemotactic responsiveness to LDCF. Cells incubated with *p*-Br-(−)-tetramisole (10^{-6}–5×10^{-5} M) also exhibited an increased chemotactic response to LDCF; however at doses higher than 5×10^{-4} M, *p*-Br-(−)-tetramisole depressed chemotaxis and was toxic to the monocytes as judged by Trypan blue exclusion. The effect of (−)-tetramisole was removed by washing the cells extensively after a 30-min incubation with the drug. Enhanced monocyte chemotactic responsiveness was not seen when (−)-tetramisole was placed in the lower compartment of the chemotaxis chamber and incubated with the chemotactic factors rather than with the cells. These data indicated that (−)-tetramisole exerts its effect primarily on the monocyte, and that enhancement of monocyte chemotactic responsiveness by (−)-tetramisole is stereospecific.

To determine whether enhancement of monocyte chemotaxis by (−)-tetramisole required binding of the drug to the monocytes, cells were incubated with medium containing various doses of (−)-tetramisole alone or with medium containing (−)-tetramisole plus (+)-tetramisole, and tested for chemotactic response to LDCF. Figure 1 illustrates that doses of 10^{-4} and 10^{-3} M (+)-tetramisole reduced the enhancing effect of (−)-tetramisole. The parallel nature of the curves indicated that (+)-tetramisole inhibited the enhancing activity produced by (−)-tetramisole by competitive binding (k_D for (−)-tetramisole$=1 \times 10^{-4}$; k_D for (+)-tetramisole$=0.8 \times 10^{-4}$). To ascertain whether (−)-tetramisole increased the rate of cell migration or the total number of cells capable of responding to a given dose of chemotactic factor, monocytes were incubated (37 °C for 30 min) with RPMI containing 10^{-3} M (−)-tetramisole or with medium alone, and the number of cells responding to LDCF determined after various times of incubation in the chemotaxis chambers. Figure 2 illustrates that (−)-tetramisole increased both the rate of monocyte chemotactic responsiveness and the maximum number of cells responding chemotactically. .

We next determined whether (−)-tetramisole exerted an effect on another type of cell capable of responding chemotactically. Human PMNs were incubated with Gey's BSS

Table 1 Effect of isomers of tetramisole on human monocyte chemotactic response

Monocytes incubated with*	Chemotactic activity† of monocytes in response to: LDCF‡	AHS‖	f-met-phe¶

*Human monocytes were isolated on Ficoll–Hypaque gradients, washed extensively, and resuspended (1.5×10^6 ml^{-1}) in medium containing various molar concentrations of the indicated isomers of tetramisole or in medium alone. After incubation (37 °C for 30 min) the monocytes were placed in the upper compartment of a modified Boyden chamber and tested for chemotactic response.

†Chemotactic activity is expressed as the average number of monocytes in triplicate samples migrating completely through a 5.0 μm polycarbonate filter per oil immersion field (×1,540) ± s.e.m.

‡Lymphocyte derived chemotactic factor (LDCF) was obtained from supernatants of concanavalin A-stimulated lymphocyte cultures. LDCF was diluted to 15% v/v in RPMI 1640 for use as a chemotactic stimulant.

‖Activated human serum (AHS) was prepared by incubation of normal serum with *S. typhosa* endotoxin (1 mg ml^{-1} serum) for 60 min at 37 °C followed by 56 °C for 30 min. AHS was then diluted to 0.5% v/v in RPMI 1640 for use as a chemotactic stimulant.

¶f-met-phe was diluted to 10^{-6} M ml^{-1} RPMI 1640 for use as a chemotactic stimulant.

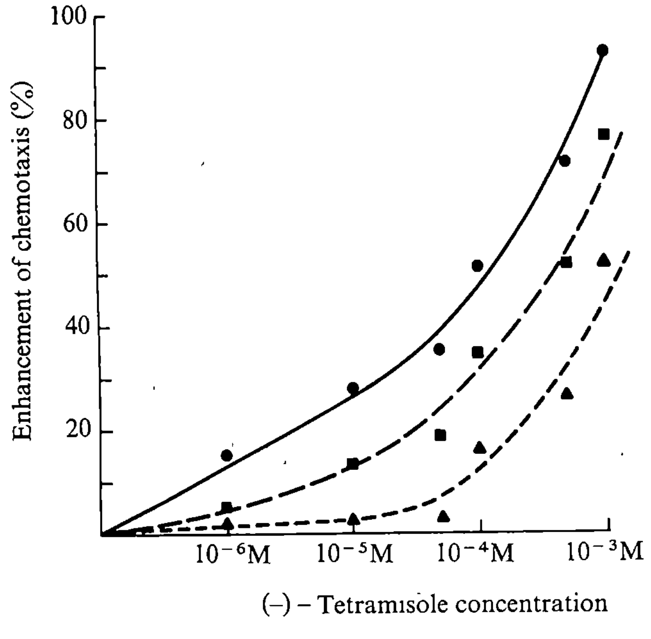
containing 10^{-3}–10^{-6} M (—)-tetramisole or with medium alone and tested for chemotactic responsiveness to various doses of AHS or to f-met-phe. At the doses tested, (—)-tetramisole had no effect on PMN chemotactic response to the two chemotactic factors, indicating a differential effectiveness of the drug for monocytes.

The above results demonstrate that (—)-tetramisole and *p*-Br-(—)-tetramisole exert stimulatory effects on human monocyte chemotactic response by increasing both the rate of cell migration and the total number of cells capable of responding to a given dose of chemotactic factor. In addition, it seems that the enhancing effect is stereospecific and that the drug must bind to the monocytes since addition of the dextroisomer competitively inhibited the enhancing effect of (—)-tetramisole. Both isomers have approximately the same dissociation constant for monocyte binding ($k_D \sim 10^{-4}$).

Our data demonstrate that (—)-tetramisole stimulates the unidirectional migration of monocytes in response to a given number of chemotactically active molecules. The ability of (—)-tetramisole to enhance monocyte chemotactic function might be one mechanism by which it augments immunological response *in vivo* The mechanism of action of (—)-tetramisole on human monocyte chemotaxis has not yet been determined but it could affect binding of chemotactic factors to the monocyte or the translation of the chemotactic factor–monocyte interaction into a directional cell movement. Little information concerning the mechanism by which chemotactic factors induce unidirectional leukocyte migration is available. The stereospecificity as well as cell-type specificity of the effect of (—)-tetramisole indicate that this drug has differential cell membrane effects on chemotactically responsive cells. This drug and its isomers can therefore be useful tools in delineating mechanisms of unidirectional cell migration.

Fig. 1 Competitive inhibition of the enhancing effect of (–)-tetramisole on monocyte chemotactic response to (+)-tetramisole. Isolated monocytes were incubated (37 °C for 30 min) with medium containing 10^{-3}–10^{-6} M (–)-tetramisole alone (●), or with 10^{-3}–10^{-6} M (–)-tetramisole plus 10^{-3} M (▲) or 10^{-4} M (+)-tetramisole (■), and tested for chemotactic responsiveness to LDCF (15% v/v). k_D for (–)-tetramisole = 10^{-4}; k_D for (+)-tetramisole = 0.8×10^{-4}. % Enhancement =

$$\left(\frac{\text{Chemotactic responsiveness of cells incubated with drugs}}{\text{Chemotactic responsiveness of cells incubated with medium alone}} - 1\right) \times 100.$$



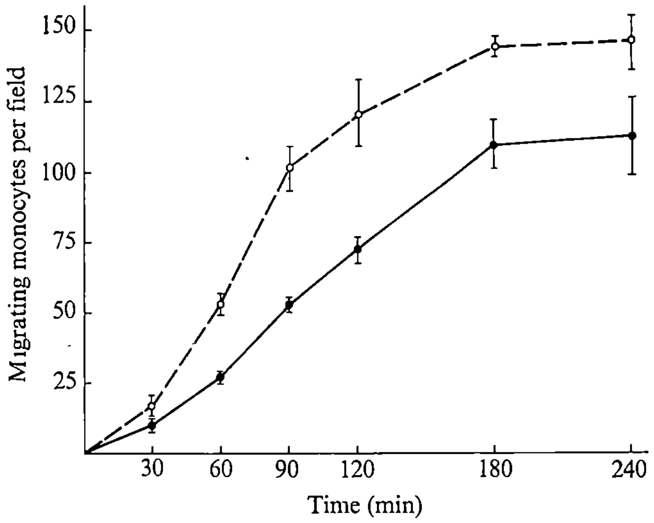


Fig. 2 Kinetics of enhancement of monocyte chemotactic response to (–)-tetramisole. Isolated monocytes were incubated (37 °C for 30 min) with medium alone (●) or containing $10^{-}\mathrm{M}^{3}$ (–)-tetramisole (○), and tested for chemotactic response to LDCF (15% v/v) after the indicated incubation time in the chemotaxis chamber. Vertical bars indicate s.e.m. for triplicate samples.

A new differentiation antigen defining a subpopulation of mouse T cells

IT is generally accepted that lymphocyte reactions such as the mitogenic response to concanavalin A (con A) and phytohaemagglutinin (PHA), the graft *versus* host (G*v*H) reaction, the helper effect in the antibody response and cell-mediated cytotoxicity (CMC) all involve the activity of thymus-derived lymphocytes (T cells). Because of the paucity of techniques for identifying cells with different functions, however, very little is known about the identity and relationships of T cells involved in these reactions.

In the mouse, a convenient way of identifying functionally distinct subpopulations of T cells has been described by the demonstration that Ly antigens can be used to distinguish between such subpopulations[1,2]. Here we describe an antigenic marker that enables the distinction between cytotoxic ('killer') T cells from T cells involved in the above reactions. Following examples of other previously described differentiation antigens demonstrated by heteroantisera (that is, MBLA[3], MSPCA[4] and MSLA[5]) we have tentatively

Table 1 Suppression of CMC function of spleen cells (SPC) and non-adherent peritoneal cells (NAPC) from H–2-primed donors by pretreatment with Ra-*nu*/*nu* and Ly 3.2 antisera and complement (C)

Cells*	Pretreatment†	CMC‡ c.p.m.	CMC‡ %	CMC‡ % Reduction
Non-immune SPC	Diluent only	2,657	0	—

Immune SPC	Ra-*nu*/*nu*+C	2,447	8	91
Non-immune NAPC	Diluent only	8,565	0	—
Immune NAPC	Diluent only	1,072	87	—
Immune NAPC	Normal rabbit serum+C	1,178	86	Standard
Immune NAPC	Ra-*nu*/*nu*+C	6,992	18	80
Immune NAPC	Normal mouse serum+C	1,255	85	Standard
Immune NAPC	Anti Ly 3.2+C	7,043	18	80
(Immune NAPC Ra-*nu*/*nu*+C)+(Immune NAPC anti-Ly 3.2+C)		6,900	19	77

*B6 donors received a single subcutaneous injection of 2×10^7 BALB/c Meth A sarcoma cells (immune SPC) or multiple intraperitoneal injections of 5×10^6 BALB/c (immune NAPC) or B6 syngeneic (non-immune) spleen cells. SPC were collected 10 d after an injection and NAPC 3 d after the last injection of four consecutive weekly injections.

†For pretreatment, equal volumes of cells (10^7 ml^{-1}), antiserum (Ra-*nu*/*nu* diluted 1:2, anti-Ly 3.2 diluted 1:15) and complement (C; guinea pig serum at 1:3 with Ra-*nu*/*nu* antiserum and rabbit serum at 1:15 with Ly 3.2 antiserum) were incubated in 5% CO_2 in air for 45 min at 37 °C The cells were then washed twice and resuspended in culture medium with or without adjustments to the same concentration of viable cells: in all cases similar results were obtained. Earle's balanced salt solution with 2.5% foetal bovine serum and 5×10^{-5} M 2-mercaptoethanol was used for cell preparation and as diluent for antisera and C.

‡^{3}H-proline CMC microassay[21], in which the radioactivity of surviving attached monolayer target cells is measured. Washed SPC or NAPC (pretreated as described above; 10^5 per well) were added to a ^{3}H-proline labelled monolayer of BALB/c sarcoma cells (10^3 per well) for 12 h. CMC percentage and percentage reduction of CMC were calculated as described previously[10].

called the antigenic determinant(s) present on cytotoxic T cells, mouse killer T-cell antigen (MKTCA).

The antiserum was prepared by intravenous immunisation of a New Zealand rabbit with spleen cells of *nu*/*nu* mice, known to be deficient in thymus and T cells[6] but not in T-cell precursors[7,8]. Male *nu*/*nu* mice that served as donors of SPC were derived from a stock that has undergone 4–5 backcrosses to BALB/c mice. The inoculation of 1.7×10^8 *nu*/*nu* SPC was followed 7 d later by additional inoculation of $7 5\times10^8$ cells. The rabbit was bled 1 week after the second inoculation. The serum was heat inactivated for 30 min at 56 °C, diluted 1 : 4 with medium 199 and absorbed repeatedly *in vitro* for 30 min on ice with 10–20% (v/v) of packed cells. After one absorption with erythrocytes and one with thymic leukaemia EL4, six consecutive absorptions with thymocytes of different strains were carried out to remove activity against thymocytes as assessed in complement (C)-dependent cytotoxicity assay[9]. Absorbed antiserum, now called Ra-*nu*/*nu* was divided into small aliquots and kept at −70 °C until used.

Our earlier work[9] established that Ra-*nu*/*nu* antiserum possesses two different specificities. In addition to activity against bone marrow-derived lymphocytes (B cells) as demonstrated by inhibition of IgM plaque-forming cells and by cytotoxicity against myelomas, the antiserum has strong activity against cytotoxic T cells[9]. Activity against B cells can be absorbed with foetal liver cells but not with lymph node cells[9] and activity against cytotoxic T cells can be absorbed with lymph node cells but not with foetal liver cells and thymocytes (see below).

Results of typical experiments demonstrating strong inhibition of CMC by pretreatment with Ra-*nu*/*nu* antiserum and C of alloimmune spleen cells and non-adherent peritoneal lymphocytes are shown in Table 1. T-cell dependence of CMC is indicated by the strong suppression of the reaction by pretreatment with anti-Ly 3 serum (specificity anti-Ly 3.2), which is specific for alloimmune cytotoxic T cells[10,11]. We have shown previously[10] that inhibition of CMC in our system is due to the elimination of T cells with antibody and C, and not to the nonspecific blocking by antigen–antibody complexes which may be operative in systems measuring non-T cell killing[12]. Moreover, the elimination of B cells by pretreatment with various anti-B-cell specific sera and C, had no effect on CMC (H. S., unpublished). It might be argued, however, that cooperation of other cells is necessary for CMC and that inhibition of the reaction by Ra-*nu*/*nu* antiserum and C is due to elimination of the accessory non-T cells. The failure to reconstitute CMC by mixing cells pretreated with anti-Ly 3 serum and C with cells pretreated with Ra-*nu*/*nu* antiserum and C (compare line 11 with lines 8 and 10) rules out this possibility and indicates that cells sensitive to both antisera belong to the same subpopulation of T cells. The evidence that Ly 3 and MKTCA antigens are not the same comes from absorption experiments reported below.

In contrast to killer T cells, those carrying out the other functions tested remained unaffected by pretreatment with Ra-*nu*/*nu* antiserum and C. Table 2 shows results demonstrating the lack of inhibition of helper effect. This lack of inhibition was similarly observed in the case of the mitogenic response of spleen cells to PHA and con A and in the case of the G*v*H reaction of parental spleen cells injected into newborn F$_1$ hybrids (data not shown). Each function was tested in two or more independent experiments; in all cases similar results were obtained. These results indicate that killer cells differ in their surface antigenic properties from T cells cooperating with B cells in the antibody response, from cells responsible for G*v*H reactions and from cells responding to PHA and con A. This confirms and extends the evidence[1,11,13–16] that cells

*Three B6 mice were injected intravenously with 0.1 ml 0.01% (v/v) sheep red blood cells (SRBC) After 4 d their spleens were pooled and pretreated with sera and C as described. Mishell–Dutton-type cultures were prepared containing increasing numbers of these pretreated primed cells (as indicated) with unprimed cells maintaining constant total 10^7 cells per culture. The cultures were sensitised with trinitrophenyl (TNP)-conjugated SRBC and assayed 4 d later for TNP-specific plaque-forming cells (TNP–PFC)[22]

†See Table 1.

causing CMC belong to a distinct subpopulation of functional T cells.

To determine the tissue distribution of MKTCA, absorption experiments were carried out. Results are summarised in Table 3. They show that MKTCA is present on cells from the lymph nodes and bone marrow of normal mice, as well as on spleen cells from *nu/nu* mice. It is absent, however, from normal foetal liver cells and thymocytes. This pattern of tissue distribution is different from that of Ly 3 alloantigen[17], indicating that although both antigens are characteristic of alloimmune killer cells, they are not the same. The relationship of MKTCA and Ly 3 antigens to Ka—another heteroantigen present on alloimmune killer cells[18]—is not known, as no other functional T cells have been examined for the presence of this antigen.

Table 3 Summary of absorption experiments with Ra-*nu/nu* antiserum showing the distribution of MKTCA antigen in lymphoid and haemopoietic tissues

Cells from	No. of cells used for absorption*	% Reduction in CMC†	Result of absorption
Thymus	5×10^8	72	–
Lymph nodes	5×10^8	9	+
Bone marrow	2.5×10^8	–2	+
nu/nu spleen	3.5×10^8	–16	+
Foetal liver	3.5×10^8	88	–

*Ra-*nu/nu* antiserum (0.5 ml) was absorbed with indicated number of cells for 30 min on ice. After absorption serum was diluted 1:2 and tested against non-adherent peritoneal cells (NAPC) from H-2-primed mice as described in Table 1.

†Mean value calculated from two to three experiments.

It is known that bone marrow from normal adult mice as well as spleen cells from *nu/nu* mice contain precursors of T cells[7,8,19]. Thus the ability of cells from these tissues to absorb anti-MKTCA activity suggest that the antigen is also present on the prethymic precursors of killer T cells.

Differentiation of T cells is generally depicted as involving transformation of prethymic cells to immunoincompetent thymocytes, which themselves are precursors of functionally mature, immunocompetent T cells[20]. The absence of MKTCA from thymocytes thus raises several possibilities which may have implications for the understanding of differentiation pathways of killer T cells. MKTCA should therefore prove to be a useful marker for further delineation and clarification of the differentiation stages involved in the process of generation of functionally distinct subpopulations of T cells. Although the majority of functional assays were carried out with cells of B6 mice, preliminary experiments in BALB/c mice and the fact that the antiserum has been produced in a heterologous system suggest that MKTCA is also characteristic of killer T cells of other strains.

We thank Dr E. A. Boyse for *nu/nu* mice and anti-Ly 3.2 serum. This work was supported by a WHO fellowship (P. K.), the Cancer Research Institute (H. S.) and the National Cancer Institute.

Virus-specific T-cell-mediated cytotoxicity across the H–2 barrier to virus-altered alloantigen

ALTHOUGH the biological function of the structures coded in the major murine histocompatibility (H–2) gene complex is poorly understood, some of these structures are crucially involved in most, if not all, cell-mediated immune functions[1,2]. To express their immunological function, thymus-derived lymphocytes (T cells) from conventional mice and the cells with which they interact must share part of the H–2 gene complex. T helper cells and bone marrow-derived lymphocytes (B cells) usually must be compatible for the *I* region of H–2 (ref. 3) to act cooperatively in T-cell dependent antibody responses. This region codes for Ia cell surface antigens and immune response (*Ir*) genes. Also, delayed type hypersensitivity to fowl γ-globulin can be transferred adoptively to intact mice only within *I*-region compatible donor-recipient combinations[4]. Distinct from these models, virus-immune T cells lyse virus-infected target cells *in vitro* only when both are compatible at the *K* and/or *D* regions of H–2 (refs 5–7). *I*-region compatibility is neither necessary nor sufficient on its own. Also T-cell-mediated lysis of chemically modified targets[8] and cytotoxicity against cells expressing either the minor histocompatibility antigens[9] or the male Y antigen[10] are similarly restricted.

Two probably mutually exclusive hypotheses have been proposed to explain this apparent restriction[5,6]. First, according to the 'physiological interaction' hypothesis, T cells specifically recognise antigens on the target cell surface; however, for cooperation or lysis to occur, self to self-like interactions are necessary. The structures responsible for such physiological interactions would have to be coded in the *I* region of H–2 for T helper cell functions[3], but in *K* and *D* for cytotoxic interactions[5,6]. Second, the altered self hypothesis proposes that T cells interact with other cells exclusively by way of the immunologically specific T-cell receptor. For cytolytic interactions this receptor is specific for virally, or for chemically or genetically (alloantigens), altered self structures coded in *K* and *D* regions (refs 5 and 6). On T helper cells this receptor may be specific for antigen-altered structures which are coded in the *I* region of H–2.

Most of the experimental evidence—at least that derived from competitive inhibition experiments *in vitro*[5] using the murine lymphocytic choriomeningitis virus (LCMV) model, selective proliferation studies *in vivo*[5] and experiments with H–2 mutant mice[1,12]—is explained best by the altered self idea. Also, cytotoxic activity against alloantigens (being a form of altered self) could be accommodated readily within this concept[5,6,12]. A physiological interaction hypothesis, however, is a possible explanation if the expression of physiological interaction structures is controlled by very complex genetic regulatory mechanisms[11,12].

If virus-specific cytotoxic T cells are specific for altered self,

[*] Mice were obtained from Jackson Laboratories, Bar Harbor, Maine and used at 7–10 weeks of age. (C3H×DBA/2) F_1 were irradiated with 900 r and reconstituted with 2×10^7 anti-θ+C′-treated C3H bone marrow cells Chimaeras were infected intravenously with 10^3 intracerebral LD_{50} of the WE strain of LCMV 11 weeks later. 7-d immune spleen cells were used.

[†] Anti-H–2 sera were obtained by hyperimmunising B10 BR ($H–2^k$) mice with B10.D2 ($H–2^d$) spleen cells and vice versa. Both antisera killed > 90% specifically when assayed at a 1:30 dilution and 5×10^6 spleen cells ml^{-1}. A selected rabbit complement was used unabsorbed at a 1:8 final concentration. After the treatment viability was determined by Trypan blue exclusion. The antisera were used at a 1:3 final dilution and 5×10^6 spleen cells ml^{-1}. The anti-H–2 sera were highly specific as indicated by the percentage of dead cells found after treatment. Cells were resuspended according to the original viable cell concentration before treatment (groups none) and assayed. Decrease of activity by nonspecific antiserum+C′ was not different from that caused by normal control serum+C′.

[‡] ^{51}Cr release assay was carried out as described previously[5,6]; J774 target cells were provided by Dr M. Bevan, Salk Institute, La Jolla, California. Spleen cells were assayed at the spleen cell–target ratios of 10:1 and 3:1 for 12 h at 37 °C; results are means of triplicates; s.e.m. was 0.4–1.5 for L929 cells and 0.7–2.4 for J774 cells. LCMV-immune spleen cells tested on infected targets caused statistically significant ^{51}Cr release when compared with release from normal targets or with the activity of normal spleen cells.

it should be possible to sensitise T cells specifically to virus-altered alloantigen across the H–2 barrier. This report demonstrates that virus-specific cytotoxic T cells from chimaeric mice can lyse across the H–2 barrier only those infected allogeneic targets to which they are tolerant. Thus, reactivities to virus-specific altered self, to virus-altered alloantigen or to alloantigen itself are obviously comparable[5,6,12].

To overcome the strong normal reactivity to alloantigens that could mask potential but experimentally undetectable reactivity for virus-altered alloantigen, alloantigen tolerant P→F_1 hybrid irradiation chimaeras reconstituted with bone marrow of one parent were used[13]. LCMV-infected C3H→(C3H×DBA/2) F_1 chimaeras generated cytotoxic T cells, with exclusively $H–2^k$ surface characteristics, which lysed

[*] Mice, immunisation and antisera, see Table 1. AKR anti-θ C3H was purchased from Bionetics, Kensington, Maryland 20795 (Cat 8301-01, Lot No 231-61-5) With a selected rabbit complement C′ thymocytes were lysed to 50% at a 1:40 dilution of the anti-θ antiserum. The antiserum was used at a 1:8 final dilution In these conditions anti-SRBC PFC were not lysed[5].

[†] The cytotoxicity assay was carried out as described previously[5,6]. Spleen cells were assayed at a 30:1 ratio for 6 h at 37 °C. Results are means of triplicates; s.e m were 0.3–0.9 for L929, 0.5–1.7 for J774 and 0.9–2.2 for C57BL/6 macrophage targets. LCMV-immune spleen cells caused statistically significant lysis of H–2 compatible or the tolerant H–2 haplotype targets; treatment with irrelevant anti-H–2 antiserum+C′ or control sera + C′ did not cause loss of activity Treatment with AKR anti-θ C3H+C′ or with the relevant anti-H–2 antiserum abolished all activity; residual activity was not significantly different from normal spleen cells on infected targets.

[‡] Peritoneal macrophages from normal mice were used as targets as described previously[5].

virus-infected H–2^d target cells but not uninfected H–2^d targets (Table 1). These T cells are tolerant for H–2^d, but can readily react to virus-altered alloantigen. Comparable results were obtained in separate experiments with five C3H→(C3H×DBA/2)F$_1$, some infected with vaccinia virus instead of LCMV (R.M.Z., unpublished). The cytotoxic effector cells of H–2^k type from chimaeric mice are T cells, as shown by their susceptibility to AKR anti-θ C3H+complement treatment (Table 2). This notion is further supported by the fact that they lysed infected target cells of the tolerant allogeneic parental H–2^d type but were still H–2 restricted in that they could not lyse infected targets of an unrelated allogeneic H–2^b haplotype (Table 2). These results add strong circumstantial evidence in favour of the altered self hypothesis. Our data suggest that altered self, alloantigen, and altered alloantigen are comparable antigens, since all are attacked by T cells because they differ from the normal unaltered cell-surface self marker.

The interaction model has been extended to accommodate similar findings in which T helper cells from chimaeric mice collaborated with H–2*I* region-incompatible B cells[13,14]. In this case, structures of T cells that interact with H–2-incompatible cells may be allowed to differentiate according to the H–2 environment in which they circulate in tolerant conditions[15]. To accommodate the crossing of the H–2 barrier by LCMV or vaccinia immune T cells of chimaeras, interaction structures on these T cells for the tolerant H–2 haplotype could, theoretically, have undergone similar adaptive differentiation. Such a mechanism, however, in addition to the complex genetic controls previously mentioned[11,12] seems to be very complicated. The concept that cytotoxic T cells are specific for altered cell-surface markers coded in *K* or *D* of H–2, and that T helper cells may be specific for antigen-altered cell surface structures coded in the *I* region, seems to be the simplest and most generally applicable explanation. Nevertheless, the physiological interaction idea cannot be disregarded until either altered *K*- or *D*-coded structures or physiological interaction structures are defined biochemically.

I am grateful to Dr Frank Dixon for comments, continuous encouragement and support and I thank Miss Alana Althage, Mrs Jeanine Gouveia and Mrs Phyllis Minick for assistance. This work was supported in part by the US Public Health Service.

Cytotoxic T lymphocytes recognise allogeneic tolerated TNP-conjugated cells

DURING a cytotoxic response, T cells can recognise and react to cell-associated virus antigens[1], minor histocompatibility antigens[2,3] or trinitrophenyl(TNP)-conjugated cell-surface components[4] only when responder, stimulator and target cells share either K- or D-region determinants of the major histocompatibility complex (MHC). Two possible explanations for these observations have been discussed: first, cytotoxic T cells recognise non-H–2 antigens but to lyse targets they have to interact with self antigens controlled by the MHC on stimulator and target cells (cell-interaction determinants), and second, T-cell clones recognise and react to new antigenic determinants created by the association of MHC gene products with non-H–2 antigens. We present evidence here that T cells which have matured in a semi-allogeneic environment can recognise, in a specific way, TNP in association with tolerated allogeneic cells not sharing *H–2K* or *H–2D* loci with the responding cells.

DBA/2 T cells, tolerant to CBA/J alloantigens were obtained from chimaeric mice, produced by injecting anti-θ-treated DBA/2 bone marrow cells into 900-R irradiated F$_1$ (CBA/J×DBA/2) hybrids (DBA → CBA F$_1$– chimaeras)[5]. Five months after irradiation, chimaeric mice as well as (CBA/J×DBA/2) F$_1$ hybrids were immunised with TNP-conjugated CBA spleen cells (TNP–CBA). TNP was conjugated to either spleen cells or ^{51}Cr-labelled LPS blasts according to a slight modification of the method of Shearer *et al*[4], using a cacodylate buffer, *p*H 7.3, containing 10 mM 2,4,5-trinitrobenzene sulphonate (1 ml per 10^8 viable nucleated cells).

The *in vitro* assay of cell-mediated lympholysis (CML)[6] as well as the assay for testing the lymphoid cell chimaerism of bone marrow chimaeras[7] have been described before.

Using H–2^k anti-H–2^d and H–2^d anti-H–2^k sera the lymphoid cell chimaerism of DBA → CBA F$_1$ chimaeras was tested. As Table 1 shows, all cells from lymph nodes were killed by anti-H–2^d sera whereas no killing above background was observed with anti-H–2^k sera, indicating the absence of F$_1$ hybrid host cells.

Table 1 Killing of cells

	Incubation with		
Lymph node cells	Anti H–2^k + C′	Anti H–2^d + C′	Saline + C′
DBA/2	5%	97%	8%
(CBA×DBA/2) F$_1$	83%	96%	9%
Chimaera CBA → DBA F$_1$	8%	97%	9%

To test the reactivity of cells from DBA → CBA F$_1$ chimaeras as well as from (CBA/J×DBA/2) F$_1$ hybrids in CML, spleen cells were prepared and restimulated with either TNP–CBA stimulators or stimulated with SJL (H–2^s) cells *in vitro*. After 5 d, cultures were tested for cytotoxicity directed against TNP–CBA, CBA, TNP–DBA/2 or SJL ^{51}Cr-labelled target cells. (CBA/J×DBA/2) F$_1$ cells restimulated *in vitro* with TNP–CBA lysed TNP–CBA targets (Fig. 1*a*) but neither CBA, TNP–DBA/2 nor SJL targets (Fig. 1*b–d*). The same responder cells stimulated *in vitro* with SJL cells lysed SJL targets but not CBA targets and to some extent also TNP–CBA and TNP–DBA/2 targets. This apparently nonspecific lysis of TNP-conjugated targets by cell suspensions containing high levels of cytotoxic activity has been found consistently, regardless of the strain combinations used. This is probably caused by nonspecific adherence of cytotoxic T cells to TNP-coupled targets. The assumption is supported by the fact that TNP–CBA-induced cytotoxic lymphocytes do not lyse non-conjugated target cells as SJL target cells (Fig. 1*d*). A result basically similar to that with TNP–CBA-primed F$_1$ responder cells was obtained with spleen cells from a DBA→CBA F$_1$ chimaera. Restimulation with TNP–CBA *in vitro* induced cytotoxic activity directed against TNP–CBA (Fig. 2*a*) but neither CBA, TNP–DBA/2 nor SJL targets (Fig. 2*b–d*). Stimula-

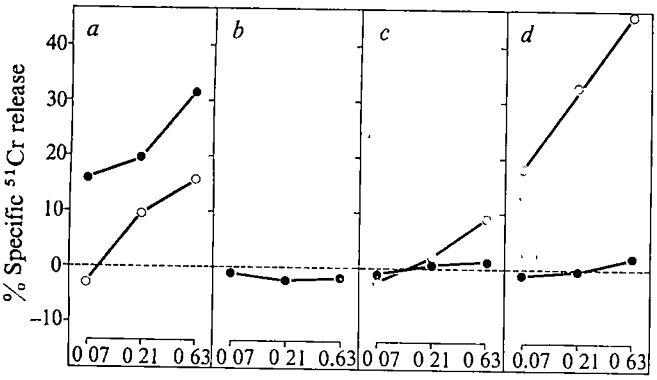

Fig. 1 Killing of TNP–CBA (*a*), CBA (*b*), TNP-DBA/2 (*c*) and SJL (*d*) targets by (CBA × DBA) F_1 spleen cells immunised *in vivo* with TNP–CBA spleen cells and restimulated *in vitro* with either TNP–CBA (●) or SJL (○) stimulating cells. The abscissa shows the known number (×10^6) of responders cultured on day 0, the descendants of which are the unknown number of killer cells added to each well containing 2 × 10^4 target cells. Each point represents the arithmetic mean of triplicate cultures. The standard deviation is less than 3%. The spontaneous ^{51}Cr release of the various targets varied between 20 and 31%.

tion with SJL cells resulted in lytic activity directed against SJL targets only (Fig. 2). On a per cell basis cytotoxicity of chimaeric cells compared with F_1 hybrid cells was lower on all targets. This is probably why nonspecific killing of TNP-coupled target cells was not seen.

Our experiments confirm conclusions drawn from work done using different experimental conditions: Doherty and Zinkernagel[8,9] as well as Shearer *et al.*[4] showed that F_1 hybrid cells sensitised to virus-infected or TNP-conjugated cells of one parental strain would only lyse 'modified' cells of that parental strain but not of the other. In addition it was shown that either H-2D or H-2K homology between modified stimulator and target cells was sufficient for generation of cytotoxicity. According to the hypothesis postulating the essential role of some MHC homology between effector and target cells for killing of modified targets one would have to postulate two separate 'cell interaction loci' which would have to be under allelic exclusion This unlikely hypothesis can be rejected on the basis of the experiments reported here, which indicate that homology of MHC products between effector and target cells is not required to obtain killing of TNP-conjugated target cells, whereas homology of MHC products between TNP-conjugated stimulator and target cells is essential. Our experiments thus show that precursors for cytotoxic T cells are triggered and react to antigenic determinants created by association of MHC gene products with non-H-2 antigens (often referred to as 'altered H-2 antigens'). In what way these determinants are formed and recognised by T cells is unknown, and the subject of speculation[10,11].

Binding of human immunoglobulins to pituitary ACTH cells

WE report the unexpected finding that the adrenocorticotropic hormone (ACTH)-secreting cells of the human anterior pituitary gland show an affinity for human immunoglobulins resembling that of normal mast cells for IgE. This phenomenon could have physiological significance if considered in relation to the messages leading to synthesis or release of the hormone.

In the course of studies which led to the identification of antibodies directed against the prolactin-secreting cells of the adenohypophysis in patients suffering from autoimmune polyendocrine deficiencies[1], it was found that most human sera exhibited a cytoplasmic immunofluorescence (IFL) on ACTH-secreting cells. The type of endocrine cell was identified by a double IFL sandwich technique in which the patients' sera were followed by an anti-immunoglobulin conjugated with fluorescein isothiocyanate (FITC)(green) and a rabbit antibody specific for ACTH counterstained with a rhodamine-labelled conjugate (red) on the same section. None of the other five types of anterior pituitary cells reacted in this way, and anti-human Ig conjugates applied by themselves did not produce any fluorescence on ACTH cells. The three main immunoglobulin classes in human serum were reactive, although the strongest staining was usually seen with anti-IgM conjugates.

Experiments carried out to investigate this phenomenon suggested that the binding occurred through the Fc portion of the immunoglobulins and was not an antigen–antibody reaction. Table 1 shows the Ig preparations applied in these experiments. Four separate pools of mixed human Ig stained the ACTH cells. Two preparations of Fc fragments[2] from separate Ig pools were fully reactive, whereas the Fab from the same pools gave negative results using appropriate conjugates. One Fc and one Fab preparation made from normal pooled IgG failed to stain ACTH cells, indicating that the binding of IgG is of relatively low affinity and requires aggregates which cannot form with Fc fragments. A similar situation exists in relation to Fc receptors on lymphocytes. The strongest IFL was obtained with IgM in all categories of sera tested. Weaker staining was generally seen with IgG and IgA. One serum containing 30,000 IU IgE ml^{-1} and several sera with normal IgE content gave negative results when tested with an anti-IgE conjugate. One IgD myeloma serum similarly failed to react when tested with anti-IgD. The staining of ACTH cells was positive when fresh human sera were followed by an anti-β_{1c} conjugate, showing that the binding Fc region was com-

Table 1 Analysis of Ig binding to pituitary ACTH cells

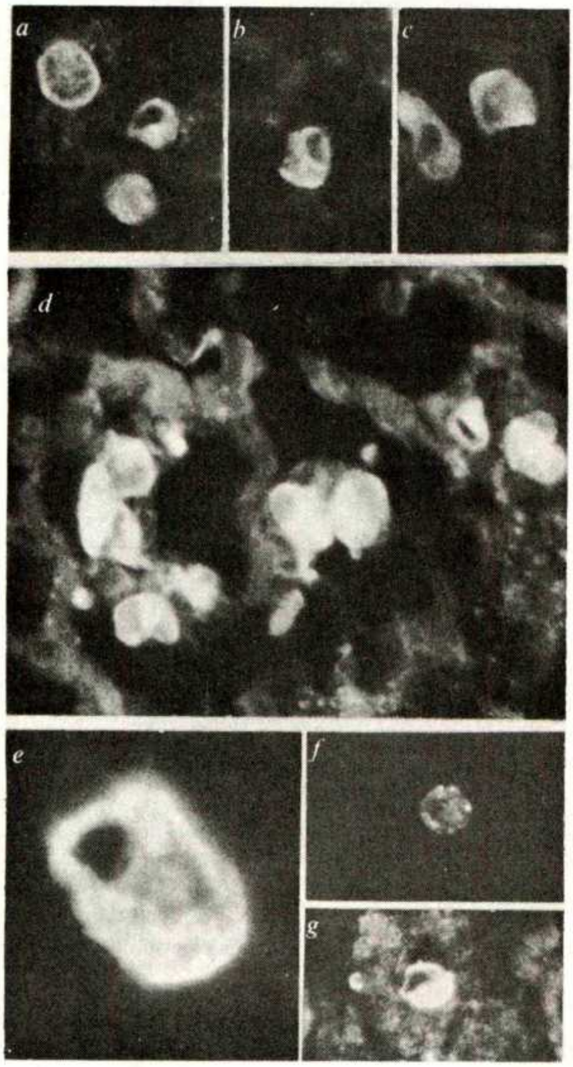
plement fixing. Most sera showed titres between 1 and 80. Sera from cases of Waldenstrom's macroglobulinaemia were applied to determine whether the staining was dependent on any special features of the IgM tested. One of these sera gave a titre greater than 10,000 and the purified 19S fraction was equally reactive. This high reactivity, together with the fact that all anti-human Ig conjugates were effective —although they were raised in different animal species injected with separate pools of Ig—excludes the possibility that this IFL is due to a serum protein other than an immunoglobulin to which the animals might have developed adventitious antibodies. Further evidence is provided by the positive β_{1c} reaction and the negative tests obtained with most hypogammaglobulinaemic sera.

Fig. 1 Human pituitary stained by immunofluorescence with normal human serum (Fc binding). *a–d*, Pituitary from Cushing's disease. Crooke cells show variable cytoplasmic staining. *e*, Single Crooke cell at high magnification. *f*, Live ACTH cell showing interrupted membrane fluorescence. *g*, Normal post mortem pituitary with small ACTH cell.



All human pituitaries showed this ACTH cell fluorescence, including six post mortem glands, and seven hypophysectomy specimens, five from carcinoma of breast cases and two removed for Cushing's disease. The reaction was still positive after fixation of the pituitary with acetone or methanol. Animal pituitaries are being tested but no conclusive results can as yet be given.

On unfixed cryostat sections of normal pituitary the ACTH cells were small with eccentric nuclei, and showed a uniform smooth staining pattern involving the entire cytoplasm (Fig. 1*g*). In Cushing glands containing numerous Crooke cells, the staining was intense and of variable pattern (Fig. 1*a–e*). When a suspension of mixed live pituitary cells was examined, normal sera gave an interrupted membrane fluorescence on cells which, after fixation, could be shown to react with anti-ACTH by the double IFL technique (Fig. 1*f*).

Results obtained with 430 individual human sera are shown in Table 2. All were first tested with anti-IgM and negative sera were retested with anti-IgG and anti-IgA; only those failing to stain ACTH cells with all three conjugates were listed as negative.

As might be expected, seven of the eight hypogammaglobulinaemic sera (supplied by Professor J. Soothill and Dr A. D. B. Webster) were completely negative. A weakly positive reaction was seen with one serum containing 13.9 IU IgM ml^{-1}. Seventeen normal sera from laboratory staff all stained ACTH cells but five healthy relatives belonging to a family with two cases of idiopathic hypoparathyroidism were surprisingly negative; and it is notable that 6 out of 15 hypoparathyroid sera also failed to stain these

Table 2 Binding to ACTH cells of human pituitary by the immunoglobulins in pathological and normal sera

Diagnosis	No. of sera tested	Negative fluorescence of ACTH cells
Hypopituitarism	20	3
Addison's disease	112	14
Hypoparathyroidism	15	6
Rheumatoid arthritis	80	11
Hypogammaglobulinaemia	8	7
Waldenstrom's macroglobulinaemia	31	2
Other conditions	143	4
Normal subjects	22	5*
Total	430	52 (12%)

* Normal relatives of hypoparathyroid cases.

cells, although they were not hypogammaglobulinaemic. Among the other categories of patients tested, the percentage of negative reactors varied from 3 to 14%.

From these data we conclude that certain sites within the Fc region of immunoglobulin molecules have a non-immunological affinity for an unknown constituent present both on the cell membrane and in the cytoplasm of ACTH cells in the human anterior pituitary. This was an unexpected finding and its physiological significance is not yet understood.

The existence of Fc receptors on subpopulations of blood lymphocytes[3] and on mast cells and basophils, is established[4]. The fixation of IgE and of anaphylactic IgG on the mast cells by their Fc portions is necessary before the 'allergen challenge' stage of histamine release. This consists of attachment of the appropriate antigen and bridging of the free Fab portions of the Ig molecules; this process triggers the cells to release their granules. In the same way macrophages can be activated when immune complexes become attached to Fc receptors. Possibly a similar role might be found in future for the Fc receptors on ACTH cells. Note that Stanworth[5] has shown that a sequence of basic amino acid residues within the ACTH molecules is capable of inducing histamine release from normal mast cells in the absence of immunoglobulins.

For the present it is important to be aware of ACTH-cell IFL when looking for autoantibodies to anterior pituitary gland in human patients. Furthermore this reaction may be used to identify ACTH cells for histological purposes, because the Ig binding seems to be as specific for the identification of these cells as for anti-ACTH sera raised in animals. It will also be of interest to determine whether lung cancers and other tumour cells with inappropriate ACTH secretion show this affinity for immunoglobulins.

We thank Dr Frank Hay for discussions and Miss Judith Pratt for assistance. Dr E. C. Franklin kindly supplied a 'μ-chain disease' preparation. A.P. was in receipt of an MRC grant and F.G.B. is a Wellcome Research Fellow.

Infection of a cell line of mouse L fibroblasts with scrapie agent

THE infection of cell cultures with the causative agents of subacute spongiform encephalopathies — scrapie, kuru, Creutzfeldt–Jakob disease and transmissible mink encephalopathy—has not yet been reported. The development of a cell line (SMB), from the brain of a mouse affected with scrapie, in which the agent multiplies has shown that replication *in vitro* is possible[1]. Studies with this cell line have, however, been limited because no control culture was available for comparative studies. This limitation has now, in part, been overcome by the successful infection of cultures of mouse L cells with scrapie agent, as described here.

The scrapie agent is closely associated with cellular fragments and attempts to release and purify the agent have been unsuccessful. Recently Millson *et al.*[2] have shown that approximately 98% of the membrane proteins from scrapie membrane preparations can be solubilised by treatment with lysolecithin, giving an increase of up to 100-fold in the concentration of the agent. It seemed worthwhile to attempt to infect cells with this partially 'purified' preparation because, first, the removal of a large proportion of the membrane components made it possible to introduce a higher concentration of agent into the cell cultures than previously, and second, as lysolecithin can cause cell fusion[3], it seemed possible that the association of bound lysolecithin with the particulate membrane fragments containing the scrapie agent might induce uptake of these fragments by the cells.

A membrane fraction was prepared from the brains of scrapie-affected mice by homogenising the tissue in 0.32 M sucrose to give a 10% suspension. Nuclei and unbroken cells were pelleted by centrifugation at 500*g* for 10 min. The post-nuclear supernatant fluid was centrifuged at 100,000*g* for 1 h and the sedimented membrane fraction was resuspended and homogenised in 25 ml of 0.05 M bicarbonate buffer, *p*H 8.3, containing 192 mg of lysolecithin. After incubation at 37 °C for 2 h, the sample was centrifuged at 100,000*g* for 1 h. The final pellet containing particulate membrane fragments was resuspended in 7 ml of Hanks' buffered salt solution. Dilutions of the suspension between 1/1 and 1/100 were then used to resuspend pellets of mouse L cells (derived from clone 929, Flow Laboratories) and the mixture was added to cell culture medium in medical flat bottles. The medium used was Eagle's minimum essential medium with 10% foetal calf serum.

The lysolecithin-prepared suspensions of membrane fragments were toxic to the L cells but some survived and two cultures were established. Culture *A* was from cells exposed to a suspension diluted 1/3 and culture *B* was from dilution 1/100. Monolayers were eventually obtained in each case about 6 weeks later. The monolayers were then submitted to 15 serial passages during a period of up to 29 weeks and on each occasion dilutions of the cells were made equal to $10^{-0.5}$.

The presence of scrapie activity at the 1st, 7th, 11th and 15th passages was determined by titration of samples of the cultures in mice as described before[4] (Table 1). In culture *A* there was a decline in titre from the 1st (3.3 $\log_{10}$ LD_{50} per 0.05 ml) to the 7th (1.6) passage and thereafter the titres remained at about the latter level. In culture *B* the titres varied between 1.8 and 1.1 from the first to the 15th passage. These titres correspond to about 3,000 cells per LD_{50}, which is a much lower level of infectivity than for the SMB cell line (100 cells per LD_{50}). The difference between the titre of the first passage of cultures *A* (3.3) and *B* (1.8) is the same as the difference in the dilutions of suspension used for the exposure of cells to scrapie infectivity. This suggests that at least some of the activity of the first passage was derived from the suspension of membrane fragments and not from multiplication of agent in the culture.

Table 1 Titre of scrapie agent in two cultures of mouse L fibroblasts at various passages after exposure

Culture	Passage			
	1	7	11	15
A	3.3*	1.6	1.0	1.8
B	1.8	1.6	1.5	1.1

* Titre of scrapie agent $\log_{10}LD_{50}$ per 0.05 ml.

The levels of scrapie activity in the original mixtures of membrane suspension and L cells were estimated at about $10^{5.5}$ (A) and $10^{4.0}$ LD_{50} per 0.05 ml (B) so that by the 12th and 9th passages, respectively, the original infectivity, if it had all been retained in the cultures at the first passage, would have been eliminated by the subsequent dilution of the cells at each passage. The presence of activity at later passages must, therefore, be due to multiplication of agent. Further, since each passage involved a dilution of cells, the observation of a similar level of activity at each passage titrated also indicated that the agent had multiplied.

Fusion of plasma membrane can occur as a consequence of exposure of cells to lysolecithin, and multinucleated forms may be seen[3]. During the development of the initial monolayers of L cells exposed to scrapie agent an increased number of multinucleated cells was noted, suggesting that fusion had occurred. The establishment of cultures in which the scrapie agent was replicating could have been due to the presence of lysolecithin which, bound to membrane fragments containing scrapie infectivity, fused with the L cells Fusion could also have resulted from the presence of free lysolecithin in the membrane suspension used to infect the cultures. Scrapie infectivity is associated with plasma membrane of SMB cells[5]; the successful infection of cell cultures in the presence of a substance known to cause fusion of membranes is consistent with the observation that the agent is located on the membrane.

Although the titres obtained in the cultures of L cells were low, the evidence that infection of cell cultures with scrapie agent has occurred is encouraging It suggests that further attempts to fuse membrane fragments from scrapie-affected tissue to cells should be made.

Renal tubular adaptation to dietary phosphorus

THE kidney is very important in the maintenance of the overall balance of inorganic phosphate (P_i). The renal response to variations in dietary P_i has been generally explained by changes in the amount of P_i filtered by the glomerulus. When a change in the tubular P_i transport has been suspected, it has usually been attributed to an alteration in parathyroid hormone (PTH) secretion[1,2]. We have shown that the renal tubule changes its capacity to reabsorb P_i according to homoeostatic requirements independently of the filtered load of P_i (ref. 3). Since such a tubular adaptation also occurs in the absence of PTH (ref. 3), the question of the relative potency of PTH and that of dietary P_i in changing the tubular transport of P_i is of interest. Here we report that variations in dietary P_i cause a much greater change in the tubular capacity to transport P_i than removal of the thryoparathyroid glands.

The renal handling of P_i was studied in pairs of sham-operated (SHAM) and thyroparathyroidectomised (TPTX) rats fed diets containing either low (0.2 g % dry weight) or high (1.8 g % dry weight) amounts of phosphorus for ten days (see Table 1 legend). The fractional excretion of P_i ($C_{P_i}/C_{In} \times 100$), measured in steady-state conditions and at the same plasma levels of P_i ($[P_i]_{Pl}$), was about five times higher in SHAM than in TPTX rats on a high P_i diet (Table 1). As expected, calcaemia ($[Ca]_{Pl}$), measured during the clearance periods, was higher in SHAM than in TPTX animals (2.43±0.04 and 1.78±0.16 mM respectively, $P < 0.01$). We found no significant differences in the weight of the animals (182±3 and 174±5 g), in urinary volume (37±5 and 30±3 µl min^{-1}), or in C_{In} (1.29±0.06 and 1.33±0.04 ml min^{-1}). Similar results were obtained in SHAM and TPTX rats, on a low P_i diet (Table 1). The ratio C_{P_i}/C_{In} was twice as high in SHAM as in TPTX animals. $[Ca]_{Pl}$ was higher in SHAM than in TPTX rats (2.46±0.05 and 2.00±0.09 mM, $P < 0.001$). Again there were no significant differences in weight (170±5 and 169±4 g), in urinary volume (38±6 and 40±6 µl min^{-1}), or in C_{In} (1.33±0.07 and 1.29±0.10 ml min^{-1}). In addition, none of these latter parameters differed significantly from those of the two groups on high P_i intake.

Table 1 Variation in the fractional excretion of P_i in response to dietary P_i compared with thyroparathyroidectomy

Diet	$C_{P_i}/C_{In} \times 100$ SHAM	 TPTX	 SHAM–TPTX
High P_i (1.8 g % dry weight)	34.7±4.4 (15)	7 1±1.8 (7)	4.9
Low P_i (0.2 g % dry weight)	0.098±0.003 (7)	0.045±0 009 (7)	2.2
High/low P_i	354	157	

Numbers in parentheses correspond to number of animals. Fractional excretion of phosphate ($C_{P_i}/C_{In} \times 100$±s e.m.) was measured at equal plasma phosphate concentrations in pairs of rats fed high P_i (1.8 g % dry weight) and low P_i (0.2 g % dry weight) diets for 10 d. The mean (±s.e m.) intake of phosphorus was 31±1 and 276±13 mg d^{-1} for rats fed on a low and high P_i diet respectively. Dietary Ca^{2+} and Na^+ contents were kept constant (1.2 and 2.45 g % dry weight respectively). Surgical thyroparathyroidectomy (TPTX) or a sham operation (SHAM) was performed on the eighth day. The effectiveness of parathyroidectomy was evaluated after the clearance experiment; the rats were returned to the lab chow for 5 d, fasted overnight and their calcaemia ($[Ca]_{Pl}$) determined the following morning by atomic absorption spectrometry Data are only presented for TPTX rats which displayed a $[Ca]_{Pl}$ below 1.88 mM (= 7.5 mg %) in these conditions and which were therefore considered to be fully parathyroidectomised. On the day of the clearance measurement animals were infused intravenously (4 ml h^{-1}) with either isotonic NaCl or neutral P_i (16% NaH_2PO_4 and 84% Na_2HPO_4) at doses of 60 or 120 µmol h^{-1}. The osmolality of the solutions was adjusted to 300–310 mosmol l^{-1} by addition of NaCl where necessary. The clearances were measured in non-fasted conscious animals according to a technique described earlier[4]. Inulin was determined by the anthrone technique[5] and P_i by the method of Chen *et al.*[6]. Data were analysed only from values of $[P_i]_{Pl}$ in the range between 2.25 and 2.90 mM. The mean $[P_i]_{Pl}$ values of the four experimental groups were not significantly different: high P_i diet, SHAM 2.54±0 01 and TPTX 2.60±0.07 mM; low P_i diet, SHAM 2 46±0.09 and TPTX 2.49±0.11 mM.

Thus, independently of the filtered load, and according to the values of the SHAM–TPTX ratio in Table 1, the presence of PTH may increase the fractional excretion of P_i about 2–5 times. The greater effect due to the removal of the parathyroid glands under high P_i diet can be explained by parathyroid hyperfunction, occurring in this condition[2]. The fractional excretion of P_i can, however, be changed more than a hundredfold in both intact and TPTX rats by varying the previous dietary intake of P_i as expressed by the ratios of fractional clearances on the high and low P_i diets (Table 1).

The dietary P_i level, therefore, seems to control a mechanism which is independent of circulating PTH and which seems to be much more potent than this hormone in changing the renal tubular transport capacity of P_i. The present data indicate that PTH would amplify the important dietary-induced change in the tubular capacity for this anion by enabling more P_i to be excreted under a high P_i diet.

Differences induced by dietary input of P_i can be observed in the presence of the same calcaemia (see above) and the same urinary *p*H (ref. 3). It is maintained under marked expansion of the extracellular volume[3]. Renal adaptation to P_i is probably independent of vitamin D_3 and its metabolites since in TPTX vitamin D-deficient rats maintained on a low P_i diet[7], tubular reabsorption of P_i is complete.

Tubular adaptation to dietary P_i seems not to be mediated by the main factors generally believed to be most important in the regulation of the renal handling of P_i. Our results have revealed a homoeostatic mechanism of great potency which must contribute to the maintenance of P_i balance by the kidney.

This work was supported by grants from the Swiss National Fund for Scientific Research and the NIH. We thank Miss T. Rolli for technical assistance and Mrs B. Gyger for help in preparing this manuscript.

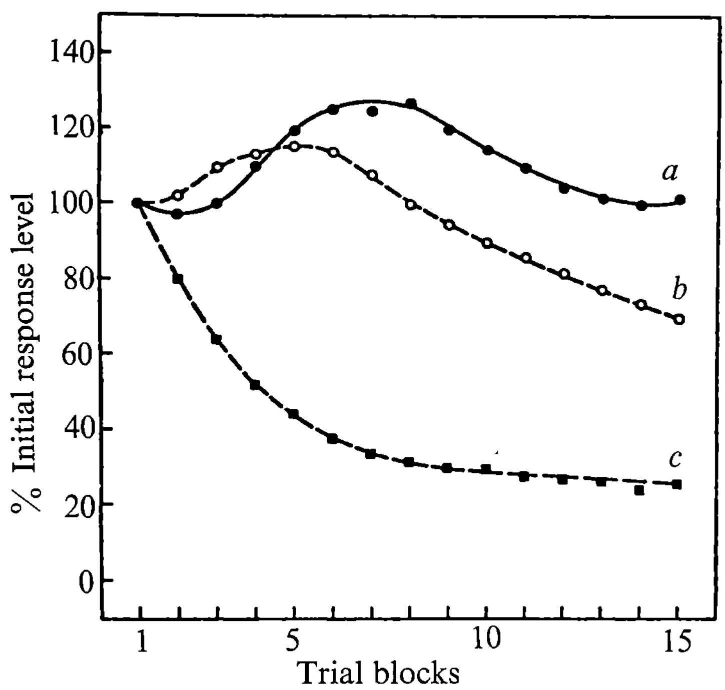
Computer simulation of a model of habituation

HABITUATION—in general defined as a reversible decrement of response to repeated stimulation—is a widely studied form of behavioural plasticity. The reversibility sets habituation apart from fatigue and accommodation. An habituated stimulus may once again be able to evoke a response after the presentation of an intervening novel stimulus. This phenomenon, known as dishabituation, rules out sensory and motor fatigue as the bases of the response decrement.

Thompson and Spencer[1] have described several characteristics which together form a widely accepted operational definition of habituation. Two of these are that relative response decrement, expressed as a percentage of the unhabituated response, proceeds more rapidly for less intense stimuli, and that both habituation and dishabituation recover spontaneously over time if the stimulus is withheld.

Although habituation has been studied at the neurophysiological level in a number of preparations, in most cases the mechanism underlying the response decrement is unknown. Several circuit models based on plausible theories of habituation have been constructed to help to interpret experimental results and to explore possible habituation mechanisms[2–5]; such models can help identify the requisite properties of decremental and incremental effects within the framework of a particular theory. With this in mind, I have explored, by mathematical analysis and computer simulation, a circuit model based on Thompson's two-process theory of habituation[5,6]. This theory was chosen as the basis of the work because of its wide applicability and acceptance in physiology and psychology. I show here how the effects of stimulus intensity can be realised by a circuit model similar to one proposed by Groves and Thompson[5].

Fig. 1 Curves of relative habituation in cat spinal cord, taken from ref. 6 with permission of the authors and publisher (their Fig. 7*a*). Stimulus strength: *a*, strong; *b*, moderate; *c*, weak.



In Thompson's two-process theory, response strength is determined by the sum of transmissions in two independent sets of channels from stimulus to response. Transmission decrements occur in direct stimulus–response channels, leading to observed response decrements at low stimulus intensities. Transmission increments, or sensitisations, occur at higher stimulus intensities in indirect channels associated with the overall state of reactivity of an organism. Dishabituation, then, is a transient facilitation superimposed on a depressed response channel following presentation of a novel, usually strong, stimulus. During habituation training, the balance between decrement and sensitisation produces a response that is stronger or weaker than the control (unhabituated) response. This balance shifts with the number of presentations at a given stimulus intensity to generate response curves of the form shown in Fig. 1, which were derived from experiments on the handlimb flexion reflex of spinal cats[6]. At low intensities the decrement prevails, whereas at higher intensities sensitisation causes the response to rise above its control level in early trials. Thompson[5] has illustrated the two-process theory with a circuit model which is proposed for cat spinal cord. In this circuit, stimulation results in synaptic depression in the direct stimulus–response path, and in synaptic increment or enhanced cell excitability in the indirect path, or state portion.

My model circuit (Fig. 2) is a simplification of Thompson's model. The circles represent cells or cell populations (referred to here simply as 'cells'). Cell H receives the external stimulus from its afferent, I. The output of cell O represents the circuit's overall response. The direct connection from H to O represents the direct stimulus–response channel. Cell S is the indirect path, or state system, of the circuit, and the channel from H to O through S represents the effect of this state system on the overall output. The output of each cell is a weighted sum of its inputs; that is

$$H = w_0 I \tag{1}$$

$$S = w_1 H \tag{2}$$

$$O = w_2 H + w_3 S \tag{3}$$

The value of each cell's output at a given moment may be interpreted either as the instantaneous firing rate of a single cell or as the number of cells in a population that are then firing. The value of the external stimulus may be thought of similarly. The value of each coupling weight may be regarded as the strength of the synapse connecting the two corresponding cells or as the effective synaptic transmission strength between two populations.

For the direct stimulus–response channel to become less effective with use, the coupling weight w_2 must become smaller on repeated stimulation. Similarly, the compound effect of w_1 and w_3 must increase with use to represent the sensitisation process. The influence of I on H does not change with stimulation, so w_0 is fixed. Changes in w_2 must occur so as to generate responses that yield a negative exponential function of the number of stimulus presentations. Further, the strengths of all coupling weights must tend towards their initial values in the absence of stimulation of the system. These requirements can all be met if each weight is modelled with a first-order differential equation which is driven by the output of the associated presynaptic cell. So

$$T_i \dot{w}_i = w_{i0} - w_i + a_i F_i(X); \quad i = 1, 2, 3 \tag{4}$$

where $\dot{w}_i$ denotes the time derivative of the associated weight value, and

$$X = \begin{matrix} H \text{ for } i = 1, 2 \\ S \text{ for } i = 3 \end{matrix} \tag{5}$$

For each i, w_{i0} is the initial value of the weight and the resting level towards which it moves when stimulation stops. The rate of return, which represents the rate of spontaneous recovery of habituation and sensitisation, is determined by the time constant, T_i. The functions F_i determine the way each weight is affected by its modifying input, X, and are non-negative for all values of X. If a_i is negative, the corresponding weight will be decreased by stimulation of its associated presynaptic cell; if a_i is positive, the weight will be increased.

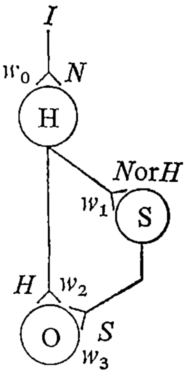


Fig. 2 Two-process circuit. N, non-plastic synapse; H, depleting synapse; S, sensitising synapse.

To determine the modification function for each weight, note first that sensitisation is a direct function of stimulus intensity[6], for now I suppose that $F_3(S)$ is simply S itself, so that the rate of increase of w_3 varies linearly with the output of cell S. Thompson maintains that relative habituation due to the decremental process alone is independent of stimulus intensity[6]. This requires that the F_i associated with each decreasing weight be a constant—that is, each weight that decreases with use must be driven by a constant at each presentation of a stimulus, regardless of stimulus intensity. More detailed circuits have been designed that obviate the need for this assumption, but in the investigations reported here I have used the circuit of Fig. 2 and the assumption of constant synaptic modification drive.

There are two ways that the circuit operating under these assumptions can generate curves of relative habituation similar to those in Fig. 1. They are based on whether or not w_1 is allowed to vary with use. If w_1 is fixed and w_3 changes more rapidly than w_2, at moderate and high stimulus intensities the overall response to repeated stimulation first increases across trials as w_3 increases, then falls as w_2 decreases. At low intensity, only the decrease in w_2 is significant, so the response only decreases across trials. Curves of relative habituation generated in computer simulation of this case are shown in Fig. 3. Note that in this case, since the output of cell S is constant across trials, sensitisation itself does not fall after rising, as required by Thompson's theory. The curves of Fig. 3 are qualitatively similar to those of Fig. 1, however, indicating that this assumption about sensitisation may not be required to generate such curves.

If w_1 is allowed to decrease with use, but more slowly than w_3 increases, sensitisation first increases, then decreases, across trials as the output of cell S decreases. This effect alone can generate response curves like those of Fig. 1. When added to the strategy in which changes in w_2 and w_3 generate the desired response curves, a small drop in w_1 causes the effect of sensitisation to be reduced further in later trials. This decrease in w_1 allows greater variation in w_3 to produce more sensitisation in early trials but with a return closer to control levels in later trials.

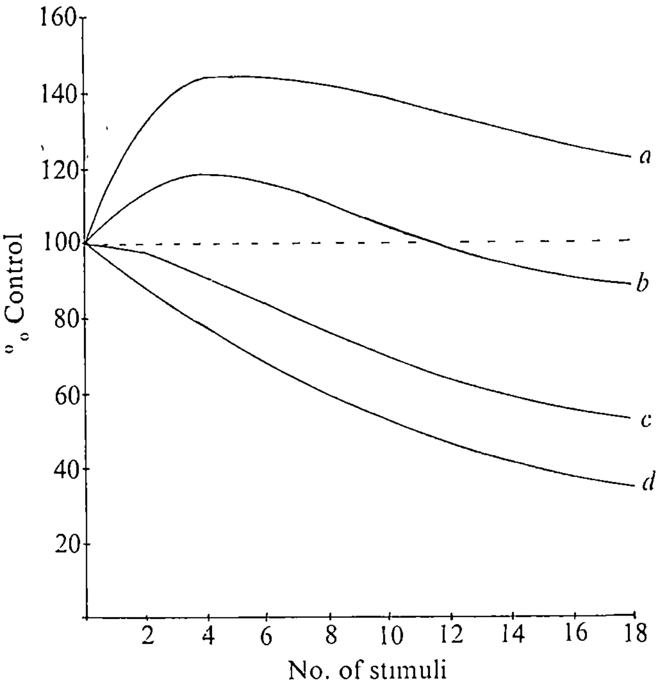

Fig. 3 Curves of relative habituation generated by computer simulation of the circuit of Fig. 2. Stimulus intensities: a, 8.0; b, 5.0; c, 2.0; d, 1.0.

Computer simulation of this simple habituation model has thus shown how the processes of decrement and sensitisation postulated in the two-process theory may vary with respect to one another to generate realistic response curves. Thompson's assumption that sensitisation decreases in later habituation trials has been shown to be unnecessary for the production of the intensity curves of Fig. 1. Such variation can lead to lower final response levels at higher stimulus intensities, however, and is necessary to explain habituation or dishabituation.

Further simulations have shown how the effects of stimulus frequency could arise in the model, and what effects nonlinear weight modifications could produce. A network using the circuit of Fig. 2 as a basic unit has also been simulated to investigate stimulus generalisation, and intensity-independent relative habituation has been produced by an augmented model that uses synaptic weights which decrease as a function of stimulus intensity. My simulations have provided insights into plausible functional organisations that may be difficult to investigate experimentally, and as such should contribute to the design of more decisive future experiments.

Sprouting and regeneration of synaptic terminals in the frog cardiac ganglion

SYNAPTIC connections are capable of a remarkable proliferation after nervous tissue has been damaged and some synapses have been destroyed. This proliferation, or 'sprouting', of remaining, intact, synapses within partially denervated tissue has been found to occur in the peripheral, autonomic and central nervous systems[1–5]. As yet, however, the functional ability of these sprouted synaptic contacts has not been extensively tested and the persistence of the sprouted synapses over long periods has not been studied. We have been investigating these problems in the parasympathetic cardiac ganglion in the frog. Earlier studies have shown that when the nerve supply to the ganglion is partially destroyed by crushing one vagus nerve, axons in the other vagus nerve sprout and synapse with the denervated neurones[1]. Here I describe experiments in which the persistence of the sprouted synapses in the cardiac ganglion was tested by allowing the damaged axons to regenerate into the tissue. The results indicate that regenerating vagal fibres are able to re-establish some, but not all, of their synaptic connections and that innervation from the sprouted nerve decreases.

The cardiac ganglion in the frog is well suited for studying synaptic transmission at sprouting synapses. Because the ganglion is very thin, individual neurones can be seen in the living isolated preparation and this greatly facilitates intracellular microelectrode recording. Ganglion cells are grouped along two branches of the vagus nerves as they traverse the interatrial septum[1,6]. Each branch contains preganglionic axons from both left and right vagus nerves since the branches are joined by a chiasma near the entry of the vagus nerves into the heart. Ganglion cells are mostly innervated by the ipsilateral vagus nerve. For example, along the left branch of the ganglion in control animals, 87% of the neurones receive inputs from the left vagus and 48% from the right (about one-third of the cells are innervated by both nerves)[1]. Many ganglion cells are innervated by two or more preganglionic fibres; usually only one fibre produces suprathreshold excitatory postsynaptic potentials (e.p.s.p.s) and stimulation of the other fibres evokes subthreshold responses (Fig. 1*a*). After crushing the left vagus nerve, the remaining vagal axons sprout and within about 1 week, all the ganglion cells are innervated by the right vagus nerve[1]. The experiments described below were carried out at longer intervals after crushing the nerve, to study regeneration and the fate of the sprouted synapses.

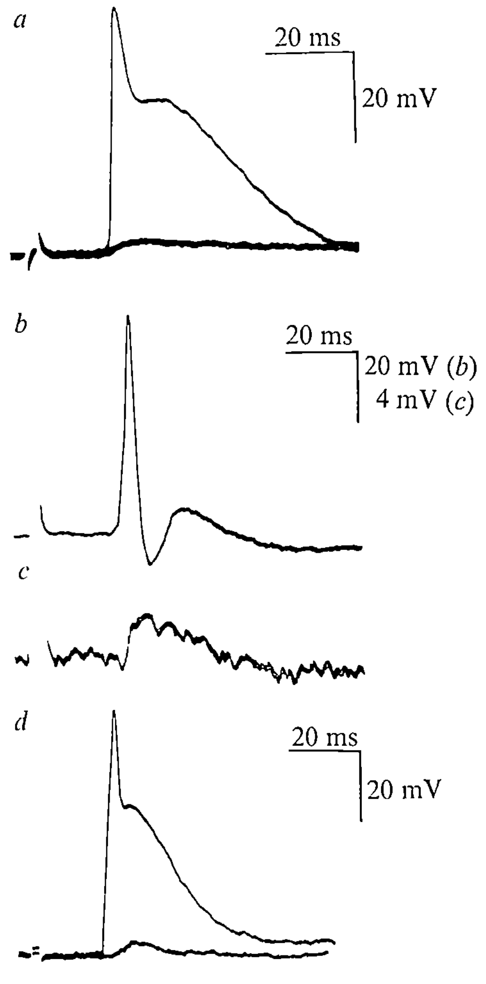
The experimental methods have been described previously[1] and will only be outlined briefly here. The left vagus nerve was crushed with fine forceps in frogs anaesthetised with 0.5% tricaine methanesulphonate (Sigma). The animals were allowed to recover for varying periods before synaptic transmission was tested. Neurones in the isolated cardiac ganglion were impaled with fine-tipped microelectrodes. E.p.s.p.s were recorded in response to stimulation of the right and/or left vagus nerves, which were drawn into separate suction electrodes.

As the left vagus nerve renegerated, it re-established some synaptic connections. E.p.s.p.s produced by regenerating fibres tended to be subthreshold early in the course of the regeneration (4–8 weeks), (Fig. 1, *b* and *c*). Later, both sub- and suprathreshold e.p.s.p.s were evoked by stimulation of regenerating fibres, as in normal ganglia (Fig. 1*d*). In addition, as the regenerating fibres re-established synaptic connections, there was a decline of innervation from the right vagus (Fig. 2). Experiments are in progress to determine whether a comparable decline of innervation from the right vagus nerve occurs when reinnervation is prevented.

At the longest recovery period studied, about 42 weeks, the innervation pattern of the ganglia was not restored to normal; the nerve supply to cells along the left branch of the ganglion was still dominated by axons from the right vagus nerve, in contrast with unoperated animals (Fig. 2). The regenerating fibres were unable to restore completely their original connections.

These data differ from the results of experiments in which the nerve supply regenerates to ganglion cells that are innervated by an implanted foreign nerve and not by sprouted synaptic terminals; Purves found that when the preganglionic supply to sympathetic ganglia (superior cervical ganglia) of guinea pigs is cut and the parasympathetic vagus nerve is rerouted into the ganglia, the vagal endings form synaptic contacts which are not displaced when the original innervation regenerates[7]. That is,

Fig. 1 Intracellular recordings from multiply-innervated parasympathetic neurones located on the left branch of the cardiac ganglion. *a*, Superimposed recordings from a ganglion cell in an unoperated animal Threshold stimulation of the left vagus nerve evoked a subthreshold e.p.s.p. Stronger stimulation produced a suprathreshold response. *b* and *c*, Ganglion cell innervated by both the right vagus (*b*) and regenerated left vagus nerve (*c*) Stimulation of the left vagus produced a subthreshold e.p.s.p. The left vagus nerve had been crushed 41 d before the experiment. *d*, Ganglion cell with multiple innervation from the regenerated left vagus nerve. The left vagus had been crushed 302 d before the experiment. Weak stimulation of the regenerated nerve evoked a subthreshold e.p.s.p. Stronger stimulation produced a suprathreshold response, as in unoperated ganglia.



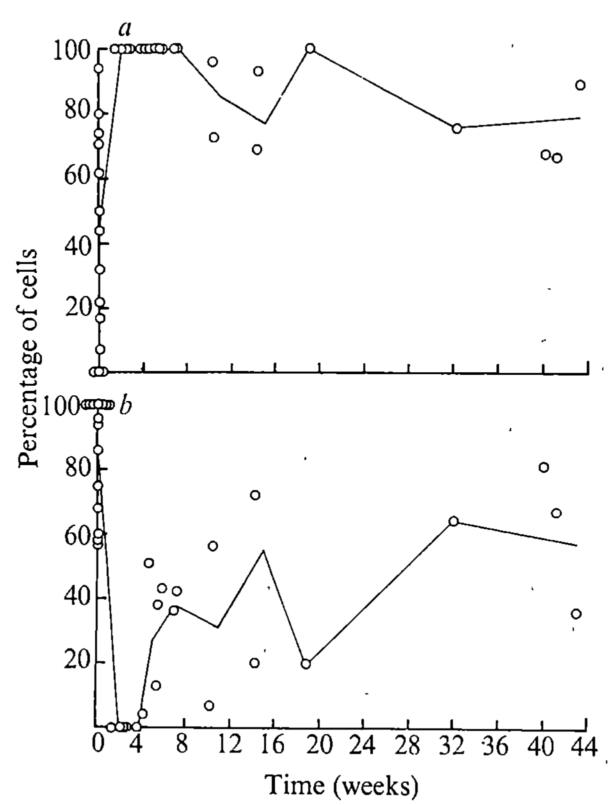


Fig. 2 Sprouting and regeneration of synapses in the cardiac ganglion. Each graph shows the percentage of cells located on the left branch of the ganglion which were innervated by the right (*a*) and left (*b*) vagus nerve at different periods after the left vagus nerve was crushed. Each circle represents data from one ganglion (15–30 cells recorded per ganglion). Circles on the ordinate show data from unoperated ganglia. A line has been drawn connecting the averages of data grouped into weekly intervals; the last three points were grouped together. Sprouting of synapses from the right vagus nerve is indicated by the increase of right vagal innervation from 48 to 100% within 1 week of the operation (*a*). Regeneration of left vagal synapses begins after about 4 weeks (*b*). At the first stages of regeneration (4–8 weeks) there did not seem to be any change in right vagal innervation (*a*), but this is misleading; slight decreases in the size of right vagal e.p.s.p.s are not indicated on this figure.

many of the sympathetic ganglion cells are innervated by both nerves. On the other hand, the present experiments confirm and extend to a cellular level the observations of Guth and Bernstein[8] who studied the reinnervation of superior cervical ganglia of cats after partial deafferentation. They reported that after damaging thoracic sympathetic rami which contributed pupillodilator fibres, remaining intact preganglionic fibres sprouted and took over this function. When the preganglionic fibres regenerated, stimulation of the sprouted nerve no longer produced pupillodilation; reinnervation by the appropriate axons was accompanied by a decrease in the innervation arising from sprouted fibres.

The present experiments do not explain the mechanism by which innervation from the sprouted right vagus nerve decreases during regeneration of the left vagus nerve or even if the reinnervation causes this decrease. Because transmission at the sprouted synapses is indistinguishable from normal synapses[1], it is not possible to determine whether sprouted or original right vagal terminals are lost during regeneration. It is possible that right vagal synapses are 'suppressed' by the regenerating axons but are left structurally intact[9]. It is also possible, however, that a slow rate of spontaneous synaptic degeneration occurs[10] and when a right vagal ending degenerate, axons from the left and right vagus nerve compete for the vacated site.

I thank Dr K. Courtney who participated in some of the experiments and Drs Brenner, Ko and Betz for discussions. This work was supported by the Colorado Heart Association, the Edward Mallinckrodt Foundation and the NIH.

Function of muscarinic and nicotinic acetylcholine receptors

ACETYLCHOLINE receptors in vertebrates can be classified in two categories—nicotinic and muscarinic—on the basis of differential sensitivity to agonist and antagonist compounds[1,2]. This pharmacological distinction, although useful both in therapeutics and in experimental physiology, has no known biological significance. I wish to show here that there are marked kinetic differences between nicotinic and muscarinic receptors, and to suggest that these differences have a clear physiological meaning.

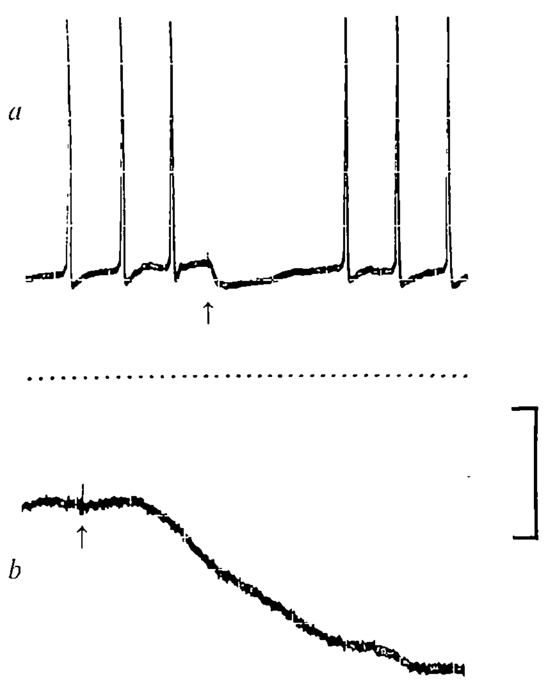
Two features are shared by all nerve-mediated muscarinic responses that have been studied electrophysiologically: the minimum latency is ~ 100 ms, and the duration after a single stimulus is 0.5 s or longer[3–7]. In contrast, however, the synaptic delay at the skeletal neuromuscular junction may be only 0.22 ms (ref. 8), and even at the slowest nicotinic synapses, the synaptic potential lasts no more than 30–100 ms (refs 9 and 10). The discrepancy in the latencies cannot be explained by morphological differences between nicotinic and muscarinic junctions, although the separation of nerve and effector is more variable at the autonomic junctions than at the skeletal neuromuscular junction[11,12]. Experiments in which acetylcholine (ACh) was applied iontophoretically to muscarinic receptors of cultured intestinal smooth muscle cells have shown that the long latency is post-junctional in origin[13]. This result has been confirmed in adult smooth muscle[14] and in salivary glands[15].

One circumstance in which a long slow response is of obvious importance is during vagal slowing of the cardiac pacemaker. This function would be ill served by an inhibitory mechanism operating at 'nicotinic speeds', for not only would most of the inhibitory input be ineffective, but the interval between beats would be critically dependent on the arrival of inhibitory impulses immediately before the projected time of discharge. There is little direct evidence that cardiac muscarinic receptors operate slowly, since estimates of the latency after single volleys have been made using preganglionic stimulation[3,4,16]. The delay due to relay in the cardiac ganglia, however, is probably small[17].

del Castillo and Katz[4] applied ACh iontophoretically to the sinus venosus of the frog, and could duplicate the main features of the response to vagal stimulation. I have examined the onset of the response to close iontophoretic application of ACh in a preparation (interatrial septum of the frog *Rana temporaria*) which allowed observation of the position of micropipettes with good phase contrast optics at a magnification of ×140 or ×220. The minimum latencies of intracellularly recorded responses (Fig. 1) were 200–300 ms at 24 °C and 400–550 ms at 15 °C. The minimum latency was affected little by lateral displacements (up to 100 μm) of the ACh pipette away from the recording site. It was also relatively insensitive to small (5–15 μm) vertical displacements. This behaviour parallels that seen in comparable experiments on smooth muscle[13]. Ganglion-blocking drugs (hexamethonium, 2×10^{-4} M, mecamylamine, 10^{-4} M) had no effect on the latencies. A striking feature of the responses was their long duration, brief pulses of 0.5–1 nC producing hyperpolarisation which could last for 8 s or more.

The effective stimulus presented to the tissue can be estimated from the diffusion equations, if some simplifying assumptions are made about the geometry. For example, ACh diffusing freely from a point source 10 ms in duration situated 10 μm above an infinite plane surface will reach its peak concentration immediately below the source in less than 30 ms. The concentration decline is also rapid, reaching 5% of the peak value by 400 ms. Since the muscle cells are interconnected electrically[18], ACh acting at some distance from the recording site presumably also contributes. The average concentration, calculated as the concentration-area product integrated over the whole plane, is perhaps a fairer measure (Fig. 2). The onset of the response lags behind the stimulus. The effective diffusion distances, which might be longer than suggested by the model, are uncertain and there may be diffusion barriers. But the minimum distance between the ACh pipette and the muscle was certainly less than the value of 10 μm assumed for calculation, since in many experiments the tip of the ACh pipette could be seen to dimple the surface of an underlying muscle cell. These results support the conclusion that inhibitory muscarinic responses in the heart are at least as slow as excitatory muscarinic responses elsewhere.

Fig. 1 Intracellular electrical records from isolated interatrial septum of the frog, showing responses to iontophoretically applied ACh. *a*, Record from a spontaneously active preparation. The arrow shows the time of application of a 15-ms, 40-nA pulse of ACh. *b*, Initial phase of response in quiescent preparation at higher amplification and sweep speed, showing well defined latency. Temperature 15 °C. ACh pulse (10 ms, 70 nA) at arrow. Vertical calibration 50 mV in (*a*), 5 mV in (*b*). Time marker, 1 s in (*a*), 0 1 s in (*b*).



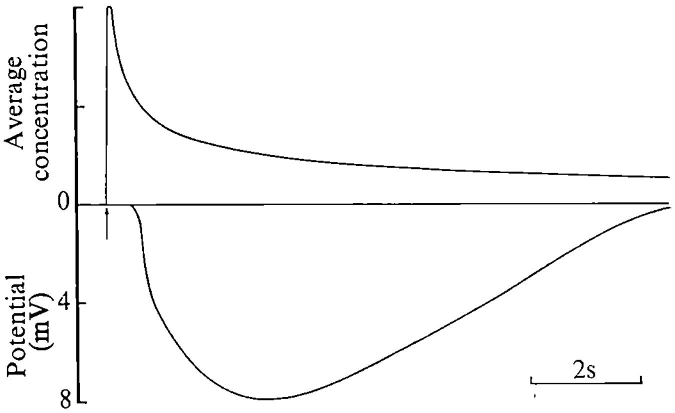


Fig. 2 Comparison of redrawn voltage response (lower curve) with calculated average concentration change of ACh Upper curve calculated as $M(\pi Dt)^{-\frac{1}{2}} \exp(-x^2/4Dt)$, where M is amount released from instantaneous point source, D is the diffusion constant (8.10^{-6} cm^2 s^{-1}), x is the vertical separation between source and tissue (10 μm) and t is time. Vertical scale arbitrary. The expression is identical with that giving the concentration at distance x from a plane source. The error made in assuming instantaneous release in place of a 10-ms source is negligible at times greater than ~ 50 ms.

The duration of the inhibition after a single vagal volley is 20 s in the turtle[16], 5–7 s in the frog[4] and 2–3 s in the cat[3]. Thus a single impulse has effects which extend over several cardiac cycles, facilitating temporal summation and continuity of successive responses, even at the low firing frequencies of autonomic nerves. It is probably no coincidence that animals with low heart rates show longer vagal responses. Conversely, at the skeletal neuromuscular junction it would be inappropriate to have provision for temporal summation, since smooth grading of contractions is obtained by other means. Nicotinic receptors provide the required 1 : 1 transmission with minimum latency and maximum temporal precision. If the argument given earlier is valid, the excitation produced by adrenergic nerves in the heart should be slow. This is indeed the case: the latency of sympathetic β cardioacceleration is several seconds and the effects of a short period of stimulation last for minutes[19,20]. Responses of excitatory α receptors, for instance in the vas deferens, are some orders of magnitude faster[21].

How are the slow responses mediated? There are indications that cyclic GMP acts as an intracellular 'second messenger' for muscarinic receptors[22–24], and there is strong evidence that cyclic AMP plays the same part for β receptors[23,25]. The evidence from latencies and time courses is not at variance with these ideas.

I propose that muscarinic receptors are specialised to allow temporal summation and thus continuity of action, whereas nicotinic receptors are specialised to prevent it. The long latency, as such, at muscarinic junctions is of doubtful biological relevance. Nevertheless, it provides a convenient pointer to a physiologically significant slowness of response.

Glutamate and quisqualate noise in voltage-clamped locust muscle fibres

GLUTAMATE-SENSITIVE receptors occur widely, both in vertebrate and invertebrate nerve and muscle membranes[1,2]. Information concerning the action of agonists on glutamate receptors and the kinetics of the associated ion channels may be obtained from a study of the noise which results from conductance fluctuations during drug action[3–8]. Analysis of voltage-clamped noise has been used in the present work to investigate the lifetime of an open channel in the presence of a steady concentration of a chemo-excitant, and to obtain an estimate of the single-channel conductance. In addition, we have examined the dependence of the channel duration on temperature and membrane potential and have compared the channel kinetics produced by different agonists and by the neurally released transmitter.

The metathoracic extensor tibiae of adult locusts (*Schistocerca gregaria*) was used[9] because its junctional glutamate receptors are easily accessible[10], and also because its fibres, being only ~1.5 mm long with a diameter of 100 μm, have a high input resistance in Cl-free medium (5–8 MΩ) and long space constant (1 cm), which makes them very suitable for voltage-clamp studies. Voltage recording and clamping microelectrodes were inserted within 100 μm of each other in the middle region of a fibre. L-Glutamate (Na salt *p*H 8; 0.1 or 1.0 M) or quisqualate (Na salt *p*H 8; 0.1 M) was applied iontophoretically from a micropipette (50–200 MΩ) positioned between recording and clamping microelectrodes, and at a sufficient distance from the junctional regions to produce a gradual increase in drug concentration at the junction and so reduce effects of fluctuations in ejection rate.

In locust muscle there are at least two types of glutamate-sensitive receptors[11]. The activation of one type (extra-junctional D and excitatory junctional receptors) leads to membrane depolarisation caused by the opening of channels which are permeable mainly to Na and K ions[10]. Activation of the second type (H receptors) produces membrane hyperpolarisation due to the opening of Cl channels. To avoid complications which would result from simultaneous activation of both membrane channels, we abolished the hyperpolarising effect by removing Cl ions from the medium[11].

The efficacy of clamping was evaluated from the residual voltage change recorded by a third intracellular microelectrode inserted at various positions along the fibres. Iontophoretic application of glutamate to the muscle membrane produced current fluctuations above the background. The variance of this glutamate noise increased as a linear function of the mean membrane current (μ_I). The energy spectra of the conductance fluctuations follows a $1/f^2$ curve (Fig. 1*a* and *b*) which fits well the theoretical relationship

$$S(f) = \frac{\gamma\mu_I(V_m - V_{eq})/\pi f_c}{1+(f/f_c)^2} \ (\mathrm{A^2\,s}) \qquad (1)$$

developed previously for the relaxation of acetylcholine (ACh)-controlled two-state channels in frog endplate[4] where f = frequency (Hz); f_c = cutoff (half-power) frequency = $1/2\pi\tau$ (where τ is the mean lifetime); γ is the conductance of a single

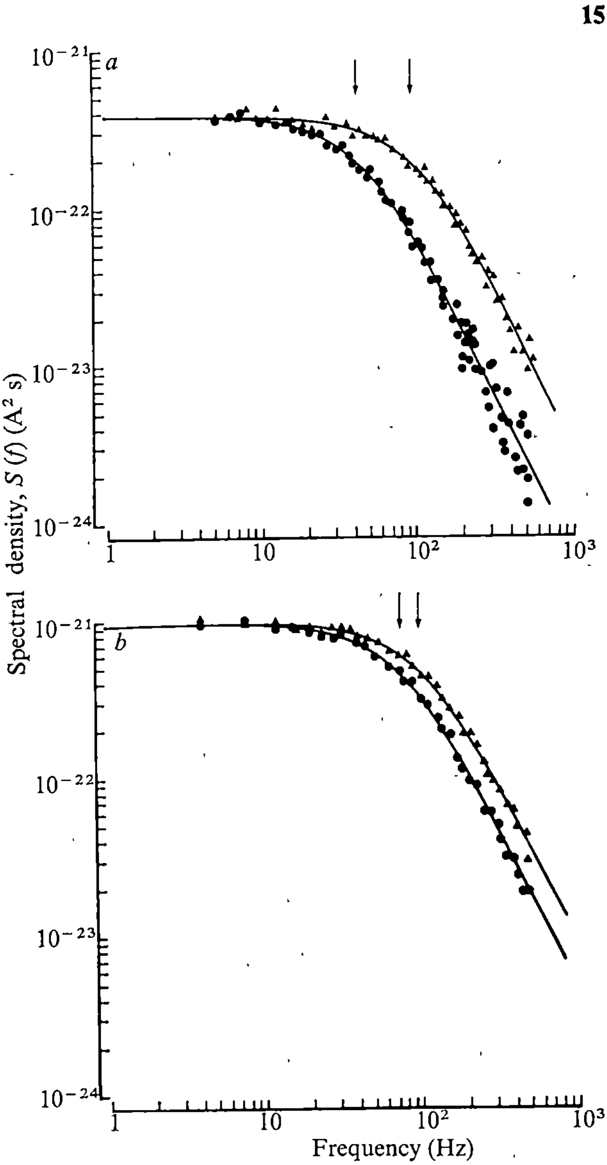

Fig. 1 Energy spectra of glutamate current noise obtained in voltage-clamped muscle fibres. *a*, Temperature dependence of the glutamate noise spectra from a single fibre at V_m = 104 mV. ●, 8.3 °C; ▲, 22.5 °C. The half-power frequencies are: f_c = 98 Hz at 22.5 °C and 45 Hz at 8.3 °C, for mean currents of 11 and 9 nA respectively. Vertical axis may be converted to conductances by multiplying ordinate values by 92.46. Single-channel conductances calculated from the fitted curves are $\gamma = 1.03\times10^{-10}$ mhos at 22.5 °C and 3.91×10^{-11} mhos at 8.3 °C. For comparison, the curve at 8.3 °C has been scaled by multiplication (simple vertical translation on log–log coordinates) by 1.5. Arrows mark half-power frequencies (R_{in} = 7.5 MΩ). *b*, Membrane potential dependence of glutamate noise spectra from a single fibre (different from that shown in *a*) at T = 23.0 °C. ●, 60 mV; ▲, 100 mV. Curves fitted to the data have f_c = 100 Hz and $\gamma = 2.54\times10^{-10}$ mhos at 100 mV, and f_c = 76 Hz and $\gamma = 2.34\times10^{-10}$ mhos at 60 mV. μ_I = 12 nA at 100 mV and 16 nA at 60 mV. Vertical axis may be converted to conductances by multiplying ordinate values by $(V_m - V_{eq})^{-2}$. Curve at 100 mV scaled by 0.97 for direct comparison of the cutoff frequencies. Arrows mark half-power frequencies (R_{in} = 5.0 MΩ). All spectra shown are from noise records taken during steady local application of glutamate. Data were edited to eliminate spontaneous miniatures. Membrane current was recorded on analog tape (bandwidth 1–2 5 Hz) through an active virtual earth and digitalised (32,768 points at 4,096 Hz sample rate) after low pass filtering (500 Hz, $1/f^8$). The Fourier transform (FFT algorithm) was calculated for 1,024 point segments and averaged after Hann filtering. Spectral values, equally spaced in frequency, are shown on log–log coordinates. No averaging across frequencies was performed. Data were processed with a Linc-8 in double precision floating arithmetic. Control noise spectra (1.25×10^{-23} A² s at 20 Hz) taken immediately before application of glutamate are subtracted point by point to remove background contributions from non-receptor membrane currents and electronics. Clamp quality at the voltage electrode was better than 99.8% at 0 Hz and better than 90% at 1.6 kHz over the entire membrane potential range used. Curves represent the relationship in equation (1).

open ionic channel; V_m = membrane potential and V_{eq} = equilibrium potential for glutamate, taken throughout as zero mV (ref. 11).

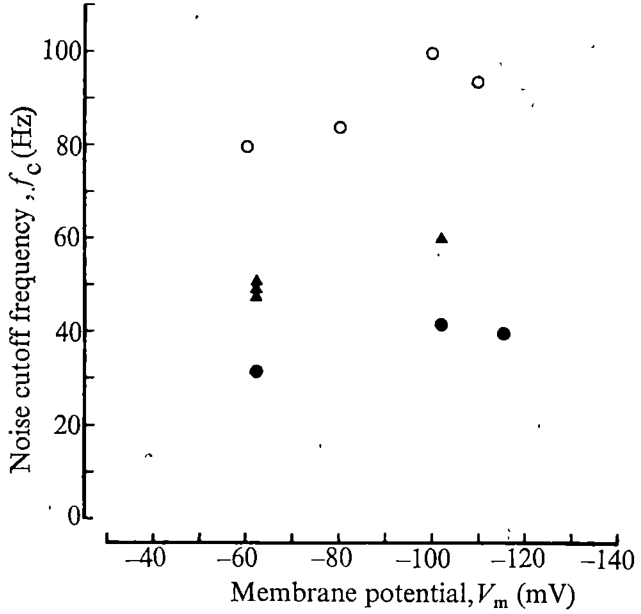
Although we positioned the electrodes near a junctional region, the glutamate presumably activated extrajunctional receptors as well. The fact that the noise spectra had a single $1/f^2$ component suggests that the contribution from extrajunctional sites is small, or that the kinetic properties of junctional and extrajunctional channels are very similar. This conclusion is supported by the fact that spectra of current fluctuations obtained during application of glutamate in a bathing solution agreed well with those obtained during iontophoretic application.

As shown in Fig. 1*a*, decreased temperature prolongs the open state of the glutamate-produced channel from 1.59 ms at 22.5 °C to 3.23 ms at 8.5 °C, giving an apparent single barrier activation energy of $E_A = 8.37$ kcalorie M^{-1} as calculated from the Arrhenius equation. The resulting Q_{10} of 1.45, is lower than that observed for ACh receptor channels[4]. Lowering the temperature has been shown to increase the value of τ derived from glutamate noise in squid nerve cells[6].

The mean value of the conductance of the single channel opened by glutamate was $\gamma = 2.31 \times 10^{-10}$ mhos at 23 °C, varying in different fibres from 1.0×10^{-10} to 2.6×10^{-10} mhos. In contrast with ACh sensitive channels[4], the conductance of the single channels opened by glutamate changes with temperature (Fig. 1*a*). By fitting equation (1) to the measured noise spectra, it was found that γ decreases as the temperature is lowered: in the fibre illustrated in Fig. 1*a*, $\gamma = 1.03 \times 10^{-10}$ mhos at 22.5 °C and 0.39×10^{-10} mhos at 8.5 °C for values obtained at the same site (*t* test for difference, $P > 0.01$). This temperature dependence ($Q_{10} = 2.12$) is greater than that of the intra- or extracellular conductivity (Q_{10} = 1.37 (ref. 12) and 1.26 (ref. 13), respectively). γ showed no significant correlation with V_m or μ_I.

Glutamate noise spectra change with membrane potential (Fig. 1*b*). The duration of an open single channel decreases with hyperpolarisation of the membrane ($\tau = 2.12$ at -50 mV and $\tau = 1.56$ at -110 mV at 23 °C). Figure 2 summarises this relationship for three cells over a 65-mV range of potentials at two temperatures. The voltage dependence of the half-power frequency has a high statistical significance at all temperatures investigated.

Fig. 2 Membrane potential dependence of the cutoff frequency for the energy spectra of glutamate noise. Results shown are from three different cells: ●, 8.0 °C; ▲, 8.5 °C; ○, 23 °C. Spectra were fitted to equation (1) and the cutoff frequencies determined. In terms of the model discussed, the average single-channel lifetime at each V_m and T may be calculated as $1/2\pi f_c$ (s).



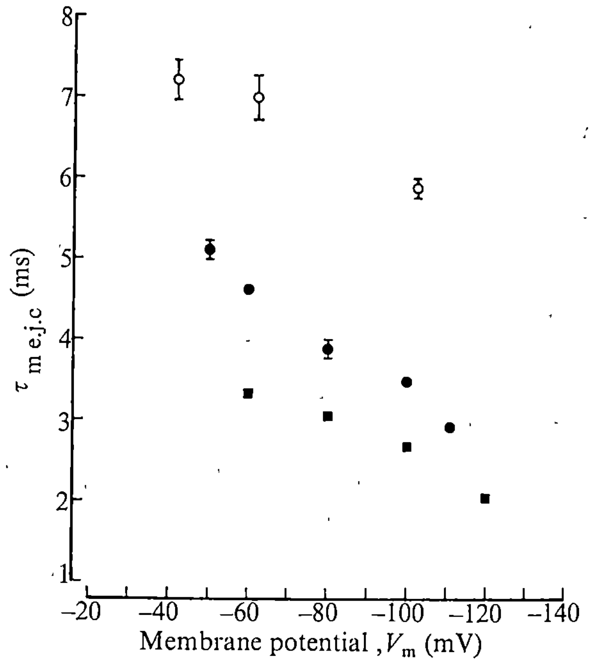


Fig. 3 Membrane potential dependence of the time constant of decay of spontaneous m.e.j.c.s. Results shown are from three different cells: ●, 20 °C; ■, 23 °C; ○ at 9 °C. Each event was digitalised at 5 kHz and the decay phase plotted on log–linear coordinates. The straight line through these points was fitted by the least squares method to give the time constant of the m.e.j.c. Approximately 100 such values were determined at each V_m and T. Histograms of the time constants used in the figure were distributed normally about the mean. The standard deviations ranged from 1.25 ms at 50 mV to 0.38 above 100 mV. *t* Tests for the confidence of the voltage dependence gave > 0.01 for a 60-mV change and between 0.15 at low V_m and 0.01 at 100 mV for a 20-mV step. The voltage residual during clamping was always less than 5%. Input resistances varied between 1 MΩ at 50 mV and 7.5 MΩ at 100 mV. All values are means±s.e. (shown only when greater than the size of the symbols). The larger s.e. obtained at low temperature result from the reduction in γ and the low frequency of m.e.j.c.s.

Quisqualic acid, a glutamate analogue derived from the seed of *Quisqualis indica*, is several times more effective than glutamate on glutamate receptors of crayfish muscle[14] and rat spinal neurones[15]. As the activation of ACh receptors by different drugs produces noise with different characteristics in frog muscle[16], it was of interest to compare the noise resulting from quisqualate and glutamate action in locust.

Iontophoretic application of quisqualate to muscle fibres produced a pronounced increase in μ_I and in current noise. The energy spectra of the current fluctuations during a steady level of quisqualate action can be described by equation (1) with f_c = 45 Hz at 23 °C and -116 mV. In an experiment in which the actions of glutamate and quisqualate were compared at the same sites, the lifetime of the quisqualate-produced channel (τ = 3.54 ms) was 1.8 times that obtained with glutamate. The conductance of the single channels produced by quisqualate ($\gamma = 2.42 \times 10^{-10} \pm 0.25$ mhos, $n = 10$, at 23 °C) and glutamate ($\gamma = 2.32 \times 10^{-10} \pm 0.12$ mhos, $n = 4$, at 23 °C) were, however, almost identical (*t* test, $P > 0.01$). In addition, quisqualate noise showed membrane potential dependence.

If glutamate is the natural transmitter, and provided the transmitter concentration during a miniature potential subsides very quickly, compared with the life span of an open channel, then the time constant of decay of the spontaneous miniature excitatory junction current (m.e.j.c.), $\tau_{m.e.j.c.}$ should approximate closely to the value of τ derived from glutamate noise (τ_{noise})[4]. Furthermore, both time constants should then display similar voltage and temperature dependence. Figure 3 shows such a relationship for $\tau_{m.e.j.c.}$ which approximately doubles for a 70-mV change in V_m or a 15 °C change in temperature (*t* test for both, $P > 0.05$).

There are conflicting reports on the voltage dependence of nerve-evoked excitatory junctional currents at glutamate-sensitive synapses[17–19]. Our results are in agreement with those previously reported for the crayfish nerve–muscle junction[18].

Time courses for m.e.j.c.s varied widely in all fibres, a finding confirmed by focal extracellular recording. The mean value of $\tau_{\mathrm{m.e.j.c.}}$ estimated from histograms obtained at different voltages and temperatures is longer than the open single-channel lifetime, as derived from the glutamate noise. Nevertheless, a proportion of the m.e.j.c.s, recorded both intra- and extracellularly at each site, gave τ values approximately the same as those of τ_{noise}. This point was checked further by simultaneous recording of focal extracellular miniature potentials and clamped intracellular miniature currents, allowing direct comparison of decay time constants of the same event. Both recordings gave similar τ values. A number of factors could contribute to the prolongation of $\tau_{\mathrm{m.e.j.c}}$, relative to the single-channel duration. These include: barriers to diffusion of transmitter across and out of the cleft; 'compression artefact'[20]; non-uniform space clamp; synaptic membrane areas with receptors possessing different relaxation times. These possibilities are being investigated.

It can be concluded that glutamate receptors, which mediate depolarisation in locust muscle, open channels with a mean lifetime which depends on temperature, membrane potential and agonist, while the single-channel conductance is dependent on temperature. The increase in conductance of the single channel with increased temperature and the decrease in mean lifetime of the channel with hyperpolarisation, are in marked contrast to the endplate channels opened by ACh. In terms of a dipole model of the glutamate receptor–channel complex, the dipole component parallel to the electric field in the membrane has a polarity opposite to that of the ACh receptor in vertebrate muscle.

We thank the Centre for Overseas Pest Research, Kensington, for supplying the locusts and Professor T. Takemoto for a gift of quisqualic acid. C.R.A. was supported by the NIH and S.G. C.-C. is a Beit Memorial Fellow.

Paradoxical response to amphetamine in developing rats treated with 6-hydroxydopamine

THE clinical syndrome of minimal brain dysfunction (MBD) in children is characterised by hyperactive motor behaviour, decreased attention span, impulsiveness and a variety of cognitive and perceptual problems. A striking feature of the disorder is the unusual response to stimulant medication. Thus, administration of amphetamine to children with MBD results in a sharp decrease in motor activity. Since the usual pharmacological response to amphetamine is an increase in motor activity, this response has been termed "paradoxical"[1]. We have described an experimental model in the developing rat that is strikingly similar to the clinical syndrome of MBD found in children[2]. Rat pups treated with 6-hydroxydopamine (6-OHDA) at 5 d of age develop increased motor activity and demonstrate cognitive difficulties in shuttle-box learning between 2 and 4 weeks of age. We now report that administration of (+)-amphetamine reduces the hyperactivity in 6-OHDA-treated rat pups, an effect paralleling the paradoxical response to this agent in children with MBD. The similarity of many of the cardinal features of MBD in an experimental model produced by depletion of brain dopamine in developing rats supports the belief that brain monoamines may be involved in the pathogenesis of this disorder.

All rat pups in a litter were randomly allocated as hyperactive or control animals at 5 d of age. Experimental hyperactivity was effected by intraperitoneal administration of desmethylimipramine (20 mg kg^{-1}) followed after 1 h by intracisternal 6-OHDA (100 µg 6-OHDA·HBr calculated as the free salt in 25 µl sterile saline)[2–5]. Control littermates received similar amounts of sterile saline intraperitoneally and intracisternally. Groups of 6-OHDA-treated and control rats were subsequently treated with saline or amphetamine (at doses of 0.25, 0.5, 1.0 and 5.0 mg kg^{-1}) 30 min before monitoring activity and activity was determined for a 60-min interval at 8, 12, 15, 19, 22 and 26 d of age using the following time-sample method[2,6,7]. Rats were randomised and placed in transparent Plexiglas cages, containing a water bottle and food, which were arranged in three rows on a steel cage rack. At the beginning of each minute the cages were scanned and a written note made of the behaviour of each rat at that time using one of the following categories· inactive—standing or sitting motionless; ambulating—walking or running about the cage; climbing—forepaws on the side of the cage or on water bottle; rearing—both forepaws clear of the floor; eating—gnawing at food; drinking—mouth in contact with water bottle; sniffing—sniffing at any part of the cage or in the air; grooming—any self-washing or licking movements; scratching—scratching body with hind leg. Any cumulative effect of (+)-amphetamine was minimised by the 3–4-d interval between administration of the agent. All measure-

Fig. 1 Effect of amphetamine on activity in control and 6-OHDA-treated rat pups. At 5 d of age animals received intracisternal injections of 25 µl saline or 100 µg 6-OHDA after pretreatment with desmethylimipramine. Activity was determined 30 min after injection of 0.5 mg kg^{-1} amphetamine throughout the first month of life. Activity is represented as mean ± s.e.m. First open column, control saline; second open column, control amphetamine; hatched column, 6-OHDA saline; solid column, 6-OHDA amphetamine. *Differs from saline, $P < 0.001$; †differs from saline, $P < 0.05$.

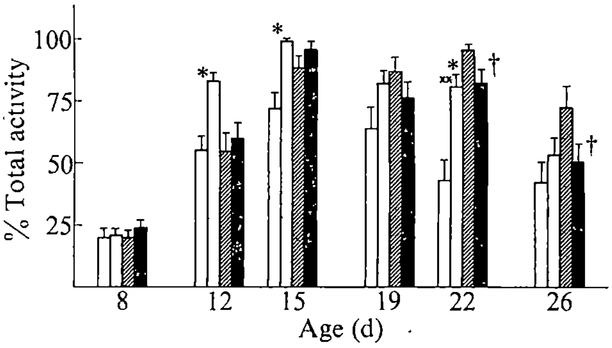

Table 1 Brain catecholamine concentrations

	Neonatal treatment			
	Vehicle		6-OHDA	
Dose amphetamine (mg kg^{-1})	Saline	Amphetamine	Saline	Amphetamine
0.25	(5)	(5)	(5)	(6)
Dopamine	532±25.1	520±36.0	114±43.2*	137±3.75*
Noradrenaline	267±11.0	265±20.5	246±8.49	241±17.4
0.5	(6)	(6)	(5)	(6)
Dopamine	488±28.9	480±17.3	191±33.4*	164±12 8*
Noradrenaline	345±27.1	278±11.0	313±23.5	283±17.7

*6-OHDA (saline or amphetamine) compared with vehicle (saline and amphetamine) $P<0.001$; †$P<0.01$; ‡$P<0.05$ (t test).

Dopamine and noradrenaline are means, ng per g wet weight±s.e.m. 6-OHDA (100 µg) or vehicle administered at 5 d of age. Amphetamine or saline administered at 8, 12, 15, 19, 22 and 26 d of age. Rats killed at 33 d of age. Number of rat pups given in parentheses.

ments were made between 1300 and 1600 to minimise the variation resulting from circadian periodicity. Total activity, ambulation and sniffing activity determinations in each group were subjected to analysis of variance. Rats were killed by decapitation at 33 d of age, their brains were removed rapidly and frozen at −80° C, and analysed within 2 weeks for dopamine and noradrenaline using a fluorimetric assay[8,9]. At each particular dose 6–8 animals were used in either control or 6-OHDA-treated groups. Differences in catecholamine concentrations between groups were analysed using t test[10].

The intracisternal administration of 6-OHDA to 5-d-old rat pups resulted in significant and comparable reductions in brain dopamine in both amphetamine- and saline-treated animals (Table 1). These reductions in dopamine concentration ranged from 21–39% of control values reflecting the variable amount of 6-OHDA actually reaching dopaminergic terminals by way of the cisternal route, and were in all cases significantly lower than their comparable littermates treated with vehicle solution. This contrasts with noradrenaline concentrations, which ranged from 91–108% of controls and were in no instances significantly reduced compared with the controls.

Total activity was significantly greater in 6-OHDA-treated rats between 2–4 weeks of age ($P<0.001$) than in littermate controls, confirming results of our previous investigation[2]. This increase in activity was primarily the result of significant increases in both ambulation ($P<0.001$) and sniffing ($P<0.001$) that occurred during this period.

Administration of amphetamine at doses of 0.25, 0.5 and 1.0 mg kg^{-1} to normal developing rat pups resulted in significant increases in activity from 12 d of age, and as early as 8 d in rat pups given 5.0 mg kg^{-1}. This increased activity was due to both increased ambulation and sniffing activity.

In contrast, administration of amphetamine between 2 and 4 weeks of age to 6-OHDA-treated rat pups resulted in a significant reduction in total activity (Fig. 1). This reduction occurred primarily at the expense of ambulatory activity, which was markedly reduced. Sniffing and other stereotyped behaviour did not change. Analysis of variance demonstrated the amphetamine-induced reduction in activity in 6-OHDA-treated rat pups at amphetamine doses of 0.5 mg kg^{-1} ($F=5.83$, d.f. 1, 370, $P<0.05$), 1.0 mg kg^{-1} ($F=6.10$, d.f. 1, 359, $P<0.05$) and 5.0 mg kg^{-1} ($F=6.49$, d.f. 1, 360, $P<0.05$). (+)-Amphetamine at a dose of 0.25 mg kg^{-1} had no significant effect on activity ($F=1.4$, d.f. 1, 320, $P>0.05$). There was significant correlation between amphetamine dosage and age ($F=6.38$, d.f. 16, 2,265, $P<0.001$) as well as between amphetamine dosage and 6-OHDA or saline treatment ($F=6.35$, d.f. 4, 2,265, $P<0.001$).

Our data indicate that, in certain conditions, administration of amphetamine results in a decrease in locomotor activity rather than an increase. Such a paradoxical response to amphetamine may be explained most parsimoniously by considering the relationship between amphetamine and brain monoamines. Although their exact nature is unclear, it is generally believed that the stimulant actions of amphetamine are mediated by way of central catecholaminergic mechanisms. Thus, amphetamine is known to increase the amount of dopamine and noradrenaline at the synaptic cleft by increasing granular release and by decreasing neuronal uptake[11–15]. Controversy exists over whether dopamine, noradrenaline, or both monoamines are responsible for the behavioural effects of amphetamine. The issue is complicated still further by the presence of two well documented dopaminergic systems within the brain. Recent evidence indicates that the mesolimbic dopaminergic pathway is essential for amphetamine-induced locomotor activity, whereas the nigroneostriatal dopaminergic system seems to mediate amphetamine-induced stereotyped activity[16–18].

We suggest that both the hyperactivity and the paradoxical response to amphetamine found in 6-OHDA-treated rat pups may be explained by considering that the nigroneostriatal dopaminergic system acts as a modulator of excitatory activity. This excitatory activity may be mediated by way of the noradrenergic pathways or by the mesolimbic dopaminergic system. Administration of 6-OHDA affects predominantly the nigroneostriatal dopaminergic pathway and thus excitatory activity, whether noradrenergic or mesolimbic dopaminergic occurs unrestrained. The denervated receptors in the dopaminergic inhibitory system are, however, supersensitive and so respond to a greater extent to catecholamines released presynaptically by amphetamine than do the undamaged receptors in excitatory pathways, leading to a predominance of inhibitory mechanisms and thus reduced activity.

That such a supersensitivity phenomenon does indeed exist may be demonstrated both behaviourally and pharmacologically. Administration of the dopaminergic stimulating agents apomorphine and L-dopa enhance both the locomotor and stereotypy response to amphetamine in adult rats treated with 6-OHDA (refs 19, 20). Furthermore, recent evidence suggests that the postsynaptic action of dopamine is mediated by way of a cyclic AMP-dependent mechanism. This adenylate cyclase response is significantly increased after denervation of striatal tissue, the presumed pharmacological correlate of supersensitivity[21–24]. The parallel between the syndrome produced in developing rats by depletion of brain dopamine and the clinical syndrome, together with the suggestion of reduced turnover of brain dopamine found in a small homogeneous group of children with the disorder[25], suggests that brain monoamines may play a role in the pathogenesis of MBD.

Lesions of ascending dopaminergic pathways decrease forebrain glucose uptake

WE describe the changes in forebrain glucose uptake following various lesions of ascending catecholaminergic pathways. These pathways include dopaminergic fibres arising from the pars compacta of the substantia nigra (A9 of Dahlström and Fuxe[1]) and from other cell bodies in the ventral tegmentum (A8, A10) and noradrenergic fibres originating from the locus coeruleus (A6) and from other cell bodies in the midbrain (A7) and medulla (A1, A2, A5)[2]. We have found that destruction of dopaminergic fibres results in decreased forebrain glucose uptake.

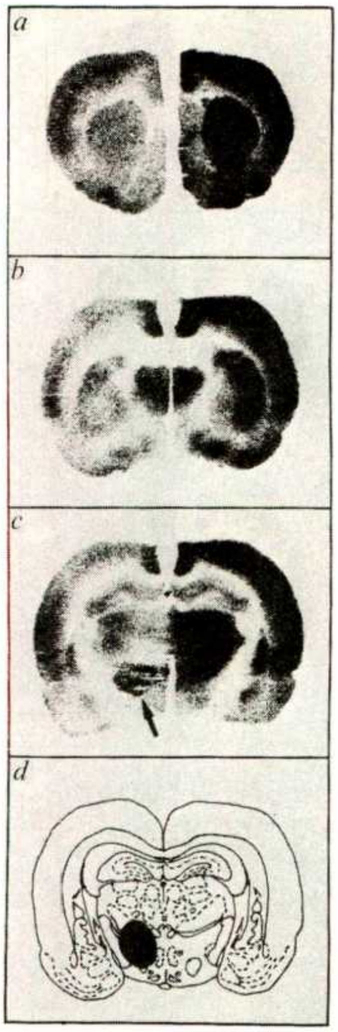

Fig. 1 ^{14}C-2-deoxy-D-glucose X-ray film autoradiographs of coronal brain sections from an animal with a unilateral electrolytic lesion of the lateral hypothalamus in the region of the ascending catecholaminergic pathways. *d* shows the extent of the lesion, which resulted in ipsilateral depression of forebrain glucose uptake seen at the level of the caudatoputamen (*a*), globus pallidus (*b*), and thalamus (*c*). In *c*, the arrow denotes an area of increased glucose uptake at the rostral end of the lesion, probably representing a region of gliosis.

Glucose uptake was measured using a new technique developed by Sokoloff *et al.*, which facilitates determination of the rates of glucose uptake of individual structures within the central nervous system (CNS) by using tracer amounts of ^{14}C-2-deoxy-D-glucose (2DG)[3,4]. A pulse of the tracer is injected intravenously and 45 min allowed for completion of the phosphorylation of 2DG to ^{14}C-2-deoxy-D-glucose-6-phosphate by brain hexokinase. Autoradiographs, made from X-ray film exposed to cut sections of a brain from an injected animal, can be used to calculate the rates of glucose uptake of all the visualised brain structures. The autoradiographs can be used to compare quantitatively the relative rates of glucose uptake of such structures. Thus, the darker the particular area on an autoradiograph, the higher is the glucose uptake[3,4] in that area.

Recent studies using this technique have mapped qualitatively alterations of regional glucose uptake associated with alterations of functional activity. Regional, activity-related increases in glucose uptake occur in the mammalian CNS during sciatic nerve[4,5], vestibular[6], and olfactory[7] stimulation; during penicillin-induced seizures[4]; and during periods of swimming[8]. Decreases in glucose uptake follow unilateral eye enucleation and unilateral occlusion of an external auditory canal[4]. Such decreases resulted from elimination of well defined sensory inputs with limited projections. We wished to extend such studies to the metabolic alterations following destruction of intrinsic diffusely-projecting sys-

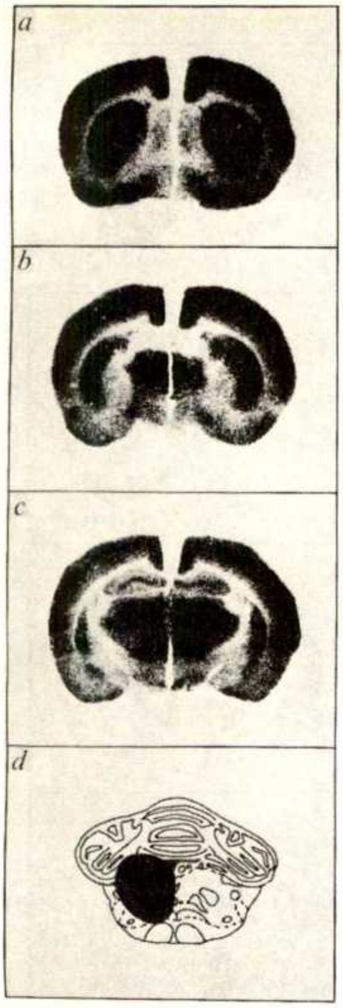

Fig. 2 Autoradiographs of coronal brain sections from an animal with a unilateral electrolytic lesion in the region of the locus coeruleus. *d* shows the extent of the lesion, which resulted in bilaterally symmetrical forebrain glucose uptake seen at the level of the caudatoputamen (*a*), globus pallidus (*b*), and thalamus (*c*).

tems. To do so, various lesions of the ascending catecholaminergic pathways were made.

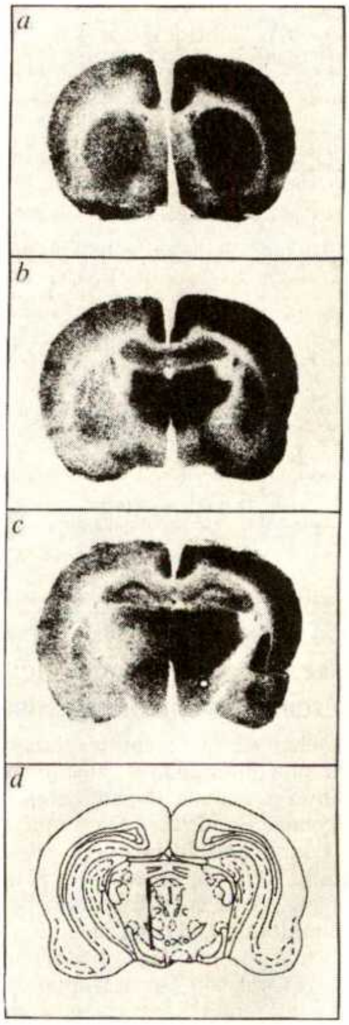
A total of 45 Sprague–Dawley albino rats, weighing approximately 150 g each, were anaesthetised with ethyl ether, and either electrolytic or 6-hydroxydopamine (6-OHDA) lesions were placed[8] stereotaxically in locations described below. For electrolytic lesions, 2 mA of current was passed for 30 s through stainless steel electrodes insulated to within 0.5 mm of their tips. 6-OHDA is believed to cause selective destruction of catecholamine-containing neurones[9]. For chemical lesions, 1 mg of 6-OHDA dihydrobromide (base) and 0.1 mg ascorbic acid were dissolved in 0.5 ml sterile saline and 4 μl of the solution (8 μg 6-OHDA) was injected over 4 min using a Hamilton syringe.

After lesioning, rats were housed in individual cages with food and water *ad libitum* for 72 h. They were then injected intravenously through the tail vein with 50 μCi ^{14}C-2DG (New England Nuclear, 53 Ci mol^{-1}) in 0.25 ml normal saline. After injection, animals were restrained in individual holders for 45 min and then killed with an overdose of sodium pentobarbital. Brains were removed quickly and frozen in isopentane cooled to −70 °C with solid CO$_2$. Frozen sections (30 μm) of brain were cut on a cryostat, dried quickly and autoradiographed on X-ray film as described previously[10].

We have made unilateral electrolytic lesions of the lateral hypothalamic area in the region of the ascending catecholaminergic pathways[2,11]. Nine animals were subjected to such a lesion and 8 had autoradiographs as shown in Fig. 1. The glucose uptake of structures rostral and ipsilateral to the lesion was depressed compared with that of the contralateral side; parts affected were wide ranging and included frontal cerebral cortex, caudatoputamen, parts of thalamus and other subcortical regions. The olfactory bulbs, hippocampus and structures caudal and ipsilateral to the lesion seemed unaffected. Control animals without lesions showed no such asymmetries.

To find out whether the ascending noradrenergic fibres cause this metabolic asymmetry, we made unilateral electrolytic lesions in the region of the locus coeruleus in four animals. These lesions were large (Fig. 2*d*), destroying much of the pons unilaterally at this level, so both the locus coeruleus and ascending noradrenergic fibres from more caudal cell groups (A1, A2, A5) were destroyed. In all these animals, forebrain glucose uptake was bilaterally symmetrical (Fig. 2). Similarly, brains of rats with unilateral ($n=4$) 6-OHDA lesions of locus coeruleus all had bilaterally-symmetrical forebrain glucose uptake. Their autoradiographs were similar to those in Fig. 2. Finally, unilateral electrolytic lesions 1–2 mm further anteriorly ($n=3$), destroying the A7 cell group and all the other

Fig. 3 Autoradiographs of coronal brain sections from an animal with a unilateral 6-OHDA lesion aimed at the substantia nigra. *d* shows the appearance of the cannula track; the lesion resulted in ipsilateral depression of forebrain glucose uptake seen at the level of the caudatoputamen (*a*), globus pallidus (*b*), and thalamus (*c*).



ascending noradrenergic fibres, likewise had symmetrical forebrain glucose uptake.

On the other hand, of 13 animals with unilateral 6-OHDA lesions aimed at the substantia nigra, 4 produced autoradiographs showing a metabolic asymmetry (Fig. 3) similar to that seen after unilateral lateral hypothalamic lesions (Fig. 1). Unilateral electrolytic lesions involving substantia nigra and ventral tegmentum resulted in depressed ipsilateral forebrain glucose uptake in 4 of 6 additional rats, and the autoradiographs were similar to those in Fig. 3.

Our lesions of noradrenergic fibres in midbrain and pons resulted in bilaterally-symmetrical autoradiographs; therefore the ipsilateral depression of forebrain glucose uptake seen after lateral hypothalamic lesions cannot be due to ipsilateral destruction of noradrenergic fibres alone. A forebrain metabolic asymmetry can be reproduced, however, by 6-OHDA lesions around the substantia nigra. Because 6-OHDA can destroy both dopaminergic and noradrenergic fibres[9], we cannot yet determine whether destruction of ascending dopaminergic fibres alone is sufficient to cause an ipsilateral depression of forebrain glucose uptake or whether simultaneous destruction of both dopaminergic and noradrenergic fibres is required. In either case, we do know that destruction of at least ascending dopaminergic fibres is required.

Our low success rate in animals with 6-OHDA lesions around the substantia nigra (4 of 13) is perhaps due to the relatively large volume occupied by the catecholaminergic elements at this level and so to the difficulty of destroying it all. At the level of the lateral hypothalamus, however, ascending catecholaminergic fibres are gathered together as bundles, and their complete interruption would seem more guaranteed. It is also possible that we destroyed other non-catecholaminergic fibres as they pass through the lateral hypothalamus, and their interruption may have contributed to the high success rate seen there.

The normal level of forebrain glucose uptake in the awake, restrained rat seems to depend, at least, on intact ascending dopaminergic pathways. We speculate that these fibres may modulate forebrain glucose uptake in the intact animal, but we do not know whether this modulation is first mediated through changes in cell firing rates or through the specific dopamine-sensitive adenylate cyclase[12,13]. Finally, perhaps some of the functions attributed to brain dopamine[14,15] are somehow related to its control of forebrain metabolic activity.

Transport of globin mRNA from nucleus into cytoplasm in differentiating embryonic red blood cells

Erythropoiesis in chick embryos provides a useful experimental system to study specific gene regulation during embryonic differentiation. As they mature, red blood cells become almost totally committed to the synthesis of one set of gene products—haemoglobin peptide chains. Thus, the transcriptional and post-transcriptional processes involved in the expression of the globin genes can be conveniently studied in erythroid cells undergoing maturation.

It is the events that occur in erythroid cells at stages before and during the onset of haemoglobin synthesis that are of the most interest. Very little is known, however, about these early processes, one reason being the lack of an appropriate system whereby precursor erythroid cells at a sufficiently early stage—that is, before haemoglobin synthesis—can be obtained in adequate amounts and purity. This report describes experiments which delineate the initial pattern of transport of a eukaryotic messenger RNA (mRNA) (globin mRNA), from the nucleus into the cytoplasm during cellular differentiation. The results indicate that the synthesis, transport, degradation and translation of globin mRNA in embryonic erythroid cells seem to follow a rigorously regulated and coordinated pattern during embryonic differentiation. Globin mRNA is synthesised and retained exclusively in the nuclei during the initial 24 h of culture. This is followed by an almost complete transfer of globin mRNA from the nuclei into the cytoplasm within the next 24 h. Globin mRNA is thereafter predominantly in the cytoplasm. The relative amounts of globin mRNA in the nuclei and cytoplasm change reciprocally, although the total amount of cellular globin mRNA does not vary significantly during erythroid maturation. Haemoglobin becomes detectable only when 75% of the total cellular globin mRNA is present in the cytoplasm.

Erythroid cells at the erythroblast and later stages of maturation are present in the embryonic circulation of the chick, but the majority of these cells have already begun to synthesise haemoglobin[1]. To this end, we have established a culture system in which precursor chick erythroid cells can grow and undergo complete maturation *in vitro*. As a result of the culture conditions and the unique nature of the erythroid cell surface, clean and homogeneous populations of erythroid cells at various stages of maturation can easily be obtained[2].

In a previous report, we followed the initial synthesis of globin mRNA during maturation of cultured erythroid cells using a very sensitive and specific molecular probe for detecting and quantitating chick globin mRNA—^{3}H-labelled, single-stranded DNA complementary to embryonic chick globin mRNA (globin cDNA)[3]. The results indicated that significant amounts of globin mRNA were already present in the proerythroblasts by 24 h of culture. These results confirmed the observations obtained using actinomycin D as an inhibitor of RNA synthesis, which showed that haemoglobin synthesis in cultured erythroid cells was no longer sensitive to actinomycin D by 24 h of culture[2]. This separation in the time of the initial synthesis of globin mRNA and the first appearance of haemoglobin was also observed in intact embryos both by direct measurement of globin mRNA using globin cDNA[3] as well as indirectly, using actinomycin D (ref. 4).

The observations on the timing of the initial synthesis of globin mRNA during erythroid differentiation led to considerations of post-transcriptional regulation of the expression of globin genes. It is now generally accepted that globin mRNAs are very stable molecules[5–7]. Very little is known, however, about the events that occur from the

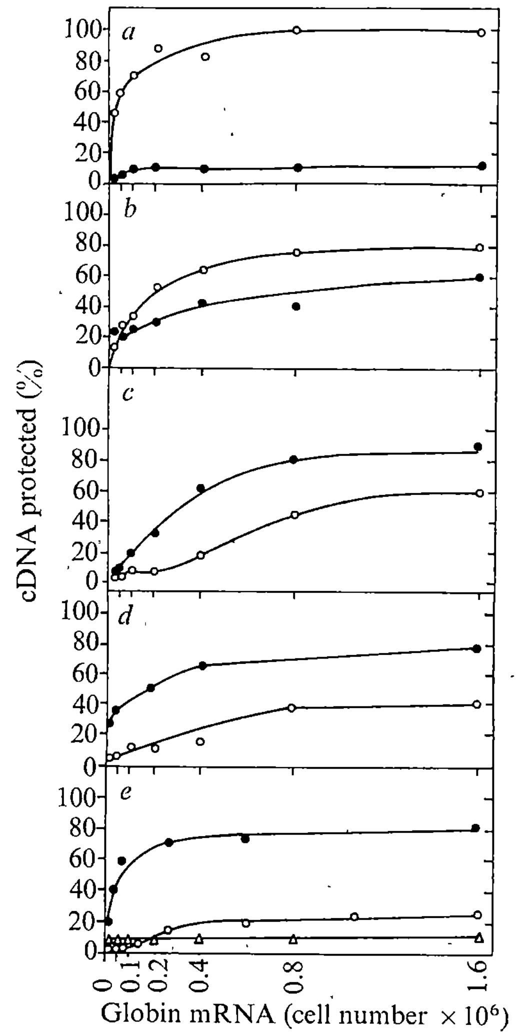

Fig. 1 Hybridisation of 7-d embryonic chick globin cDNA to nuclear and cytoplasmic RNA from erythroid cells at different times of culture. Erythroid cells were collected from the culture medium after various culture periods and washed several times with isotonic saline. Aliquots were taken for cell counts using a haemocytometer counting chamber and for preparation of slides. The slides were fixed in methanol, stained with benzidine reagent for haemoglobin and counterstained with mixed Wright Giemsa. The sensitivity of benzidine is estimated to be in the range of a few picograms haemoglobin per cell[11]. A total of 200 cells was scored with respect to their reaction to benzidine, and the percentage benzidine-positive cells calculated. The separation of nuclei from cytoplasm was accomplished as follows: the cell pellet was resuspended in 9 volumes buffer containing 0.01 M NaCl, 0.01 M Tris, pH 7.4, 0.003 M $MgCl_2$, 0.5% NP40 and 100 µg yeast transfer RNA (tRNA) for 2 min. Nuclei were pelleted by centrifugation at 1,400*g* for 15 min and the supernatant collected. The nuclei were washed once with the same buffer except no yeast tRNA was added. The supernatants were pooled, and 100 µg yeast tRNA was added to the nuclear pellet. RNA was extracted from the nuclear pellet and the supernatant using the phenol–chloroform–isoamyl alcohol technique. The ^{3}H-cDNA input was 300–350 TCA-precipitable c.p.m. per hybridisation reaction. The actual nanogram quantities of chick RNA used per reaction could not be determined because of the presence of yeast tRNA carrier, and therefore was normalised to the number of erythroid cells from which the RNA was extracted. Total cellular RNA extracted from cultured embryonic chick heart fibroblasts was used as control. ○, Nuclear RNA; ●, cytoplasmic RNA; △, total cellular RNA from embryonic chick heart fibroblasts. *a*, 24 h, 0% benzidine+; *b*, 30 h, 0% benzidine+; *c*, 44 h, 2% benzidine+; *d*, 50 h, 15% benzidine+; *e*, 72 h, 60% benzidine+.

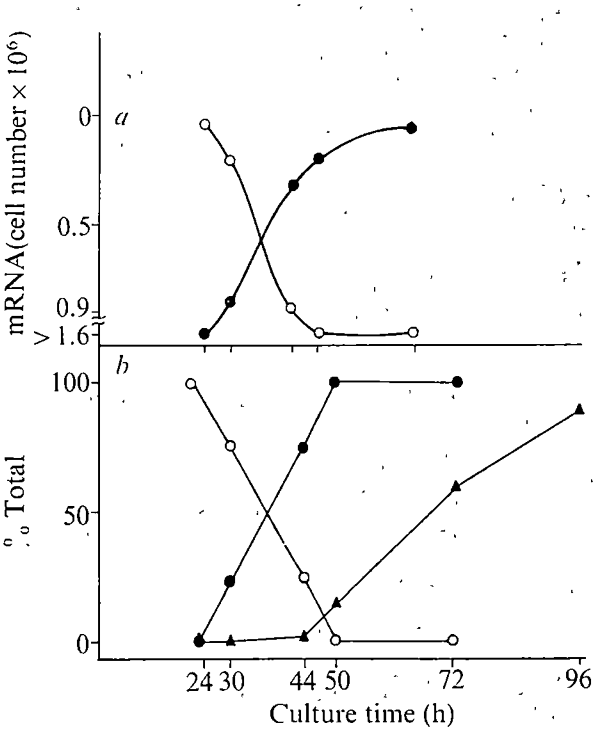
time of the initial synthesis of globin mRNA in the nuclei until the time when they are used for globin synthesis in the cytoplasm. It is reasonable to assume that the mRNA molecules must somehow move from the nuclei into the cytoplasm. But when and in what fashion mRNA transport occurs is hitherto unknown.

The experimental design used globin cDNA as a probe to quantify, as well as establish, the intracellular location of globin mRNA in erythroid cells during differentiation. Erythroid cells were collected after various times of culture, the nuclei were separated from the cytoplasm and the globin mRNA content of each fraction measured using labelled globin cDNA: cDNA was prepared using globin mRNA isolated from 7-d chick embryonic red cells as template[3]. Molecular hybridisation was carried out using the technique described by Ross *et al.*[8], except that 5-µl reaction mixtures were used. The amount of labelled cDNA protected by hybridisation with homologous RNA was determined by digestion with *Aspergillus oryzae* S1 nuclease as described previously[3].

Figure 1*a–e* shows the results of the hybridisation reactions between globin cDNA and RNAs extracted from the nuclei and cytoplasm of cells after various culture times. The percentage of cDNA protected was plotted against increasing amounts of RNA present in each reaction mixture. Total cellular RNA from cultured chick fibroblasts was used as control (Fig. 1*e*).

The results show that the initial transport of globin mRNA from nuclei into cytoplasm in differentiating erythroid cells follows a well regulated time course. Globin mRNA is synthesised and retained in the nuclei during the initial 24 h of culture, whereas very little, if any, is present in the cytoplasm. A considerable amount of globin mRNA

Fig. 2 *a*, Amounts of globin mRNA in nuclei and cytoplasm of erythroid cells at different times of culture. Ordinate shows amount of globin mRNA needed to give 50% protection of the cDNA in each reaction. Units were normalised to the number of erythroid cells from which the RNA was extracted. ○, Globin mRNA in nuclei; ●, globin mRNA in cytoplasm. *b*, Relative amounts of globin mRNA in nuclei and cytoplasm of erythroid cells and cells containing haemoglobin at different times of of culture. ○, Globin mRNA in nuclei; ●, globin mRNA in cytoplasm; ▲, cells containing haemoglobin.



then moves into the cytoplasm during the next 24 h of culture such that, by about 36 h, there are equal amounts of globin mRNA in the nuclei and the cytoplasm. By 44 h and thereafter, globin mRNA is predominantly in the cytoplasm.

From the 50% protection levels of cDNA in the hybridisation reactions, it is possible to estimate the absolute, as well as the relative, amounts of globin mRNA present in the two cellular compartments after different times of culture (Fig. 2*a* and *b*). The most striking observation is that the transport of globin mRNA does not follow immediately on synthesis. It is possible that this delay of transport may be due to the processing of mRNA from precursor molecules. The signal for the initiation of transport is unknown. Furthermore, since there is no overall change in the total amount of cellular globin mRNA during the 3-d culture period, this maximum level of globin mRNA is maintained regardless of its intracellular location. Note also that the amount of globin mRNA in the cytoplasm is a direct reciprocal of the amount of globin mRNA in the nuclei. There are several possible explanations to account for this observation: one is that globin mRNA is stable and does not turn over, so that once it is synthesised during the initial 24 h of culture, it remains intact in the cells for the duration of the culture period; a second possibility is that there is no new synthesis nor degradation of globin mRNA during the 24 h when it is being transported into the cytoplasm, but a steady state of synthesis and turnover is established thereafter. Neither of these possibilities seems likely, however, when we consider that the erythroid cells divide approximately once every 10–14 h at this time[8,9], but that no dilution of globin mRNA on a per cell basis occurs. A more likely explanation is that new globin mRNA is synthesised during this time, but the rates of synthesis, transport and degradation are coordinated such that the relative amounts of globin mRNA in the nuclei and cytoplasm change reciprocally, but the total amount of cellular globin mRNA remains unchanged. Evidence for this possibility awaits a thorough study of the rates of synthesis as well as rates and site(s) of degradation of globin mRNA in differentiating chick erythroid cells.

With regard to haemoglobin synthesis, the results show that haemoglobin becomes detectable only after 75% or more of total cellular globin mRNA is present in the cytoplasm (Fig. 2*b*). It is possible, however, that globin synthesis commences immediately after the first molecule of globin mRNA appears in the cytoplasm, but cannot be detected as haemoglobin until some time later. Studies are under way to establish the time when globin mRNA is first used for globin synthesis.

Effect of ribothymidine in specific eukaryotic tRNAs on their efficiency in *in vitro* protein synthesis

RIBOTHYMIDINE (m^5U or rT), the most common methylated nucleoside found in tRNA, is always at the 23rd position from the 3′ end in the nucleotide sequence GTψCPurine[1,2]. So far ribothymidine has been found in essentially all prokaryotic tRNAs which function in protein synthesis, but not in several eukaryotic 'elongator' tRNAs[3–6]. In the case of wheat germ, all the glycine tRNAs, several species of threonine tRNA and one species of tyrosine tRNA have an unmodified uridine in the position usually occupied by ribothymidine (ref. 5 and K.B.M., D. Marcu, and B.S.D., manuscript in preparation). To determine the significance of the absence of rT in these tRNAs, we have methylated them enzymatically with a crude preparation of *E coli* rT-forming uracil methyltransferase and then compared their efficiency with that of the unmodified tRNAs in a wheat germ cell-free protein synthesising system directed by various natural mRNAs. We report here that these tRNAs function significantly more efficiently in protein synthesis when lacking rT and that the inhibitory effect of rT can be reversed by the polyamine spermine.

The existence of a class of tRNAs containing an unmodified uridine in place of rT is especially significant in view of the evidence suggesting that rT and the tetranucleotide in which it is located are involved directly in the role of a tRNA in protein biosynthesis[7–16]. Using a crude rT-forming uracil methyltransferase isolated from *E. coli* MRE 600 and *S*-adenosyl-L-methionine (SAM) as a methyl donor, we methylated *in vitro* the specific rT-lacking tRNAs from wheat germ. Analysis of the methylation reaction showed that rT was the only product, and in the case of pure wheat germ $\text{tRNA}_{\text{I}}^{\text{Gly}}$, all the rT was found at the 23rd position from the 3′ end, as is normal in other tRNAs (ref. 5). About 18% of crude wheat germ tRNAs lack rT and are substrates for methylation: this agrees with the level of rT detected in crude wheat germ tRNA by Littlefield and Dunn[17]. Crude wheat germ tRNA was methylated to a level of 0.06 mol of rT produced per mol of crude tRNA, which corresponds with about 30% of the available tRNA substrates. There was essentially no degradation of tRNA during methylation, as shown by the level of aminoacylation of glycine and leucine tRNAs (Table 1) and the absence of an observable change in the elution position of crude wheat germ tRNA and $\text{tRNA}_{\text{I}}^{\text{Gly}}$ on Sephadex G-100 before and after methylation (data not shown).

Initial experiments were performed with a wheat germ cell-free protein synthesising system[18] using tobacco mosaic virions (TMV) RNA, brome mosaic virions (BMV) RNA or chorion polysomal RNA obtained from the chorionating follicular cells of *Anthereae polyphemus* as mRNAs. Analysis of the protein products produced on sodium dodecyl sulphate (SDS)-polyacrylamide gels gave results similar or identical to those reported before for these mRNAs[19–22], and confirmed the fidelity of the translation described. But this wheat germ protein-synthesising system could not be used directly to study protein synthetic activity of specific *in vitro* methylated tRNAs because of its high content of endogenous tRNA. We therefore fractionated the wheat germ system and essentially removed the endogenous tRNAs as described before[23–24]. tRNA was then clearly needed for the incorporation of ^{3}H-leucine and ^{3}H-glycine in the translation of either TMV RNA, BMV RNA or chorion polysomal RNA (Table 2, lines 1 and 2 and Fig. 1*a*). The extent of protein synthesis with the sham-methylated or untreated crude tRNA controls described above was essentially indistinguishable for all mRNAs tested (Table 2, lines 3–6). The use of an equivalent amount of 6% methylated crude tRNA, however, led to a significant reduction in protein synthesis for all mRNAs tested (Table 2, lines 7 and 8). Incorporation of ^{3}H-leucine decreased by 43% and 36% for TMV and BMV RNAs, respectively, and the amount of ^{3}H-glycine incorporated with chorion mRNAs decreased by 54% compared with untreated or sham-methylated tRNA.

The time course of protein synthesis directed by TMV RNA was observed in the presence of untreated, sham or partially methylated wheat germ tRNAs. As Fig. 1*b* shows, protein synthesis during the first 60 min was inhibited with *in vitro* methylated tRNA compared with untreated or sham-methylated tRNA, and the degree of inhibition depended on the level of *in vitro* methylation.

To study specific tRNAs involved in the inhibitory effect, pure (1.5 nmol per absorbance unit) 100% methylated tRNA$_1^{\mathrm{Gly}}$ was mixed with untreated crude wheat germ tRNA and the mixture was tested for protein synthetic activity. With BMV RNA translation, no effect on ^{3}H-glycine incorporation was observed (Table 2, lines 9 and 10). There was, however, 48% inhibition of chorion mRNA translation (Table 2, lines 11 and 12). Thus, methylated tRNA$_1^{\mathrm{Gly}}$ is not involved in the inhibitory effect on BMV RNA translation but inhibits chorion mRNA translation. This was not surprising in view of the very high glycine content of the chorion proteins produced[22]: it was the reason we chose this mRNA for study.

Protein synthesis studies were then performed with precharged tRNA$_1^{\mathrm{Gly}}$ to establish that inhibition is at the level of the ribosome. No appreciable inhibition was observed for

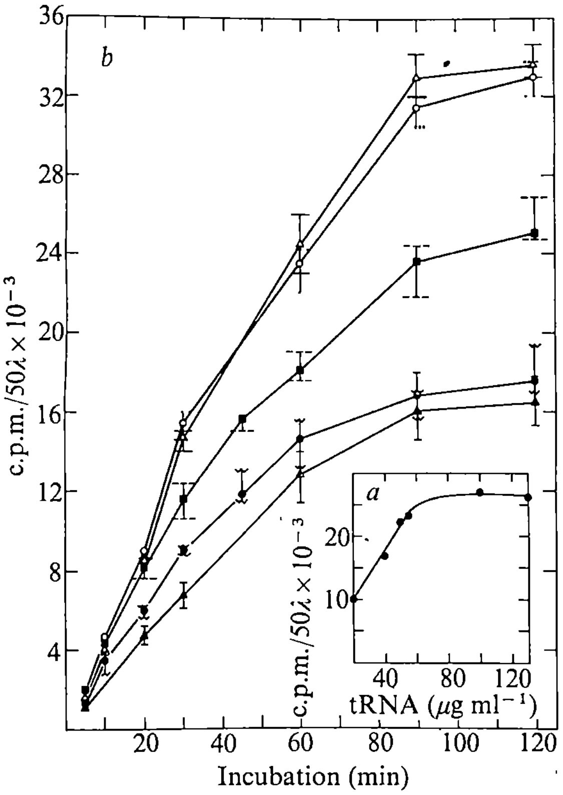

Fig. 1 *a*, Optimum concentration of crude wheat germ tRNA for the fractionated protein synthesising system. The levels of ^{3}H-leucine (2 Ci mmol^{-1}) incorporated into protein in a 50-λ protein synthesis assay (with washed ribosomes and an $(NH_4)_2SO_4$-concentrated DEAE-cellulose-treated S100) directed by 4 μg of TMV RNA is shown at various exogenously supplied levels of crude wheat germ tRNA. Reactions were terminated by adding 1 ml of 5% trichloroacetic acid (TCA), heated to 90 °C for 15 min, then cooled and collected on to Whatman GF/A filters which were dried at 150 °C and counted in Omnifluor–toluene as described before[18]. Each point represents the average of at least three determinations with a fluctuation not greater than 5%. *b*, Kinetics of protein synthesis directed by TMV RNA with *in vitro* methylated, sham-methylated and untreated crude wheat germ tRNA. All protein synthesis assays were performed with 2.5 μg of the particular tRNA in 50 λ. Samples of 5 λ were taken at the times indicated, precipitated, counted as before[18], and corrected for the total incorporation in 50 λ. All five assays were performed in triplicate except for the experiments with non-preincubated tRNA and 6% methylated tRNA, which were performed in duplicate. The 60-min time point for the non-preincubated tRNA sample was obtained in six other experiments with a deviation of not more than 10%. The 60-min time point for the 6% methylated tRNA assay was obtained in three other determinations, also with a fluctuation of not more than 10%. In addition, the 60-min time points for the preincubated, 1.2% and 3.2% methylated tRNAs were reproduced in at least two other assays. The same level of inhibition of methylated tRNA compared with sham or untreated tRNA controls observed at 2.5 μg of tRNA per 50-λ reaction were also observed at a tRNA concentration of 5.0 μg per 50-λ reaction. Proteins were labelled with ^{3}H-leucine (2 Ci mmol^{-1}). ○, Untreated; △, sham-methylated; ■, 1.2% methylated; ●, 3.2% methylated; ▲, 6% methylated.

Fig. 2 *a*, Protein synthetic activity directed by TMV RNA in the fractionated cell-free system with crude tRNA (50 μg ml^{-1}) at various concentrations of spermine. The reactions were carried out as described in Fig. 1 and ref. 18. Each point was obtained at least in triplicate and the fluctuation was not greater than 12%. *b*, Kinetics of protein synthesis directed by TMV RNA with *in vitro* methylated and sham-methylated crude wheat germ tRNA in the presence of spermine. All protein synthesis assays were performed with 2.5 μg of the particular tRNA sample in 50 λ. Samples of 5 λ were taken at the times indicated, precipitated and counted as before[18], and corrected for the total incorporation in 50 λ. The sham-methylated and 3.2% methylated tRNAs were determined in triplicate and the 1.2% and 6% methylated tRNAs were obtained in duplicate. The 60-min time points of all four assays were redetermined in two separate experiments. Proteins were labelled with ^{3}H-leucine (2 Ci mmol^{-1}). Symbols as in Fig. 1.

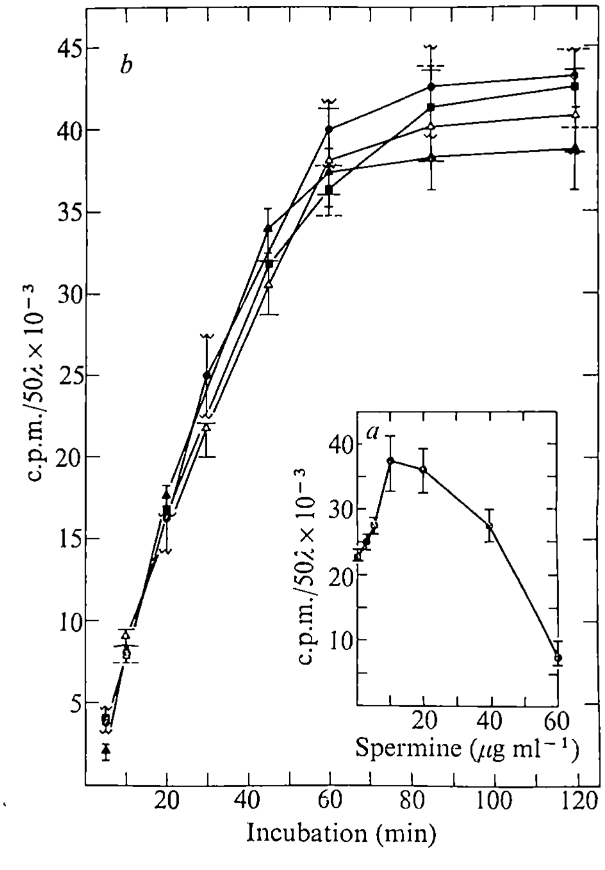

Table 1 Aminoacylation of *in vitro* methylated, sham-methylated and untreated crude wheat germ tRNA

tRNA	^{3}H-leucine incorporation (c.p.m.)	^{3}H-glycine incorporation (c.p.m.)
Untreated	2,450	1,040
Sham-methylated	2,400	1,100
1.2% Methylated	2,260	940
3.2% Methylated	2,250	915
6% Methylated	2,200	975

Performed in a final volume of 50 λ containing 50 mM Tris buffer, *p*H 7.6, 0.5 mM EDTA, 20 m $\mathrm{MMgCl_2}$, 2.5 mM ATP (disodium salt), 10 μM amino acid (^{3}H-leucine, 2 Ci mmol^{-1} or ^{3}H-glycine, 1 Ci mmol^{-1}), 2.5 μg of each tRNA sample and 10 λ of ribosome and tRNA-free wheat germ protein extract. The reaction was incubated at 30 °C for 30 min. Values listed are c.p.m. above a tRNA control performed in duplicate with ~ 10% deviation, and, in the case of methylated tRNAs, they are also corrected for the radioactive methyl label. Sham-methylation refers to the methylation reaction performed in the absence of SAM.

BMV RNA translation (Table 2, lines 13 and 14), which agreed with the comparison of uncharged *in vitro* methylated $\mathrm{tRNA_1^{Gly}}$ and uncharged, untreated $\mathrm{tRNA_1^{Gly}}$ (Table 2, lines 9 and 10). Chorion mRNA-directed protein synthesis was inhibited using precharged, methylated $\mathrm{tRNA_1^{Gly}}$ ~48% (Table 2, lines 13 and 14). The degree of inhibition is essentially identical to that observed without precharging the tRNA before protein synthesis (Table 2, lines 11–13), showing that the inhibition does not occur at aminoacylation.

Polyamines stimulate natural mRNA translation in various cell-free systems[18,25–28]. When an optimum concentration of spermine (10 μg ml^{-1}) was added to the cell-free system (Fig. 2*a*), the inhibitory effects of methylated $\mathrm{tRNA_1^{Gly}}$ on chorion mRNA translation and of methylated bulk tRNA on TMV RNA translation were eliminated (Table 2, lines 15 and 16 and Fig. 2*b*). The relative protein synthetic activity was increased to the same extent for both sham-methylated and untreated tRNA controls, but the increase was much greater for the methylated tRNA.

The ability of spermine to abolish the inhibitory effect of methylated tRNA may reflect a specific effect of spermine on tRNAs and their function in protein synthesis, perhaps mediated by altering the conformation of the tRNAs. Polyamines bind to ribosomes[29] and tRNAs (refs 30–33), and spermine differentially stimulates the translation of specific proteins directed by adenovirus mRNAs so as to reflect the relative levels of the specific proteins made *in vivo*[28].

The inhibitory effect on cell-free protein synthesis resulting from *in vitro* rT formation in specific wheat germ tRNAs may explain the absence of rT in these tRNAs *in vivo*. These same tRNAs also lack rT in 14-d-old wheat seedlings (data not shown). rT formation with these specific tRNAs may result in a less active tRNA conformation which is further altered in the presence of spermine to improve tRNA efficiency. The level of spermine varies widely in different organisms[29], and the level of spermine in wheat germ is not known and may be insufficient to prevent the inhibitory effects observed. The level of spermine (and perhaps even rT) could vary and constitute an effective regulatory mechanism for protein biosynthesis.

This investigation was supported by grants from the National Cancer Institute and the American Cancer Society. B.S.D. is the recipient of an NIH career development award.

We thank Drs Barbara Filner for TMV-infected leaves;

Hot TCA-precipitable radioactivity above background (−mRNA control) for 50-λ reactions incubated for 60 min at 30 °C as before[18]. All assays contained 2.5 μg of tRNA unless otherwise noted. Data was obtained at least in duplicate and in some cases in quadruplicate or sextuplicate (TMV data) with an average deviation of 10%. The maximum protein synthetic activity of the fractionated cell-free wheat germ system directed by TMV RNA was approximately 1/8 the level (with and without spermine) observed for the unfractionated extract. This drop in activity was also noted for BMV RNA (1/5) and for chorion polysomal RNA (1/7). The high level of activity of the crude extract was only consistently obtained if the extract was prepared quickly (total preparation time 75–90 min) and stored in liquid N_2 (up to several months) or at −80 °C (up to several weeks). Probably the time required to prepare the fractionated system (10–12 h) resulted in significant loss of protein synthetic activity. This drop in activity was also observed for the crude unfractionated extract after several weeks of storage at −20 °C.

* 4 μg TMV RNA per 50-λ assay.

† 4 μg BMV RNA per 50-λ assay.

‡ 10 μg crude polysomal RNA per 50-λ assay.

§ ^{3}H-glycine, 1 Ci mmol^{-1}; ^{3}H-leucine, 2 Ci mmol^{-1}.

¶ ^{3}H-glycine, 20 Ci mmol^{-1}.

‖ 20% of the 2.5 μg of crude tRNA added was $\mathrm{tRNA_1^{Gly}}$ or methylated $\mathrm{tRNA_1^{Gly}}$.

** 2.5 μg of either methylated or untreated $\mathrm{tRNA_1^{Gly}}$ precharged with ^{3}H-glycine (20 Ci mmol^{-1}) + 2.5 μg of crude untreated tRNA. A standard 50-λ protein synthesis reaction was performed with a 50-fold excess of glycine to prevent deacylation and reacylation of ^{3}H-glycine. Reactions were performed in duplicate with ~ 10% deviation.

Richard Gelinas for chorion RNA; Paul Kaesberg for BMV virions and Masayori Inouye for dansylated protein standards. We also thank R. Levenson for running the SDS gels and D. Marcu for carrying out the tRNA methylations.

Myoglobin of the orangutan as a phylogenetic enigma

THE primary structure of the myoglobin of nine anthropoid primates is known from previous work on three ceboids, two cercopithecoids and four hominoids[1,2]. The most striking result of these investigations has been the nature of residue 110. With the exception of the cercopithecoids and hominoids this position is occupied by alanine in all mammalian myoglobins known, including those of the South American monkeys. In the Old World monkeys, however, residue 110 is serine, and in man and the three apes so far investigated it is a cysteine. It is noteworthy that two of the codons for Ala can change to codons for Ser by a single point mutation, and each of these can change to a codon for Cys by a further single point mutation. There seemed, therefore, to be an evolutionary sequence Ala → Ser → Cys at this position in myoglobin[3] In the α chain of human haemoglobin and that of many other animals the homologous position is also occupied by cysteine[4]. The myoglobin residue at position 23 is also of particular interest among the primates, being serine in the gibbon and the monkeys investigated so far, whereas it is glycine in all other mammalian myoglobins for which the primary structure is known, including those of man, chimpanzee and gorilla.

Fig. 1 Orangutan (*Pongo pygmaeus pygmaeus*) myoglobin. Comparison with human myoglobin shows only two differences at positions 23 and 110 where the human residues are Gly and Cys, respectively. Methods used have been described elsewhere[13]. ——, Tryptic peptides; – – – –, peptic peptides; ⇀, dansyl-Edman degradation.

The amino acid sequence of the myoglobin of the orangutan (Fig. 1) differs from that of man at only two positions, surprisingly 110 and 23. At position 110, orangutan resembles the Old World monkeys by having serine, whereas the other hominoids have cysteine. At position 23 the orangutan resembles the gibbon and monkeys by having serine, rather than glycine as in man, chimpanzee and gorilla. Bearing in mind recent discussion of the phylogeny of catarrhine primates[5] these findings were unexpected and we have sought to investigate their possible implication.

If the conventional classification of the hominoids is assumed to reflect their phylogenetic relationships, then

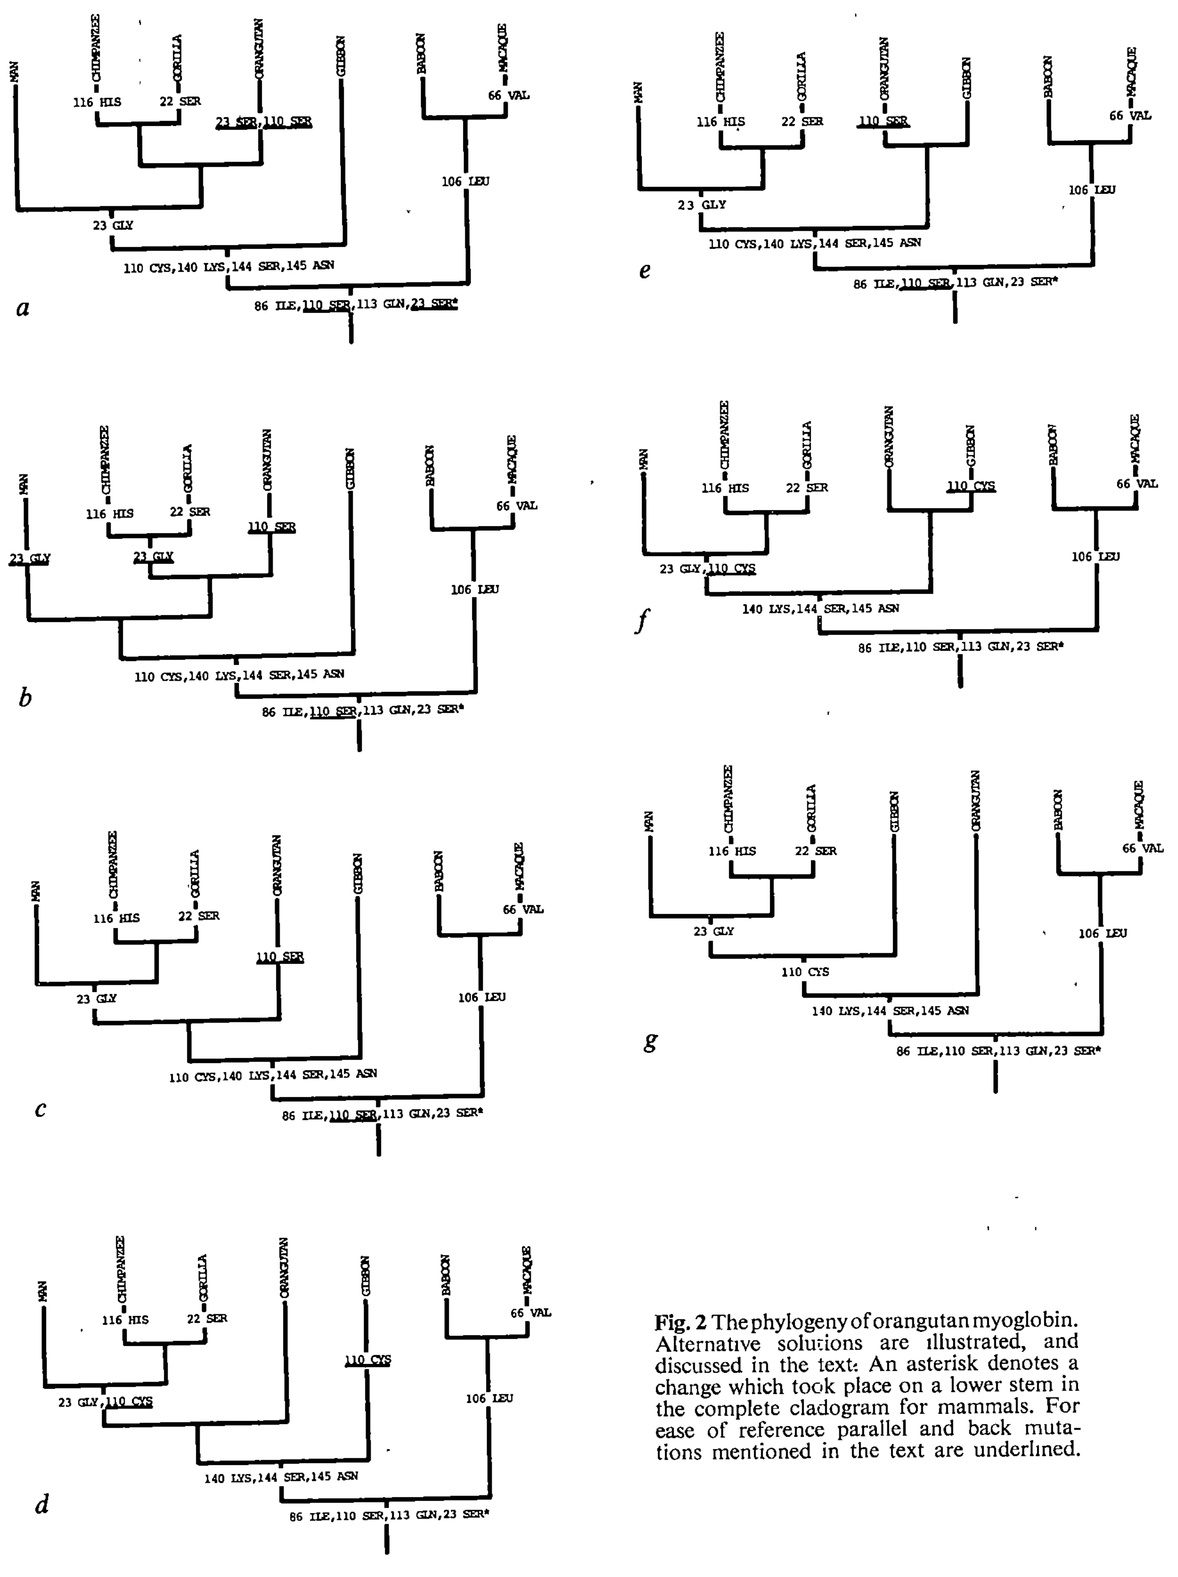

Fig. 2 The phylogeny of orangutan myoglobin. Alternative solutions are illustrated, and discussed in the text. An asterisk denotes a change which took place on a lower stem in the complete cladogram for mammals. For ease of reference parallel and back mutations mentioned in the text are underlined.

the orangutan would share immediate common ancestry with the chimpanzee and gorilla, all being included within the Pongidae, whereas the Hominidae would form a separate lineage leading to man. This pattern of phylogeny is shown in Fig *2a* and *b* In both of these cladograms, to account for the observed pattern of residues at the two positions 23 and 110 within the phylogeny of the anthropoids, a total of six single point mutations (hits) is required. In cladogram *2a*, 23 Ser and 110 Ser are both shown as back mutations in the line leading to the orangutan, whereas in cladogram *2b* the mutations to 23 Gly are shown as parallel events in the lineage leading to man and in the common stem leading to chimpanzee and gorilla, but 110 Ser remains as a back mutation in the orangutan lineage.

On the other hand, it is generally believed that the family Hominidae originated within the family Pongidae and so it is possible that the orangutan lineage branched from the pongid stem before the divergence of the Hominidae. In this event the chimpanzee and gorilla would share common ancestry with man subsequent to the divergence of the orangutan. This pattern, shown in cladograms *2c* and *d*, can be resolved more economically than *2a* and *b*.

It requires only 5 hits to account for the observed distribution of residues at positions 23 and 110. In cladogram 2*c*, 110 Ser remains as a back mutation in the orangutan lineage whereas in cladogram 2*d* 110 Cys is shown as being the product of parallel mutations in the gibbon and in the common stem leading to man, chimpanzee and gorilla.

An equally economical pair of solutions, involving exactly the same series of mutations as those in cladograms 2*c* and *d*, can be obtained by linking the orangutan to the gibbon (rather than to man, chimpanzee and gorilla) as shown in cladograms 2*e* and *f*. Such a phylogenetic pattern might be taken to imply that there is a fundamental division between African and Asian apes, and that the lineages leading to orangutan and to gibbon separated in Asia rather than in Africa. This is not necessarily so because any hypothesis relating African and Asian apes demands the presence of a viable migration route, and so the divergence between the orangutan and gibbon lineages might have occurred in Africa, along the migration route, or in Asia.

If one seeks the most economical solution to the phylogeny of the residues at positions 23 and 110 then one has to construct cladogram 2*g* (4 hits), in which the gibbon is so placed that it shares 110 Cys with man, chimpanzee and gorilla, and 23 Ser with the orangutan. This pattern implies that the line leading to the orangutan separated from the hominoid stem before that leading to the gibbon, which is contrary to the current consensus of opinion. Nevertheless, in trying to assess the relative merit of the alternative phylogenetic patterns discussed above, we have taken note of recent statements which seem to indicate that opinion on primate phylogeny is still in a state of flux.

Several years ago, Goodman[6] and Sarich[7] cast serious doubts on the phylogenetic pattern represented by cladograms 2*a* and *b*. The weight of immunological evidence and the sequences of fibrinopeptides[8], support patterns 2*c* and *d*. Nevertheless, Groves[9] expressed the view that gibbons were probably descended from the *Dryopithecus* complex, and he regarded their specialisations as being associated with the development of brachiation and reduction in size. Such a view could be accommodated by cladograms 2*e* and *f*, and Schultz[10], having reviewed skeletal features within the Hylobatidae, concluded that the siamangs resemble the great apes more closely than do other gibbons, and that this resemblance was particularly to the orangutan. On the other hand, Andrews and Groves[11] have little doubt that the gibbons branched off first from the hominoid common stem and their suggestion that *Dryopithecus africanus* is representative of a stage of hominoid evolution when *Pongo* had already branched off the stem but *Homo* and *Pan* had not yet separated, brings us back to cladograms 2*c* and *d*.

The only evidence known to us which provides support for the most economical phylogenetic pattern for myoglobin (2*g*) is given by Darga *et al.*[12], who reported that "with rabbit anti-human albumin serum, gorilla and chimpanzee seem to be almost identical to man while gibbon and siamang show slight divergence and orangutan shows yet more divergence although only about a third as much as Old World monkeys". On the other hand, for rabbit anti-human transferrin, gibbon and siamang diverge more than orangutan, and Darga *et al.*[12] concluded that the weight of immunological and molecular evidence indicated that within the Hominoidea, from the lineage leading eventually to man and the living African apes, an early branch led to the Hylobatidae and a later one to the orangutan.

If we accept the phylogenetic pattern of cladograms 2*c* and *d*, then we are forced to accept either a back mutation or a parallel mutation to arrive at the myoglobins of living hominoids. The same number of hits is required for cladograms 2*e* and *f* the pattern of which implies that orangutan and gibbon are phylogenetically equidistant from man. This pattern provides the least demanding circumstances for resolving the conflicting evidence from albumin and transferrin. If we reject cladogram 2*g* then we are rejecting the most economical solution. The evidence of other molecules is awaited with interest.

We thank Miss T. I. Molleson and Mrs P. H. Napier for their help in making available a sample of muscle of *Pongo pygmaeus pygmaeus*, British Museum (Natural History) Registration No. 1973.1570, the late 'Oscar' of Jersey Zoo. This work was supported by the Muscular Dystrophy Foundation of Great Britain, and O. C. is supported by a research training grant from the CONCIT, Government of Venezuela.

Host DNA replication or excision repair requirement for ultraviolet induction of bacteriophage λ lysogens

THE mechanism of prophage induction by radiation or chemical agents is unknown, although during the past decade a variety of hypotheses have been advanced[1–6]. Sussman and Ben Zeev[7] have presented biochemical data that seem to favour the suggestion that DNA intermediates in repair of DNA damage are competitors with the prophage operators for repressor binding. When sufficient repressor is bound to these regions none remains for prophage repression and so induction follows[7]. A consequence of this hypothesis is the prediction that induction

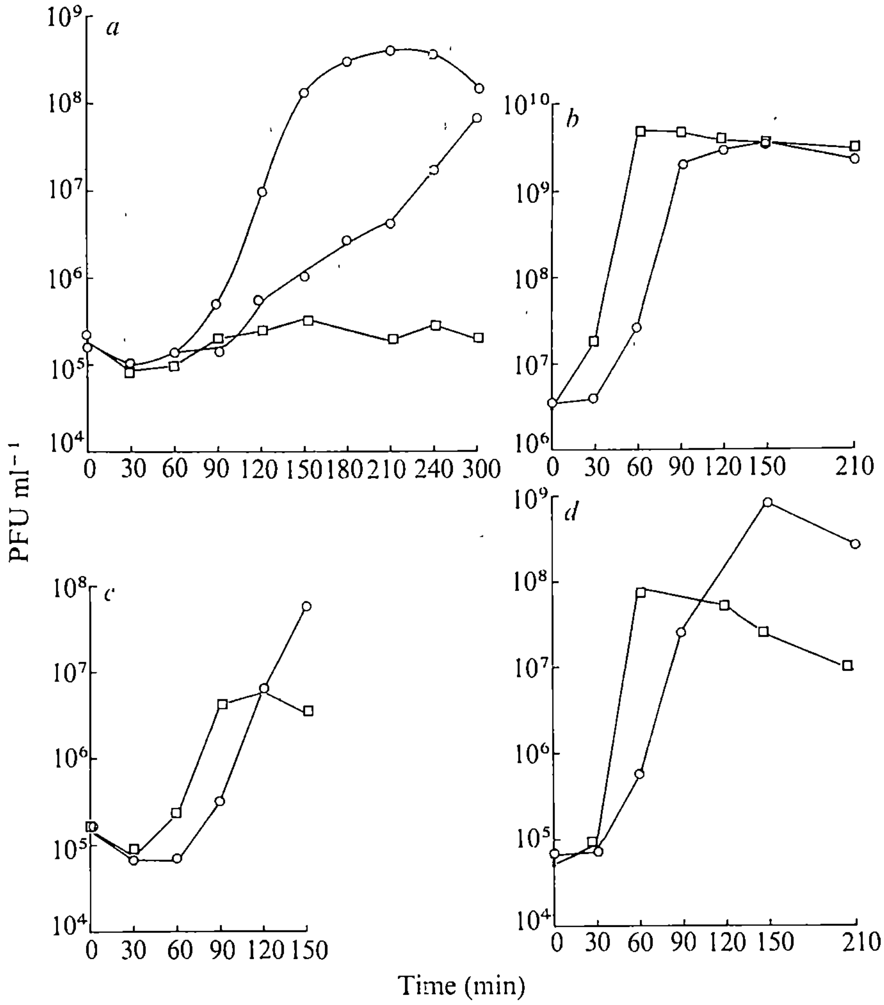

Fig. 1 *a*, *b* and *c*, Cells were grown to about 10^8 cells ml^{-1} in 10 ml 1% tryptone (Difco), 1% NaCl, 0.2% maltose and 0.01% yeast extract at 34 °C. Cultures were shifted to 42 °C for 1 h and poured into a pre-warmed 600-ml beaker in a 42 °C water bath. At $t = 0$ the culture was irradiated with 254-nm light. All subsequent steps were carried out in subdued light A sample was then transferred to a flask at 34 °C, and the remaining culture was incubated at 42 °C. At intervals samples were removed, shaken with chloroform and titred for plaque-forming units (PFU) on C600 (*uvr*$^+$ *rec*$^+$) by standard techniques. *a*, A second sample was removed from the 42 °C culture at $t = 60$ min and incubated at 34 °C (middle curve). *d*, Cells were grown at 34 °C until $t = 0$, when they were irradiated with the rest of the experimental protocol as in *a*, *b* and *c*. ○, Incubated at 34 °C; □ incubated at 42 °C. *a*, *dnaA uvrB* λ lysogen irradiated with an incident ultraviolet dose of about 55 J M^{-2}, yielding a cell survival of 0.02%. This dose was found to yield maximum phage induction in control experiments. Cell density at $t = 0$: 9 × 10^7 ml^{-1}. *b*, *dnaA* λ lysogen. Incident dose 110 J M^{-2}; cell survival, 3%; cell density at $t = 0$, 1.3 × 10^8 ml^{-1}. *c*, *uvrB* λ lysogen. Incident dose 55 J M^{-2}; cell survival, 0.09%; cell density at $t = 0$, 1.6 × 10^8 ml^{-1}. *d*, *dnaA uvrB* λ lysogen without 42 °C preincubation. Incident dose 55 J M^{-2}; cell survival, 0.08%; cell density at $t = 0$, 1.8 × 10^8 ml^{-1}.

should not occur in the absence of these normal repair processes. Here we test and verify this prediction.

Only two repair processes are known to alter the structure of DNA during repair· excision repair, which is absent in *uvrA*, *uvrB* and *uvrC* mutants[8], and post-replication repair, which seems to be a consequence of the passage of the DNA replication point past a damaged region of DNA[9,10].

Both forms of repair were eliminated using a bacteriophage λ lysogen of a *dnaAuvrB* double mutant. The *dnaA* mutation of Abe and Tomizawa[11] is temperature sensitive in the initiation of DNA replication, and grows normally at 34 °C. When shifted to 42 °C replication already started continues until complete but no new rounds of replication are initiated. DNA synthesis was undetectable in lysogens of these mutants after 1 h at 42 °C as measured by the incorporation of H^3-thymidine. DNA synthesis resumed shortly after the lysogens were returned to 34 °C. The *uvrB5* used here was obtained from strain AB2499 of Howard-Flanders[8].

Lyosgens were grown at 34 °C to a density of about 10^8 cells ml^{-1} and shifted to 42 °C for 1 h They were then irradiated at 42 °C and a sample transferred to 34 °C with the remainder kept at 42 °C. At intervals, samples were removed and assayed for free plaque-forming units.

Figure 1*a* shows that induction does not occur when the irradiated culture is held at 42 °C, whereas it does in the aliquot transferred to 34 °C. When the transfer was delayed until 1 h after irradiation, induction was also delayed (Fig. 1*a*, middle curve). Figure 1*b*, *c* and *d* shows control experiments, in *b* and *c* the same experimental protocol was followed with lysogens of single *dnaA* or single *uvrB* mutant hosts In both cases induction occurs in cultures held at 42 °C as well as at 34 °C, indicating that either excision or replication alone is adequate for induction. In Fig. 1*d* the *dnaAuvrB* lysogen was irradiated before the shift to 42 °C. Induction occurs at 42 °C, an indication that there is no defect in bacteriophage maturation in this double mutant at 42 °C.

Experiments with the radiomimetic antibiotic mitomycin C at 1 μg ml^{-1} as the inducing treatment have yielded quantitatively similar results.

As is shown in Fig. 2, little induction was observed over a wide range of ultraviolet doses in non-replicating, non-excising lysogens. The slight inducibility at 5 J m^{-2} has been observed repeatedly and may indicate either residual replication or excision repair, or the presence of alternate, minor pathways of prophage induction.

The absence of ultraviolet induction in non-replicating, non-excising lysogens found here is in disagreement with earlier results of Monk and Gross, who found induction in similar conditions[12]. The Monk and Gross experiments differed from these principally in the technical detail of dilution after irradiation. When this dilution step was used with the *Escherichia coli* lysogens of the present study, induction was obtained in cultures held at 42 °C. It is thus possible that dilution somehow initiates replication in a small fraction of the cells, a possibility which was not examined by Monk and Gross.

Although the results reported here can be taken to favour the alternate binding site hypothesis of Sussman and Ben Zeev, they do not rule out the possibility that the

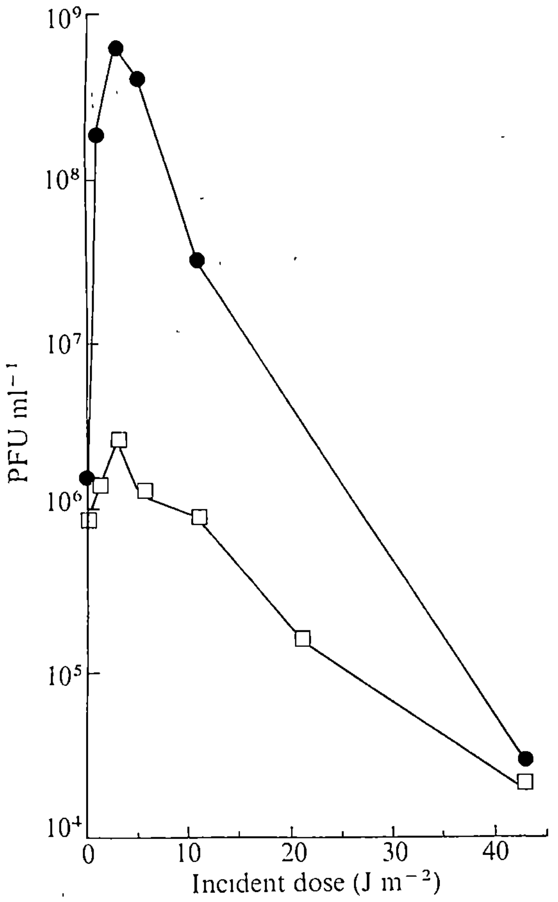

Fig. 2 Dose response of ultraviolet induction: 10 ml *dnaAuvrB* mutant was grown to a concentration of about 2×10^8 cells ml^{-1} at 34 °C in tryptone salt medium described in Fig. 1, collected by centrifugation and resuspended in 20 ml M9 medium[13] supplemented with 0.5% decolourised casamino acids, 0.01% thiamine and 0.2% glucose This culture was incubated with shaking at 42 °C for 1 h, and irradiated as described in Fig. 1. At various doses two samples of 1 ml each were removed with a preheated pipette. One sample was incubated at 42 °C, the other at 34 °C for 3 h. Great care was taken to prevent cooling of the samples before the 3-h incubation was over Chloroform (0.1 ml) was added to each of the incubation tubes, and the tubes shaken at 34 °C for 2 min. The titre of free phage was assayed as before. ●, Incubated at 34 °C. □, incubated at 42 °C.

repair intermediates are also alternative binding sites for repressors of other operons. For example, it is possible that the resulting derepression could induce an 'error-prone' repair system which in turn would cause bacteriophage induction[6] In view of Sussman's[7] observations, however, that the λ repressor binds to DNA isolated from ultraviolet-irradiated and mitomycin-treated cells[7], competition between prophage operators and repair intermediates for λ repressor seems to be the simplest way to account for the observed results.

Supported by grants from the NIH, the NSF and the ERDA. I thank R. Sussman, R. Feldberg, J. Doniger, and P. Howard-Flanders for discussions, and D. Freifelder for facilities.

Structure of insulin in 4-zinc insulin

DURING his experiments on slow acting clinical preparations of insulin, Schlichtkrull found that a second form of rhombohedral insulin crystals appeared when the sodium chloride ion concentration in the solution was 6% or more[1]. The new crystals contained four zinc ions per hexamer of insulin compared with two in the original crystals. Both forms crystallised in the space group R3 and had similar lattice constants: $a=82.5$ Å, $c=34.0$ Å for 2-zinc insulin, and $a=80.7$ Å, $c=37.6$ Å for 4-zinc insulin crystals[2] Both, from an early application of the rotation function[3], also seemed to be very similar in structure, and to contain in each asymmetric unit, two insulin molecules related to one another by non-crystallographic twofold axes of symmetry. We have now found, from electron density calculations on 4-zinc pig insulin, that the apparent similarity of the crystal structures conceals a surprisingly large change in the conformation of one only of the two insulin molecules in the unit.

The electron density map of 4-zinc pig insulin was phased on data from three isomorphous derivatives; a lead acetate derivative (3 sites) to 2.8-Å resolution; a mercuric acetate-2-hydroxybenzaldehyde derivative (3 sites) to 4.5 Å; and an iodo derivative formed by covalent attachment of iodine to tyrosine (4 sites: one of which proved to be a change in off-axial zinc ion occupancy or temperature factor) to 4.5 Å (ref. 4); measurements on anomalous scattering were made on each crystal. The contributions of the last two derivatives in the phasing calculations were small and the overall figure of merit 0.67. The map is easily interpretable, however, by comparison with that of 2-zinc insulin[5]; over one of the pair of insulin molecules in each unit the electron density is superimposable, over the other marked changes in residue arrangement can be followed. Only a few residues, which are on the protein surface, are not well defined.

In 4-zinc insulin, as in 2-zinc insulin, there are three equivalent dimers associated around the threefold axis to form a hexamer; the two structures are compared in Fig. 1 There are two zinc ions on the threefold axis in 2-zinc insulin, attached through B10 histidine residues to the two very similar molecules, I and II, of each insulin dimer. In 4-zinc insulin, one zinc ion appears on the threefold axis, attached to molecules nearly identical with molecule II of 2-zinc insulin The remaining zinc ions occupy general sites surrounding the threefold axis, linked by much-changed molecules at position I (Fig. 2). The change is effected by a major rearrangement of the first eight residues of the B chain. These, originally extended, now follow a generally helical course continuing at an angle of about 30° in the direction of the main B9–B19 α-helix.

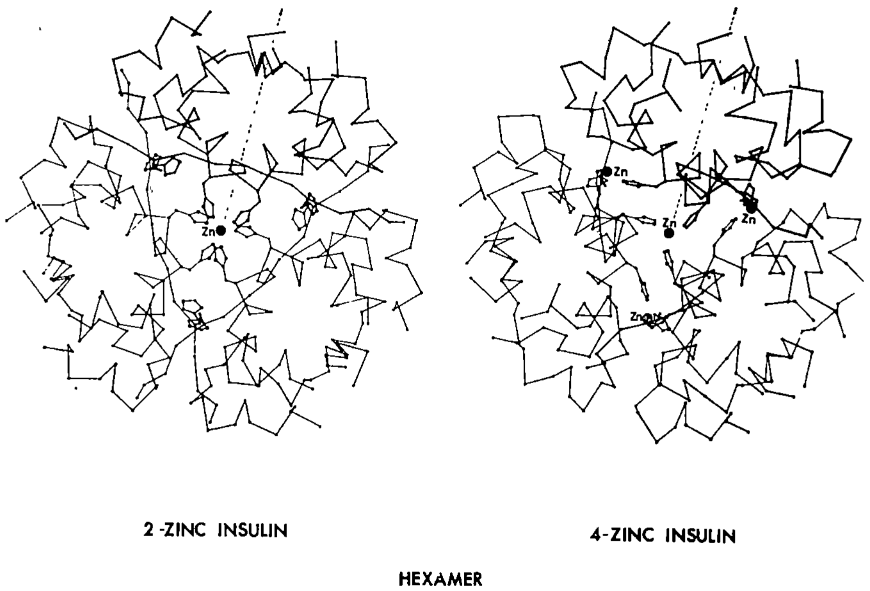

Fig. 1 A comparison of the 2-zinc insulin and 4-zinc insulin hexamers viewed down the threefold axis. Only α-carbon atoms, histidine side chains and zinc ions are shown. The local twofold axis of the dimers drawn in bold lines is also indicated.

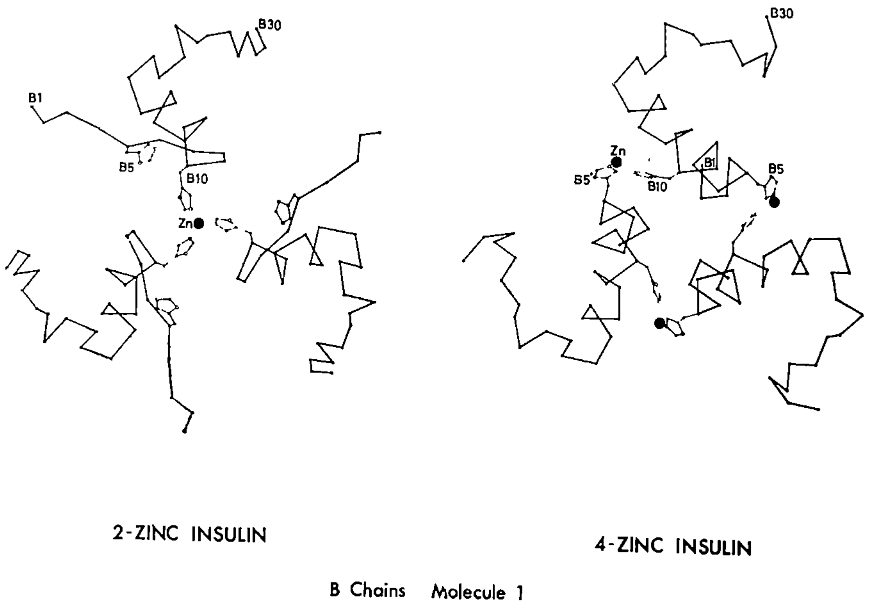

Fig. 2 An identical view to Fig. 1 comparing the molecule I B chains of 2-zinc insulin and 4-zinc insulin, illustrating the changed conformation and zinc coordination.

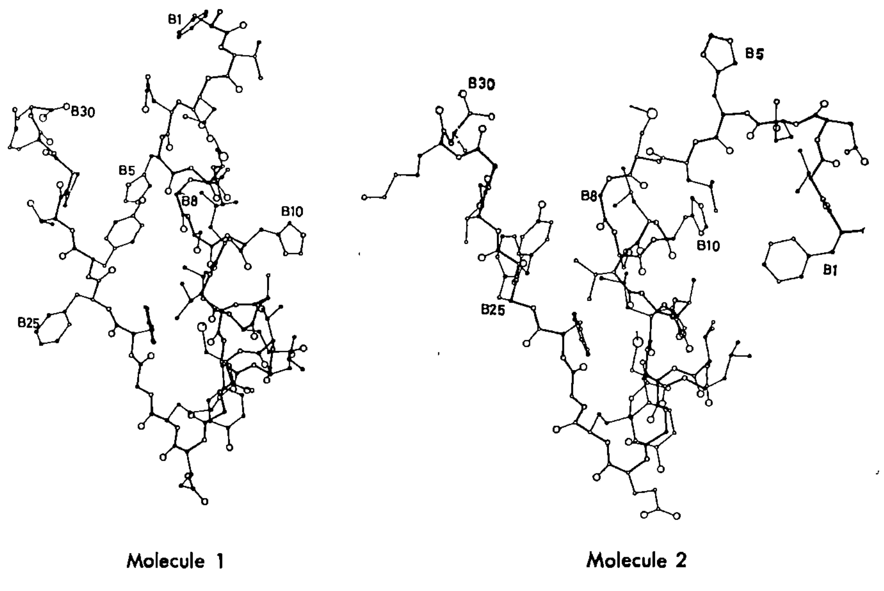

Fig. 3 The B chains of molecules I and II viewed from an equivalent direction.

The B5 histidine is moved in the transformations—15 Å across the cell, close to the B10 residue of a neighbouring molecule, which turns towards it. The zinc ion is held between these two histidine residues, tetrahedral co-ordination about it being completed by two water molecules. The change in the B-chain structure pivots about the B8 glycine residue which moves from the 'right-handed' amino acid conformation still present in molecule II, to the helical region of the Ramachandran plot.

The local twofold symmetry which is obeyed quite well in the 2-zinc insulin structure is therefore completely violated by the arrangement of the first eight B-chain residues of insulin molecules in 4-zinc insulin. Between B9 and B30, on the other hand (Fig. 3), the conformations of the two B chains are very similar. Correspondingly, the β-pleated sheet structure and the close non-polar contacts between them are unchanged in this region. The constancy of the structure here confirms our view that these B-chain contacts define the region of aggregation within the insulin dimer present in solution. The A chains of the two molecules in the 4-zinc insulin dimer are found to be quite similar to one another in conformation, but not in position relative to the B chains. The A chain of molecule I has moved in response to the movement of the A7–B7 disulphide link away from its usual contacts with the B-chain residues. As a consequence, a cleft appears within molecule I (compare Fig. 4). This encourages the asymmetric iodination in the crystal of the tyrosine side chains. The main reaction, which does not occur in 2-zinc insulin, is at tyrosine A19 (two sites with 36% and 26% substitution) and tyrosine B26 (one site with 19% substitution) of molecule I. The enhanced reactivity of molecule I in the insulin dimer is similar to the behaviour of enzyme complexes, such as malate dehydrogenase, in which only half the subunits are active[6].

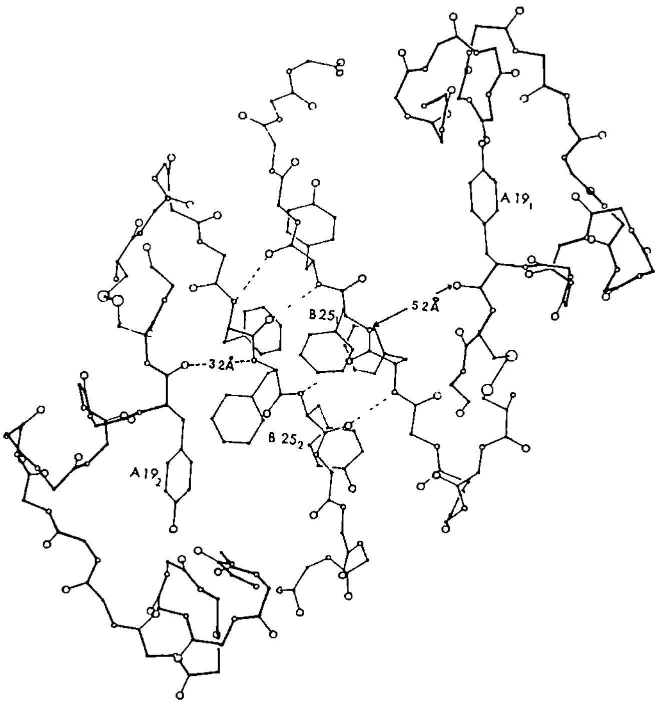

Fig. 4 Part of the 4-zinc insulin dimer viewed along the local twofold axis, showing the appearance of the cleft in molecule I. The region B1–B19 is omitted in both monomers and only the side chains of A19, A20, B19, B24, B25 and B26 are drawn.

The principal change we have observed, the coiling of the initial residues of the B chain, may be encouraged by the sequence in pig and cattle insulin, which is helix-forming in character. Preliminary experiments suggest that ions other than chloride may initiate the transformation, and that the ions enter the crystals. With sodium iodide the crystals formed are similar to, but not exactly isomorphous with, those obtained in sodium chloride solutions; difference electron density maps indicate that the ions enter at different positions on or near the threefold axis. We also have evidence that the 2-zinc crystals themselves can be transformed to 4-zinc insulin crystals simply by adding additional chloride to the mother liquor surrounding them, and that the transformation is reversible (G.A.B., G.G.D. and A. Lewitova, unpublished). The changes are shown by changed lattice constants and by the intensities of diffraction spectra in projection. As might be expected, variable crystal disorder occurs with crystal change; the pathway through the water between the molecules along which the peptide chains must move is clearly tortuous and difficult to follow.

Although the experimental conditions used to effect the transformation to 4-zinc insulin are far from physiological, the phenomena observed are very suggestive in relation to insulin action. 4-zinc cattle insulin displays markedly prolonged hypoglycaemic action and this has led to its use in clinical medicine. Since slow action is less pronounced in 4-zinc pig insulin, it seems that the change must be correlated mainly with different contacts between the molecules which affect solubility and thus insulin release. It is noticeable that the A10 residue, which varies between these species, makes a direct contact with the B5 histidine in the extended helix. The variation of the structure of insulin molecule I, and particularly the opening of the cleft between the A and B chains in the neighbourhood of tyrosine A19, does not seem to impair the overall biological activity of the insulin; evidently it is easily reversible. Many lines of evidence have implicated this region in the action of insulin. Our observations suggest that its flexible character may be one of the important factors in generating biological responses[7,8].

We thank the Science Research Council for support, the Wolfson research fund of the Royal Society, the Diabetes Association of Southern California and the US Public Health Service for fellowships to D.A.M., the New Zealand University Grants Committee for a fellowship to G.A.B., and the British Diabetes Association. We also thank Dr J. Schlichtkrull for gifts of insulin.

Possible dosimeter for ultraviolet radiation

WHILE evaluating the weathering characteristics of the plastics polysulphone and polyphenylene oxide (PPO) we found that they both darkened when exposed to ultraviolet radiation[1]. We realised the potential of these polymers as monitors for ultraviolet radiation and are developing them for this use. PPO is now being used to monitor continuously solar ultraviolet radiation at forty sites throughout the world[2]. We are developing polysulphone as a possible personnel dosimeter to measure exposure of the skin to ultraviolet radiation. Two requirements for any ultraviolet dosimeter are: (1) that the wavelength response of the dosimeter should be similar to the erythemal action spectrum of human skin, and (2) that the dosimeter should have a monotonic response as the ultraviolet dose increases. The results presented here indicate that polysulphone might well satisfy these criteria.

The polysulphone used (P 1700 Union Carbide) has the structure shown in Fig 1. It has good stability to thermal[3], thermal oxidative[4] and high energy radiation[5]. It readily undergoes changes in surface properties when exposed outdoors. These changes are accentuated if the material is used as a film, and so this was the form we used

A high pressure xenon arc lamp was used in conjunction with a single grating monochromator to investigate the response of the polysulphone film to ultraviolet radiation. Irradiance was measured by a thermopile.

When exposed to ultraviolet radiation, polysulphone film was degraded and lost tensile properties At the same time the initial broad absorption band in the near ultraviolet extended with dose towards the visible. As a measure of the degree of degradation of the polymer, the change in absorbance measured at 330 nm (ΔA_{330}) was noted. This can be done on any standard ultraviolet spectrometer and takes about 10 s.

The change in absorbance was investigated as a function of incident ultraviolet dose for wavelengths ranging from 254 nm to 335 nm. (The film does not respond to wavelengths greater than 340 nm.) At each wavelength, measurements were made for increasing doses until the ΔA_{330} of the film reached approximately 0.3. The values of A_{330} of the unirradiated film were in the range 0.155 to 0.175. Figure 2 shows the results obtained for irradiation at 297 ± 5 nm, that is, at a bandwidth at half-maximum intensity of 10 nm.

For none of the wavelengths studied did the ΔA_{330} increase linearly with dose. The first differential of ΔA_{330} with respect to ultraviolet dose decreased as the dose increased. If, however, the dose–response curves for all wavelengths were normalised at an absorbance of 0.2 to eliminate the different wavelength sensitivities, the mean deviation of each curve from the 297-nm curve was less than 5% at all absorbances up to 0.2. The response of a film exposed to stable sunlight also showed this degree of agreement with the 297-nm curve up to an absorbance of 0.2. At higher absorbances, the agreement lessened; the shorter the wavelength, the less rapid was the increase in absorbance with increase in ultraviolet dose.

This nonlinearity in the response of the film to ultraviolet radiation was not due to oxygen starvation, for a film exposed under high vacuum showed a dose response almost identical to that of one exposed in air, and indicates the photolytic rather than the photo-oxidative nature of the process. The decrease observed in the response of the film at high doses was attributed to the protective filtering effect of the new absorption centres produced. This was supported by the observation that doping unexposed polysulphone film with a known ultraviolet absorbant, 2-hydroxybenzophenone, produced, on exposure to ultraviolet radiation, the same reduction in rate observed in an exposed but undoped sample with the same ΔA_{330}. Investigations with diphenyl sulphone revealed similar radiation sensitivity and build up of filtering products, which suggest that the diphenyl sulphone group in the polymer is responsible for the properties observed.

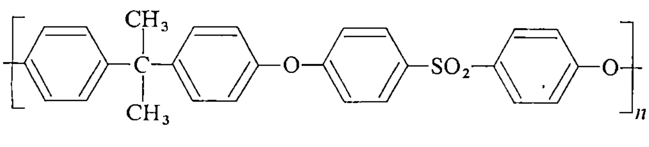

Fig. 1 The structural unit of polysulphone. To prepare the film, the polysulphone was first purified by reprecipitation: the chloroform solution of the polymer was added to a stirred volume of methanol and then the filtered polymer was dried in a vacuum oven at 60 °C. The film was made by spreading a 10% chloroform solution of reprecipitated polymer on a flat glass plate with an adjustable casting blade, producing a film between 36 and 44 μm thick. The film was removed from the glass plate, dried overnight in a vacuum oven at 60 °C and stored in the dark before use. The choice of film thickness was a compromise between minimising the absorption of wavelengths greater than 330 nm and achieving mechanical strength to facilitate handling. The film was mounted in a standard 5 × 5 cm photographic transparency holder, constituting the film badge. The badge was usually worn in a matt black holder to eliminate ultraviolet radiation reflected back from the subject.

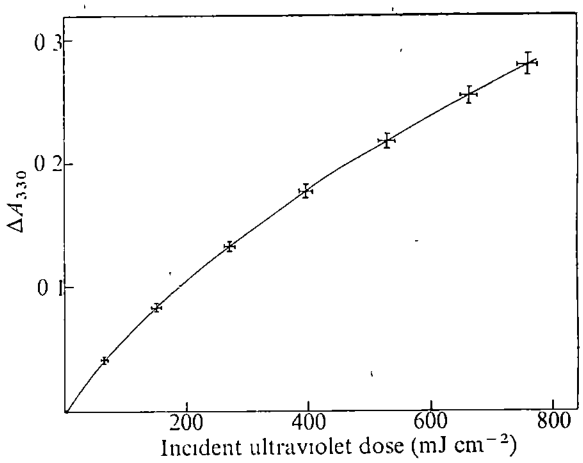

Fig. 2 The variation of ΔA_{330} with incident ultraviolet dose at 297 nm.

When stored, a previously exposed polysulphone film underwent a 'dark reaction', that is, the film exhibited a slight increase in absorbance. After 24 h the ΔA_{330} had increased by about 4%, after 1 week by about 5%. Allowance was made for this factor when necessary.

To derive the wavelength response of the film, the reciprocal of the dose required to produce a ΔA_{330} of 0.1 at each wavelength was plotted as a function of wavelength (Fig. 3). The results were normalised to unity at the most sensitive wavelength. In Fig. 3 the erythemal action spectrum of human skin[6,7] is compared with the action spectrum of polysulphone. Although the agreement is not ideal, it is possible to allow for this, if the relative spectral distribution of the incident radiation is known.

Samples of polysulphone film were irradiated at five levels of irradiance ranging from 0.056 mW cm^{-2} to 0.337 mW cm^{-2} to give equal doses of 250, 500, 750 and 1000 mJ cm^{-2} at a wavelength of 305 ± 5 nm. The resultant values of ΔA_{330} at each dose from the five intensities were within the experimental error of 5% of each other, which indicates that the response of the polysulphone film was independent of dose rate.

For wavelengths less than 315 nm, practically all the radiation is absorbed in a 40-μm film and so a change in the angle of incidence of the radiation will produce negligible changes in response. The refractive index of polysulphone between 315 and 330 nm was 1.63 and at an angle of incidence of 80° the increase in path length was about 25% relative to radiation normally incident on the film. At this angle of incidence, about 20% of the incident radiation was reflected, so the overall effect on the increase in absorbance was minimal.

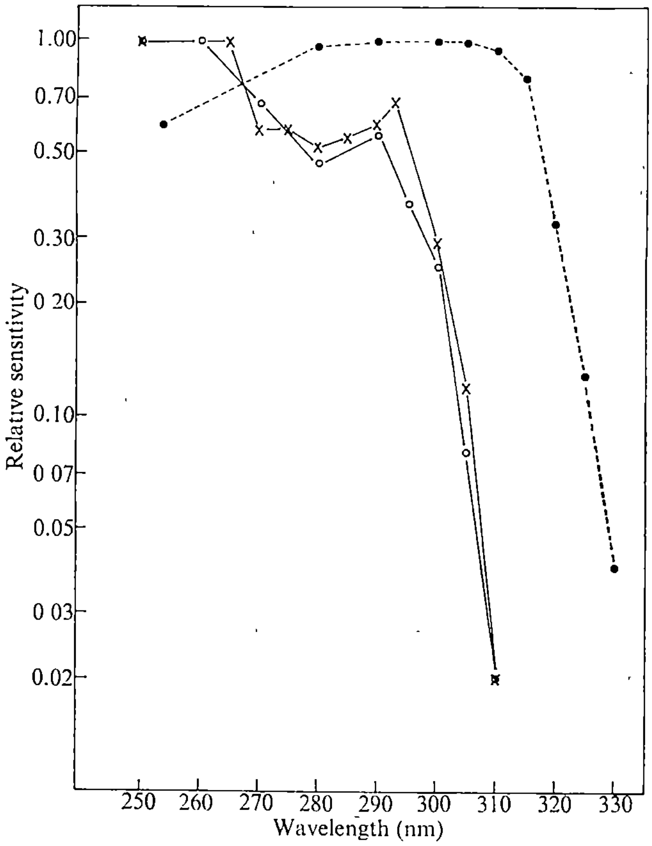
From a calibration curve of the type shown in Fig. 2 it is possible to relate the change in absorbance of a film irradiated by heterogeneous ultraviolet radiation of known relative spectral distribution to an equivalent exposure (F) of 297-nm radiation. The effective erythemal dose (D) at 297 nm is then given by

$$D = F\left[\frac{\int I(\lambda)E(\lambda)\mathrm{d}\lambda}{\int I(\lambda)G(\lambda)\mathrm{d}\lambda}\right] \qquad (1)$$

where $I(\lambda)$ is the relative spectral distribution of the incident radiation at wavelength λ, $E(\lambda)$ is the erythemal effectiveness at wavelength λ relative to that at 297 nm, assuming the mechanism of response does not change with wavelength and $G(\lambda)$ is the spectral sensitivity of polysulphone in terms of absorbance change, ΔA_{330}, at wavelength λ relative to that at 297 nm, as the biological effects produced by this wavelength have been studied extensively.

The results of this preliminary study of polysulphone as an ultraviolet dosimeter look promising. The method is being used to measure the ultraviolet exposure of bedridden geriatric patients, laboratory personnel working indoors for an 8-h day and hospital gardeners, with a view to estimating the amount of solar radiation needed for the synthesis of vitamin D in the skin. It is hoped that the results will help to quantify previous observations[8,9].

Fig. 3 Action spectra of polysulphone and human skin. ●, Polysulphone; ——, human skin; ×, ref.6; ○, ref.7.



Although the reproducibility of response of the polysulphone film to a known spectral distribution is of the order of 5%, it is important to know the uncertainty associated with the transformation of polysulphone response to an effective biological dose. This error depends on the nature of the ultraviolet environment and the action spectrum of the biological process under consideration. Careful attention must be paid to the action spectrum of the process to ensure that it declines to zero while the action spectrum of polysulphone is finite. The possibility of making the film thinner and therefore obtaining a better match with the erythema action spectrum is being investigated.

We thank Professor I A. Magnus for interest and constructive criticisms. B.L.D. thanks Mr J. R. Corfield for encouragement.

Slaves to the machine

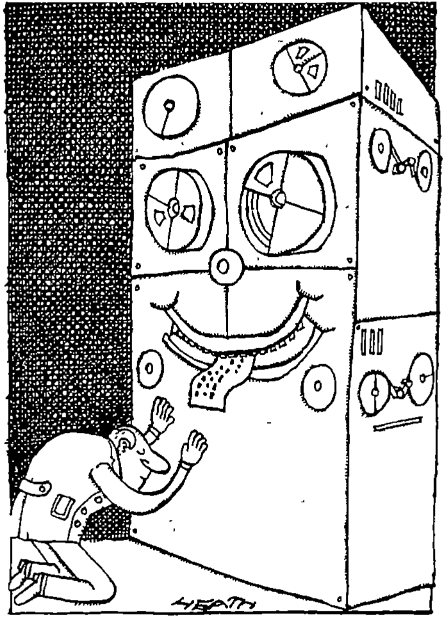
P. N. Johnson-Laird

Computer Power and Human Reason: From Judgment to Calculation. By Joseph Weizenbaum. Pp. xii+300. (Freeman: San Fransico and Reading, January 1976.) $9 95; £5 95

No computer centre is complete without one—a gaunt-faced hollow-eyed youth slaving over a hot teletype, working for hours on end long into the night and rarely pausing to satisfy his bodily needs. Should the time available to him on the machine begin to run out, his intensity of work rises to a feverish pitch: he lives dangerously, staking all on some irretrievable alteration of his program. Once off the machine, his life assumes a dull grey quality and is sustained only by sheaves of computer print-outs. He cannot wait to return to where the action is, and will sacrifice all social relations and obligations just to get back on to the system.

Who are these strange dedicated obsessive individuals? They are the new breed of slaves to the machine, the computer 'hackers'. And what are they doing? Almost invariably, they are developing some grandiose general all-purpose super-duper system that once completed will enable other less able programmers to write their own super-duper systems. Weizenbaum, in the most brilliant chapter of his provocative book, has delineated the psychology of computer hackers with a deep and convincing clinical expertise. He shows how the compulsive character of their work relates to a worldview similar to that of their second cousins, the gambling addicts. The computer provides the hacker with a universe, subtle but not malicious, over which he can exercise an absolute and god-like control. The programmer who is corrupted by this power is likely to develop great expertise, but he pays a price. His general all-purpose system is almost always an empty exercise in disembodied programming—that is to say, it fails to make intellectual contact with any other discipline.

The computer hacker is the central metaphor of Weizenbaum's book. He stands for the person who places a single-minded reliance on science as a source of understanding of life, who believes that man is nothing but a machine, and who cheerfully hands over responsibility for making decisions to computers. Weizenbaum's humanistic scruples are particularly offended by the equation of human thinking with computational processes, and therefore by the new scientific discipline of Artificial Intelligence (AI).



The aim of AI is to construct intelligent machines, and its practitioners are notably devoted to composing computer programs that can perceive the world, or analyse two-dimensional representations of it, and that can conduct conversations in natural language. The first programs capable of rudimentary versions of such skills were written some years ago, but it soon became obvious that it was extremely difficult to test them against human performance A cynic might say that it was for this reason that the goal of simulation was abandoned in favour of a science of the artificial. Weizenbaum, however, is no cynic; he advances a rather different argument against AI. Since some of his work laid the foundations for the new science, the impact of his book is comparable to that of an anti-vivisectionist tract written by a physiologist whose reputation rests on his operating skills.

What, in essence, is Weizenbaum's case? One can distill three main points from his book. First, certain tasks are too important to be handed over to a computer. It would be immoral as well as dangerous to make computers responsible for certain forms of psychotherapy. Such a proposal, relying on a program in fact devised by Weizenbaum, seems to have been the critical event that led to the present book. Second, artificial intelligencers suffer from hubris as an occupational disease. They are much given to promising to solve the riddle of the universe . . . tomorrow. "The only reason we have not yet succeeded in simulating every aspect of the real world is that we have been lacking a sufficiently powerful logical calculus. I am working on that problem." So spoke Professor John McCarthy in a perfect specimen of the megalomania that can grip the best of minds at the end of a long day's programming into the night. Weizenbaum, of course, considers that there are certain human propensities, such as the ability to feel desperate or to fall in love, that computers will never be able to display simply because they are not human beings. Third, AI programs are increasingly in danger of exceeding their progenitors' ability to understand them It is confidently expected that scene analysis programs will soon exceed 1,000K in size, and no-one is likely to be able fully to understand or to communicate their mode of operation.

These are serious criticisms of AI, but even with the worst will in the world they hardly convict the discipline of triviality or immorality. Current computers cannot pick their noses, nor can they fall in love. There is every reason to suppose that they could be devised to carry out the former task, and no reason other than a humanist conscience for supposing that they could not be devised to do the latter. It *is* a frightening thought—almost as frightening as the idea that our ancestors were apes and that we live on an insignificant planet revolving round an insignificant star. Weizenbaum deserves our gratitude for writing an instructive book that can be read with profit by anyone from a humanist to a computer scientist. It should force us to think more carefully about what we set our computers to do. It should force the artificial intelligencers to reappraise their discipline. No serious practitioner is likely thereby to abandon his science. And the hackers, of course, know that life is nothing but an enormous program devised by the Great Programmer in the sky. ☐

Dr Johnson-Laird is a reader in the Laboratory of Experimental Psychology at the University of Sussex, UK.

Rudiments of physics

Elementary Particles and Symmetries (Documents on Modern Physics.) By Lewis Ryder. Pp. xxvi+249. (Gordon and Breach : New York, London and Paris, December 1975.) £9.80; £5.00 (International Student Edition).

LEWIS RYDER'S book grew out of lectures given to third-year undergraduates at the University of Kent, and it shows. In my opinion, it is not enough simply to tell students about particle physics. I share what I take to be the author's view that it is preferable, or at least equally important, to teach them how to calculate something—almost anything will do! Any like-minded teacher will find a wealth of material in this admirable book. Of course the topic of symmetries is well suited to this task The discrete symmetries (time reversal, charge conjugation, parity reversal), the additive conservation laws (charge, strangeness) and the non-abelian groups (isospin, SU_3) are all covered and applied to concrete examples of the strong, weak and electromagnetic interactions. Ten of the thirteen chapters are essentially free of phrases like: "It can be shown that . . .", which usually herald the onset of the narrative approach. And en route quite a lot of basic information, including some modern developments, is imparted. One surprising omission occurs in the section on the deep inelastic electron–proton scattering data Having explained why these very important experiments suggest that the nucleon "is like a pomegranate, not like a jelly", I expected, but did not find, some treatment of the naive quark–parton model. Showing how the data suggests that the "seeds" of the pomegranate have one-third integral charges, would have lent further weight to the subsequently raised hot question of particle physics: do quarks actually exist? Towards the end the narrative style inevitably prevails. But even in the last chapter, on the unified theories of weak and electromagnetic interactions, there is enough to show a (keen) beginner how to embark on his own rudimentary model building.

All in all, I think that the book is remarkably successful, and that it caters well for its intended market. The price too is reasonable by current standards, at least for the paperback edition.

D. Bailin

Organic mechanics

Mechanical Design in Organisms By S. A Wainwright, W. D Biggs, J. D. Currey and J. M. Gosline. Pp. xii+425. (Arnold: London, January 1976.) £8.50.

THIS is an ambitious work which brings together much biological information about structural macromolecules and skeletal tissues with the increasing knowledge of their mechanics. It is a book for the specialist and general reader alike, although comparatively few biologists will be sufficiently familiar with materials science, or adequately equipped mathematically, to follow all the engineering phenomena. The first part deals with various tensile, pliant and rigid materials incorporated into skeletal systems The second part looks into the design of skeletal elements and mechanical support systems, and the third part examines organism-environment interactions. The literature has been assiduously searched and digested, but the book is not an uncritical collection of research results. The authors have rigorously argued their central theme: that structural elements are designed to carry out specific functions in an environment of stresses and strains. Biologists have long appreciated this interplay between form and function, but for many the concept is possibly more an article of faith than a complete understanding. This book provides the comprehension as well as the creeds.

Editorial and technical production reaches a high standard. The book is written throughout in a simple, lucid style (with the occasional touch of humour) making it easy and enjoyable to read. It is elegantly illustrated with numerous drawings and diagrams combining pleasing clarity with meticulous draughtsmanship I detected few errors, but a curious recurrent mistake is the term 'keratin sulphate' which should be keratan sulphate, or keratosulphate. Naturally there are some points of contention. The dogmatic statement (p105) that α chitin alone exists in Arthropoda is some three years out of date: well-defined examples of β and γ chitin are present in some insect peritrophic membranes and larval cocoons. The '9+2' theory for the structure of α-keratin microfibrils is given another airing, but there is no mention of the 'ring-core' model which fits more closely the X-ray diffraction data and computational studies.

Mechanical Design in Organisms is bound to attract and stimulate considerable interest among biologists and others. It will be an important reference book for some time to come, and as a text it will provide a basis for interdisciplinary teaching of new topics in biophysics and biology degree courses

W. Kenchington

Molecular spectroscopy

Theory of Molecular Spectroscopy. Vol 1 · Quantum Mechanics and Group Theory of Vibrating and Rotating Molecules. By C. J H Schutte. Pp. xvi+512 (North-Holland: Amsterdam and Oxford; American Elsevier: New York, 1976) Dfl. 170; $67 95.

THIS is volume 1 of a two volume work and it is not too easy to judge in isolation. It is a strongly mathematical introduction covering vector spaces, matrices, group theory, Hamiltonians in general, both the classical and quantum mechanical form of vibration–rotation interactions, diatomic potential functions and their evaluation, and the interaction of radiation with matter.

The mathematical treatment is thorough and a number of advanced topics are covered, such as the Wilson and Howard Hamiltonian and its modification by Watson, and also the Rydberg–Klein–Rees method of fitting potential curves The treatment is mostly sound and comparatively free of misprints, and the first impression, strengthened by the early chapter on group theory, is favourable. But I became increasingly unhappy as I delved deeper. It is doubtful whether a standard treatment of the hydrogen atom would be expected in an expensive book on rotating molecules And as the text gets to real problems, rather than abstract algebra, a lack of authority becomes apparent. Section 1.4 on normal co-ordinates is especially confused; for example, Schutte's use of Cartesians weighted with the square roots of the masses means that the kinetic energy matrix should be the unit matrix, but this is not recognised in this text And the statement (p241) that the energy "is then ~ kR^2, since k is defined as Nm^{-1}" leads to a lack of confidence as does that on p307· "If a molecule does not have a permanent dipole moment, the selection rules for dipole radiation prohibits the occurrence of an infrared spectrum".

There is a need for a comprehensive advanced treatise on the theory of ro-vibration, but part of the difficulty of writing is to choose the important features and give them once only in a modern and consistent form. This text, which has some good sections, tends to give a rather indigestible slab of everything The price is high and the second companion volume, which will contain the more specific features, is not likely to be less.

D. H. Whiffen

Desert rats

Rodents in Desert Environments. (Monographiae Biologicae, Vol. 28.) Edited by I. Prakash and P. K Ghosh. Pp. xvi+624. (Junk: The Hague, 1975.) Dutch Guilders 180.

THIS is one of several recent books devoted to the adaptations of desert organisms. Most have centred around a unifying disciplinary theme, such as comparative physiology, providing integration. This book of 23 invited chapters focuses on a single taxon of organisms sharing a common habitat Desert rodents, however, are so diverse that appreciating their adaptations requires synthetic interpretation by specialists Although some of the chapters use a synthetic approach (especially those by Newsome and Corbett; Mares; Rosenzweig, Smigel and Kraft; and Ghosh), many are purely descriptive. As a result the value of the book for the general biologist interested in evolutionary and/or ecological phenomena is diminished; the overall quality would have been greatly enhanced by inclusion of a comprehensive, synthetic chapter based on a thorough reading of the invited chapters, indicating those adaptive patterns which are unique to desert rodents and the advantages they offer.

The primary value of the book is that for the first time (and mainly in a single language: English) there are detailed accounts of the biology of rodents from most of the world's deserts, providing a wealth of comparative information on distributions, general ecology and life histories, activity patterns and population fluctuations, behaviour, competitive interactions, and adaptive physiology. The lengthy chapter on Russian jerboas and gerbils by Naumov and Lobachev is particularly welcome. The chapters vary tremedously in quality and scope with some reporting original research or comprising state-of-the-art messages, whereas others reflect woeful neglect of the current literature or are merely rehashes of ideas and materials previously treated. Lapses in editorial rigour are indicated by numerous typographical errors, and occasional misinformation Statements of misinformation I found particularly distressing include: “Tropical Dasyurids such as *Antechinomys* . . . do not normally venture into arid habitats”, p 394 (the only species of these small Australian Marsupials, *A. spenceri* and *A laniger* occur exclusively or primarily in arid habitats); “ . . . Heteromyidae . . . the most common rodents in Arizona and the Sahara Desert.” p 417 (heteromyids are endemic to the new world).

I found the most interesting paper to be that by Rosenzweig, Smigel and Kraft, a state-of-the-art message on coexistence and resource allocation in North American desert rodents. As well as summarising what is known, they emphasise equally what is still unknown about the enormous complexity of competitive interaction Our continuing fascination with desert rodents is well reflected in their statement, “ . . clearly allocation occurs . . . But something that is known to occur ought to have an explanation” (p 251).

To the careful reader this book provides a great deal of information on desert rodents, some synthetic explanations, and stated suggestions or unstated gaps where future research could be productively directed.

Richard E. MacMillen

Drug resistance

Acquired Resistance of Microorganisms to Chemotherapeutic Drugs. (Antibiotics and Chemotherapy, Vol 20.) Edited by F E. Hahn. Pp. xi+272. (Karger: Basel, London and New York, 1976) Sfr 139; DM132; $53.50.

THIS book is a collection of nine chapters by different authors, as follows: Inducible bacterial resistance (Connamacher), Chromosomal mutation to drug resistance in bacteria (Sirotnak); Molecular modifications of anti-microbial agents to overcome drug resistance (Neu); Anti-mutagens and the prevention of chromosomal mutations to drug resistance (Hahn); Genetics of *R* factors (Mitsuhashi *et al*), Molecular biology of *R* factors (Clowes); Experimental elimination of *R* factors (Hahn); Drug resistance in leukaemia (Hutchinson and Schmid), and Drug resistance in the human malarias (Tiggert and Clyde). There is a preface by Hahn.

Although there are valuable data in the volume, the diversity of authors has produced a very uneven presentation; in parts the English is poor in style and even in grammar; and the same data are presented by different authors, not always with the same lucidity or interpretation.

The price of this book—over £29 at the current rate of exchange—is outrageous In view of its uneven quality and the many better sources of information, it is not recommended. If information is needed about plasmids and various other genetic aspects of drug resistance, for example, the reader is advised to consult Falkow's *Infectious Multiple Drug Resistance* (Pion: London, distributed by Academic: New York and London, 1975); for review see *Nature*, **258**, 368 (1975). The two books are of about the same size, but Falkow's treatise is greatly superior and costs only £7.70 ($19.95).

E. S. Anderson

Auger spectroscopy

Photoelectron and Auger Spectroscopy. (Modern Analytical Chemistry.) By Thomas A. Carlson. Pp. xiii+417. (Plenum: New York and London, 1975.) $39.

THE improvements in electron spectrometers and electron detectors which have been achieved over the past two decades have provided new techniques for the study of the nature of the electron orbitals which hold together the positive framework of matter. The three most profitable areas in which these developments have been applied are ultraviolet photoelectron spectroscopy, X-ray photoelectron spectroscopy and Auger electron spectroscopy. The author of this book, who has had long experience in each of these fields, writes about them in a very lively and authoritative manner

After the initial chapters which deal with instrumentation and fundamental concepts the subject matter is divided into: photoelectron spectroscopy of outer electron shells; photoelectron spectroscopy of inner shells, and Auger electron spectroscopy. The first of these topics is mainly concerned with the ultraviolet photoelectron spectroscopy of gaseous molecules and the nature and ordering of the molecular orbitals as revealed by their spectra. The second topic deals largely with the binding energies of the core electrons and how these are shifted by the state of the valence shell environment in which they find themselves—that is, the so-called ‘chemical’ shift In the third—the Auger effect—a beam of electrons rather than photons is focussed on the sample, and valence or core electrons removed in an identifiable manner.

Apart from the importance of the basic information on the electronic structure of matter which these effects reveal the fact that they are of low penetrating power makes them extremely valuable for studying surface phenomena such as catalysis, corrosion, adsorption, and so on.

The book is well referenced and contains a great deal of useful tabulated data It should be valuable both to the general reader and the specialist in the field. **W. C. Price**

Books brief

The Encyclopedia of World Regional Geology Part 1: Western Hemisphere (Including Antarctica and Australia). (Encyclopedia of Earth Sciences, Vol. 8.) Edited by Rhodes W. Fairbridge. Pp. xv+704. (Dowden, Hutchinson and Ross: Stroudsburg, Pennsylvania; Wiley: New York and London; 1975.) $44 40; £22 30

THIS is an unusual and successful book written by some 90 authors. Most contribute one or two articles, although the Editor weighs in with a valiant 60 ranging from Antarctica to the Windward Islands. Oceanic islands are done particularly well throughout. It is a true encyclopedia covering the out of the way as effectively as the well known in contributions extending from a column or two on an atoll, to 140 pages on the US. Long contributions are subdivided so any district can be readily picked out, and regional reviews link accounts of individual countries. Ocean floors are not covered the book sticks to dry land. It will provide basic answers to almost any enquiry requiring knowledge of the geology of a part of the Western Hemisphere. Professor Fairbridge and his colleagues have done a first class job. I look forward to the promised companion volume on the Eastern Hemisphere. **J. Sutton**

Twentieth Century Physics. By Joseph Norwood. Pp. ix+405. (Prentice-Hall: Englewood Cliffs, New Jersey, 1975.) $16.95.

IN this useful book an attempt is made to present in outline our present understanding of the interactions involving matter. The topics covered are special and general relativity, old quantum theory, wave mechanics and atomic, nuclear and particle physics. On the whole the attempt is successful: the author has striven hard to present arguments which are as simple as possible while at the same time powerful enough to enable results to be derived (or, sometimes, made plausible) rather than merely stated. There is a set of problems at the end of each chapter and this is a particularly valuable feature of the book. Unfortunately, the whole is marred by frequent inaccuracies and an informality of style that sometimes degenerates into sloppiness For example, Kepler's Laws are wrongly stated, geodesics in space and space-time are confused, it is asserted that terms in $1/C^2$ are small because their value is 10^{-17} (no units being introduced), and so on. In spite of these shortcomings the book will be useful as an auxiliary text for physics undergraduates. **Michael Berry**

Radio and Microwave Spectroscopy By David J E. Ingram. Pp. 167. (Butterworth: London and Boston, December 1975) £4.50.

THIS is very much a book intended for undergraduates in physics or chemistry and must be judged accordingly. This is not easy for someone who knows more about the topics covered—gas microwave rotational spectroscopy, electron resonance and nuclear magnetic resonance Certainly the language is straightforward, no previous knowledge is expected and the level is appropriate with a text comparatively free of mathematics The examples are largely taken from Dr Ingram's earlier book, *Spectroscopy at Radio and Microwave Frequencies* (1955), and the diagrams do not give a fair view of modern sophistication and one (3.1c) is such a poor photographic reproduction of an oscilloscope screen that it should never have been passed at the galley proof stage. And certainly in 1976 one can no longer maintain, (p109), that for proton chemical shift references "The two protons most commonly used for this purpose are the protons in water . . and the protons in benzene . . .": tetramethylsilane is not mentioned In places, ideas are simplified to a point where explaining more correct views as students advance may be difficult Thus, zero field parameters in triplet states are referred to as "effective" and then allowed to depend on the direction of the zero amplitude magnetic field (p151) This short book is more appropriate for a weak student in a hurry to get an overview than for more able students It is also an example of how difficult it is to write a really good elementary text. **D. H. Whiffen**

Graph Theory: An Algorithmic Approach. (Computer Science and Applied Mathematics: A Series of Monographs and Textbooks) By Nicos Christofides. Pp. xv+400. (Academic New York and London, October 1975) £12.50; $31 00

THIS book presents a comprehensive and up-to-date account of algorithmic development, which has been going on quietly for over 20 years. The problems of optimisation associated with graphs are well known, and the lack of mathematical progress in solving them is universally appreciated What has happened, with the advent of the computer, is the development of some quite powerful and numerically effective methods for solving some of these problems This book expounds, in a clear style and with ample illustration, the detailed steps of the most important algorithms known at present The first four chapters are concerned with the theory of graphs, and with the introduction of ideas important in the numerical study of graphs. The chief topics treated are reachability, connectivity, colouring and set covering. There are chapters on the location of centres and medians, on trees, and on shortest paths. Chapters nine and ten are concerned respectively with Eulerian and Hamiltonian circuits, and there is a detailed discussion of some of the classical problems of operational research mathematics, relating to scheduling and the travelling salesman Chapter eleven deals with flow in networks and the last chapter deals with matchings, transportation and assignment

No practitioner (whether of operational research or of the social sciences generally) concerned with numerical studies can afford to neglect this book. **L. S. Goddard**

Chromatographic Analysis of the Environment. Edited by Robert L. Grob. Pp. x+734. (Dekker: New York, 1975.) $49.50.

CHROMATOGRAPHY is undoubtedly a prime method for the analysis of trace components in the environment, and a good book on the subject would be welcomed. The present multi-authored work starts with an introduction to theory and practice, and follows with 18 chapters covering most of the possible permutations of air, earth, water and waste with gas, liquid, paper, thin layer and ion exchange chromatography. One or two of the chapters are very good but too many are narrowly based and simply catalogue methods—many of them rather old. There is a monumental author index of 38 pages and a very poor subject index, which is the reverse of what is required in a book of this kind. This book fails to give the kind of overall picture of environmental analysis required at this stage in the subject and will mainly be useful to those already expert who wish to have comprehensive reference lists before undertaking development of new methods.

John H. Knox

obituary

Grigorii Sergeevich Pod"yapol'skii, the Soviet geophysicist and human rights campaigner, died on March 8, 1976.

Pod"yapol'skii was born on October 22, 1926, in Tashkent. In 1949, he graduated from the Moscow Petroleum Institute, and from then until 1953 he worked as a geophysical engineer, doing field work in various regions of the Soviet Union (Ukraine, Siberia, Central Asia, the Arctic). In 1953, he began research work at the Institute of Earth Physics.

During the next seventeen years Pod"yapol'skii was mainly concerned with the theory of earthquakes (in particular the statistics of their occurrence and the propagation of shockwaves). In 1969, he spoke at the International Conference on Tsunamis, in Honolulu on the relationship between tsunamis and the earthquakes which trigger them.

Pod"yapol'skii's presence in Honolulu was, in retrospect, somewhat surprising. The composition of Soviet delegations to international conferences is decided more in accordance with the political rather than the academic soundness of the would-be participants By 1969, Pod"yapol'skii was already in official disfavour as a leading member of the growing movement of dissent within the Soviet Union; he was a founder of the Initiative Group for the Defence of Civil Rights in the USSR and a close associate of Academician Andrei Sakharov. His attendance at the Honolulu conference can only be explained, it would appear, by a desire on the part of the Soviet authorities to make a good showing in the international arena, and as an implicit acknowledgement of the high value they placed on his work. This value, however, they would not acknowledge at home. In the same year, 1969, Pod"yapol'skii was prevented from defending his thesis, and the following year he was dismissed from the Institute on the pretext of "staff cuts", so that his scientific career was effectively brought to a halt

According to his fellow dissidents, Pod"yapol'skii was a man of great personal charm, and skilled in reconciling the incipient disputes inevitable among those eager to exercise freedom of speech and opinion. He was also a poet; his work reflecting his scientific and humanitarian interests.

announcements

Appointments

Dr **K. G. Binmore** to the Chair of Mathematics at the London School of Economics.

Professor **Gabriele Veneziano** to the Amos De-Shalit Chair in Theoretical Physics at the Weizman Institute.

Professor **Gerald Holton** as the Mallincrodt Professor of Physics and Professor of the History of Science at Harvard University.

Dr **J. D. Hodge** to the Chair of Botany at Royal Holloway College.

Awards

The **Lenin Prizes** for 1976 were awarded as follows:

to Agasi N. Charakhch'yan, Galina A. Bazilevskaya, Yurii I Stozhkov, and Taisiya N. Charakhch'yan for work on cosmic ray bursts from the Sun and the solar modulation of galactic cosmic rays;

to Nikolai N. Krasovskii, Aleksandr B. Kurzhanskii, Yurii S. Osipov, and Andrei I. Subbotin for work on the mathematical theory of control systems,

to Nikolai N Semenov for work on the kinetics of complex chemical reactions,

to Vladimir S. Sobolev, Nikolai L. Dobrentsov, Vladimir V. Reverdatto, and Vladimir V. Khlestov for work on geological metamorphism;

to Aleksandr S. Spirin, Georgii P. Georgiev, Ol'ga P. Samarina, Murat A. Aitkhozhin, Nadezhda V. Belitsina, and Lev P. Ovchinnikov for the discovery and study of informosomes;

to Sergei V Anichkov and Vasilii V. Zakusov for work on the effect on synapses of physiologically active substances;

to Vladimir I Burakovskii, Leonid A. Bokeriya, and Vitalii A. Bukharin for work on hyperbaric oxygenation in heart surgery;

to Feliks G Arzhanov, Valeri I. Graifer, Valentin V. Karibskii, Aleksandr V. Sinel'nik, Tevgat S. Gainutdinov, and Valentin D Shashin (Minister of the Petroleum Industry) for work on the automation of petroleum production;

and to Vasilii T. Babenko, Anatolii I. Manokhin, Tamerlan S. Shishkhanov, Nikolai P. Lyazhishev, Nikolai P. Slotvinskii-Sidak, and Aleksandr N. Morozov for a new method of producing vanadium.

The National Academy of Engineering Founders Award to Professor **Mason Benedict** for work on nuclear energy.

The NAE Vladimir K Zworykin Award to Dr **C. K. N. Patel** for contributions to laser technology.

The Marconi International Fellowship to Dr **H. Inose** for work on computers.

The Royal Society has elected Professor **S. Benzer**, Professor **W. H. Munk**, Professor **R. W. Sperry** and Professor **C. H. Townes** Foreign Members of the Society.

The Rank Prize for Nutrition to **Norman W. Pirie** for work on the extraction of protein food from herbage.

The Charles Frederick Chandler Medal to Professor **Kai Seigbahn** for developing ESCA.

International meetings

May 18–21, **Drug Receptor and Drug–Enzyme Interactions,** Namur, Belgium (Services des Relations Publiques, Facultés Notre-Dame de la Paix, 61, rue de Bruxelles, B-5000 Namur, Belgium).

May 20, **Onchocerciasis,** London (Betty Harrison, Royal Society of Tropical Medicine and Hygiene, Manson House, 26 Portland Place, London W1N 4EY).

May 27–28, **Oncogenic Transformation,** Lake Placid (Course Secretary, W. Alton Jones Cell Science Center, Old Barn Road, Lake Placid, New York 12946).

July 5–7, **Theoretical Methods in Polymer Physics,** Leeds (Meetings Officer, Institute of Physics, 47 Belgrave Square, London SW1X 8QX, UK).

July 6–8, **Breeding Endangered Species in Captivity,** London Zoo (Dr Michael Brambell, The Zoological Society of London, Regents Park, London NW1 4RY, UK).

July 8–9, **Nutrition and Growth,** Cambridge (Dr J. D. Sutton, Hon Programmes Secretary, National Institute for Research in Dairying, Shinfield, Reading RG2 9AT, UK).

July 12–16, **Properties of Liquid Metals,** Bristol (Meeting Officer, The Institute of Physics, 47 Belgrave Square, London

Is the Sun being oversold?

THE United States will spend £36 million in 1976 on solar energy research and development. Japan will spend £18 million, France and West Germany £3 million each, and the European Economic Community £2 million. Meanwhile expenditure in the United Kingdom will be less than £500,000. It that the right level, and if not, what is? The UK section of the International Solar Energy Society (ISES) has just published a major report (*Solar Energy: a UK assessment*, available from the Royal Institution, 21 Albemarle Street, London W1, 375pp, £10) which looks at prospects in the UK, attempts to predict the future for solar energy and tries to outline a research and development programme.

The Sun can be used for a variety of energy-related purposes: although heating applications with flat-plate collectors and electricity generation with solar cells are the best known, the report carefully outlines many other prospects. There is simply better building design, there are agricultural and biological applications of photosynthesis, including energy plantations and there are photochemical reactions; and within each of these areas there are many ingenious schemes, some of which work, many of which might, given appropriate investment of time, money and (dare we say it) energy.

The report is optimistic. It is supposed to identify areas particularly worthy of support, but after reading it one is left wondering whether anything is not worth supporting. Projects that are near to fruition should be encouraged; projects that are rank longshots should be encouraged; projects that are particularly suitable in Britain should be encouraged, projects with export potentials should be encouraged. Of course with nearly 40 scientists, engineers and civil servants collaborating enthusiastically in the report, it was unlikely that anything but an advance-on-all-fronts view would emerge, but even so the report does seem to suffer from a weak link in moving from scientific statements to policy recommendations. It is sometimes difficult to link the recommendations made at the end of each chapter to any very clearly enunciated argument within that chapter, and one suspects that the phrase "this technique could have export potential" has been added too often to have retained its credibility.

By the year 2020, the report argues, solar power could provide 35 million tonnes of coal equivalent of energy annually in the UK. It is almost impossible to estimate accurately what fraction of total energy consumption this might represent; it represents roughly 10% of present UK annual consumption. But elsewhere the report postulates that the contribution is 10% of 2020 needs, which is different, maybe by a factor of two. And one ever-optimistic Fleet Street correspondent persists in reading the figure as 30%. The report is not strong on its projections; it sometimes claims figures which are difficult, if not impossible, to find, but insofar as the projection of 35 million tonnes means anything, it probably implies that by 2020 up to 20% of all houses would be fitted with solar water heaters, and that there would be a significant contribution to our electricity supply from solar cells. (Solar energy could, of course, contribute in many valuable ways to isolated, local needs well before 2020.)

Do these predictions ring true? On the heating side they require, for instance, that in the next twenty years 0.5% of all present housing stock should be fitted with solar heaters each year. At a charitable £300 per installation and with the knowledge (not perhaps wide enough at present) that solar heating does not eliminate the need for a conventional heating system, one can only describe this prediction as hopeful. On the solar-cell side, the assumption has to be made that present costs of cells can be cut by a factor of a hundred to bring costs per watt into line with those prevailing in other electrical generators. The evidence for such a prospect seems tenuous in view of the lack of any spectacular progress up to the present in reducing costs. Further, the severe problem of cheap electrical storage will have to be confronted; the report rather lamely asserts that since the problem is receiving a great deal of attention and no fundamental scientific barrier is known to exist, "a breakthrough in the reasonable future may be expected". The same can presumably also be said of nuclear fusion.

And if solar cells experience all the required cost reductions, the land issue will have to be faced. To produce 10% of our 2020 total energy requirements from solar cells would require between 1 and 2% of the land area of Britain to be covered with solar farms (roads at present occupy a similar percentage). This is not a trivial fraction; the report asserts that the problem is "unlikely to be acute for many years as the use of solar energy will only develop slowly". But if and when solar farms do come, the size of the problem will be much greater than that of building superhighways through the country. To say, then, that solar energy is "particularly attractive in physical environmental terms" is simply to put off the day of reckoning.

The impression that the report leaves behind us is of a good survey of the science, but a loose job on the policy. This leaves the proposals for more national expenditure on research and development very exposed. ISES calls for £2 million in 1976, rising to £8 million by 1980 and £20 million in 1986. Very crudely, this would compare, in the early 1980s, with British plus EEC expenditure on fusion research. There is a real danger that over-optimism now may cause resistance to even a fraction of such money being made available later. ☐

International science and the Third World

NOTHING is ever done in this world until men are prepared to kill one another if it is not done. So said Shaw. Whether or not the United Nations offers a failsafe mechanism good enough to prove him wrong (it probably doesn't), the issues its agencies discuss receive too little attention. True, the UN may be ineffectual. It may be over-bureaucratic. But it is one of the few highly visible structures addressing itself to the "big" issues.

That, in fact, may be another of its problems. Whatever distance governments now put between themselves and those they purport to serve, it is but a miss compared to the mile between the UN's "big" concerns and the everyday experience of the millions whose problems it wishes to solve. But there it is —recently, as the United Nations Environment Programme (see opposite) addressing itself to persistent if now less fashionable "eco-issues"; last month as the United Nations Law of the Sea Conference, tackling questions about economic zones and deep sea mining; right now, as the United Nations Conference on Trade and Development discussing the transfer of technology, commodities and debt problems.

If there is a common thread to all this, it concerns the ever more fragile relations between the developed and underdeveloped countries. The problem of commodities, which bears directly on the world food problem (see page 181), and questions about the transfer of technology, encapsulate the principle issues.

But they all remain "macro" issues. If re-presentation in "micro" form is now necessary, the plea below, from a scientist in Lesotho, is a useful start in the area of science.

Lesotho is one of the poorest countries in the world. Poverty links the "macro" and the "micro" issues. And poverty, to quote Shaw once again, is the greatest of evils, and the worst of crimes.

Accommodating the Paradisian wilderness

Professor A. Brock of the Department of Physics at the National University of Lesotho in Southern Africa, draws attention to the position of the scientist working in the Third World

"PARADISIA and Dominatia: Science and the Developing World", the title of an article by Michael Moravcsik and John Ziman which appeared last year in *Foreign Affairs* (**55**, 699–724; 1975), struck so many familiar notes that, as a scientist working in a less developed country, I feel impelled to bring it to wider attention.

The problems are those of the individual scientist and of the small scientific community in a typical third world country—Paradisia; the relationship to be explored is the one between Paradisia and the powerful metropolitan country, Dominatia, in whose sphere of influence it once lay, in the context of science and technology, rather than that of politics, culture or economics. Science and technology are almost always viewed as desirable goods by Paradisians, and to this end the basic sciences are taught in the schools and universities, and modern technologies are adopted in industry and agriculture.

The picture of scientific poverty and intellectual isolation will be all too familiar to anyone who has visited or worked in Paradisia. Expatriate scientists will also know the feeling, but they usually enjoy the benefits of regular visits to Dominatia, and often have a network of contacts built up before they left for Paradisia. The Paradisian scientist, on the other hand, has fewer opportunities of this type because he cannot qualify for "home" leave, and his contacts in Dominatia derive mainly from his days as a research student rather than from a period of mature scientific practice For him the keyword is isolation.

The concern here derives from the view that science flourishes through the efforts of individual scientists, but only in the context of an active scientific community which provides many channels (both official and unofficial) for encouragement, criticism, review, stimulation, interaction and publication. This is the rich soil in which science grows. But in Paradisia the scientific climate is semi-arid and the soils desert-like.

Take, for example, the keen Dominatian scientist on secondment to Paradisia, prepared to improvise in the absence of technical facilities, but handicapped beyond measure by the arrival of *Phys. Rev.* a year late and the absence of colleagues to discuss his work with. His productivity, it is suggested, will rapidly decay under these circumstances. A more personal example: as a palaeomagnetist, I have been fortunate to find my material in Paradisia—fresh Precambrian lavas, or richly fosilliferous Plio-Pleistocene lake sediments. But my results take shape in correspondence with colleagues in Canberra, Stanford, Berkeley or Leeds, rather than over the tea table in my own laboratory How much more difficult for a Paradisian scientist forced by circumstances to rely almost exclusively upon his own resources. And what a triumph for those who manage to produce substantial scientific work.

The task of helping Paradisian scientists working under such circumstances is more difficult than that presented by more normal aid programmes, in which buildings or equipment or funds are provided for some specific purpose, such as a soil science laboratory, or a natural resource survey, or a feasibility study. The task is that of trying to create and maintain indigenous scientific activity in Paradisia. The suggestion is that the world scientific community bears some responsibility towards its less fortunate members in Paradisia, by extending to them some of the advantages that are taken for granted in Dominatia. Lavish funding *per se* is not envisaged here, although it is worth remarking that even the most heavily "squeezed" research budget in the UK would look lavish to a Paradisian.

It is the opportunity for full and free participation in the scientific processes of discussion and exchange, the feeling of "belonging", that Paradisians particularly lack. Topics such as the provision and distribution of journals, the suitable placement of research students, attendance at conferences, the exchange of staff, academic visits, are suggested as areas in which careful attention to the needs of Paradisia would pay dividends. The development of an active lively scientific community is a lengthy process, and cannot be the object of any single aid programme.

One suggestion, though, is a device for opening a range of scientific appointments in Paradisia to young scientists from Dominatia as a normal stage in a research career. Another is that free copies of the major scientific journals be sent to all accredited scientific institutions in the less developed countries. What a blessing this would be to "out of touch" scientific workers. These suggestions apart, however, the concern should be to alert the world scientific community to the general plight of the small fraction of its members in Paradisia, and to suggest that there is much that can be done at the individual as well as the institutional level to help. □

Two steps forward, one step back

The United Nations Environment Programme seems to be faltering. **Richard Sandbrook** reports on the efforts to deal with environmental problems on a global basis

THE United Nations Environment Programme (UNEP) has been having an uncomfortable time of late. Not only are funding problems now severely hampering the agency; there also appears to be increasing dissent about the work programme, both within and without the Secretariat. Nothing new in one sense for the UN; but at a time when many states are taking a new look at the UN in general following the recent "group of experts" report on its structure, and when its major donor, the United States, is severely pruning budgets, uncertainty in UNEP is not going to help its causes.

Initially UNEP was set up to carry through the 109 recommendations that came out of the UN Stockholm Conference on the Human Environment held in 1972. It was structured to consist of a Programme, which is the outline of the projects being tackled by UNEP, other UN agencies, national governments or non-governmental organisations; the Environment Fund, into which states make voluntary contributions; the Secretariat, consisting of 100 professional staff; and a Governing Council, composed of 58 UN nations, which meets annually to review the programme and state of the fund. In addition, the executive director of UNEP chairs the Environment Coordination Board, which includes the heads of all other agencies in the UN family.

The fund started out with pledged contributions of $110 million to carry it through its initial five years, and the energetic services of Maurice Strong, its first executive director. Strong had left his mark by the time he departed in January. He had tried hard to dispense with many of the usual UN nonsenses that slow up the whole business of running the existing UN agencies. Contracts were handed out in an almost commercial manner—rather as if a new research and development programme was in the making—and initially he circumvented the delaying process of UN recruitment by appointing consultants. The relationships between UNEP and non-governmental organisations, governments and other specialised agencies was—and still is—fluid and open. The programme itself was neatly compartmentalised into priority levels and clear-cut objectives.

But UNEP had its fair share of teething problems too. Nairobi, the home of the programme, is not as accessible as the more "traditional" Geneva and New York, a particular disadvantage since the whole venture was set up partially to get existing outfits, such as the FAO, UNESCO and WHO, to cooperate together through the newly created Environment Coordination Board. Mr Strong and his team spent many months in the first three years commuting between the world's capitals for planning and promotional meetings. Back in Nairobi permanent staff recruitment was very slow, and the planning of programme projects became delayed. By the 1975 governing council meeting the fund was carrying forward large surpluses and certain states were complaining that not enough was being spent; UNEP had too much government money in its bank earning interest. Ironically this now forms the central excuse of the US Government for delaying their "promised" contributions (initially a 40% slice of the first five-year $110m).

Changing attitudes

Attitudes to the "environment problem" also began to change. Strong was above all a superb salesman who generated great interest and concern before Stockholm and immediately after it. In the early 1970s "the environment" was an important issue for western politicians. Now, some four years on, the environment issue is clearly not as politically pressing as it was; and, besides, many governments would argue that national pollution control is advancing rapidly. Initially the less developed world was very suspicious of the whole affair. Strong's answer was to promote "eco-development"—or "environment and development"—and a challenging declaration that united these themes was developed (the COCOYOC Declaration 1974). Gradually a constructive relationship built up between UNEP and the doubting Third World nations.

UNEP, however, has never been seen as a route for aid or technical assistance in the eyes of the major western donor countries—it is much more a "catalyst" (the most used word by delegates to the recent 1976 governing council) for sound environmental management. The idea of UNEP growing into an enlightened development agency with funding capabilities is certainly not acceptable. All this leaves the impression that the idea was potentially good; but for some the fashion is now passing, while for others UNEPs objectives are becoming less relevant. The current acting executive director, Dr Tolba, is nobly conducting a holding operation, but eventually the big issues will have to be resolved.

The first and major issue to be sorted out is the leadership question. Dr Tolba, an Egyptian, is due to leave this year; he could emerge as the new man from the horsetrading that goes on in New York, but the OECD countries and the South Americans may put up a challenge. Then there is the problem of replacing before the end of the year Mr Steadman, who runs the fund, and Mr Munro, who directs the programme. Both are available for office for only a short period. UNEP has always been beset with changes at the top, and this has created uncertainty all the way down.

Financial problems

The second issue is the state of the fund. The long lead time on project approval in the formative years has pushed the peak cash needs of UNEP toward the end of its first quinquennium. The cash requirements double between 1975 and 1976 to $40 million and then slowly climb to an annual requirement of $55 million by 1979. (It is worth noting that the US Federal outlay in 1976 on pollution control and abatement was $683 million for research and development activities alone.) Currently, the agency predicts a shortfall of some $10 million to $12 million a year from 1977 onwards. This figure is based on the revised pledges known at March 15 this year, some of which are well below those originally given when the agency was established. Commenting at the governing council in April, Tolba said that only $41 million of the pledged $109 million had so far been paid up, and some of that was in non-convertible currency from the USSR. The US was singled out as the major turncoat. Special visits to Moscow and probably the US are planned, but matters look bad: some 42 projects, Tolba reported, had already been delayed because of the cash crisis. Things could conceivably become a little easier for the agency after the US elections.

The third problem concerns the dream of Stockholm itself: how effective it will be in practical terms will in turn affect the long-term support UNEP gets. To date UNEP has successfully translated a few good ideas, such as that of the FAO for a Mediterranean pollution convention, into actual events (Barcelona, March 1976). They have also been closely involved in planning and funding the UN Water

---

The author is at the International Institute for Environment and Development.

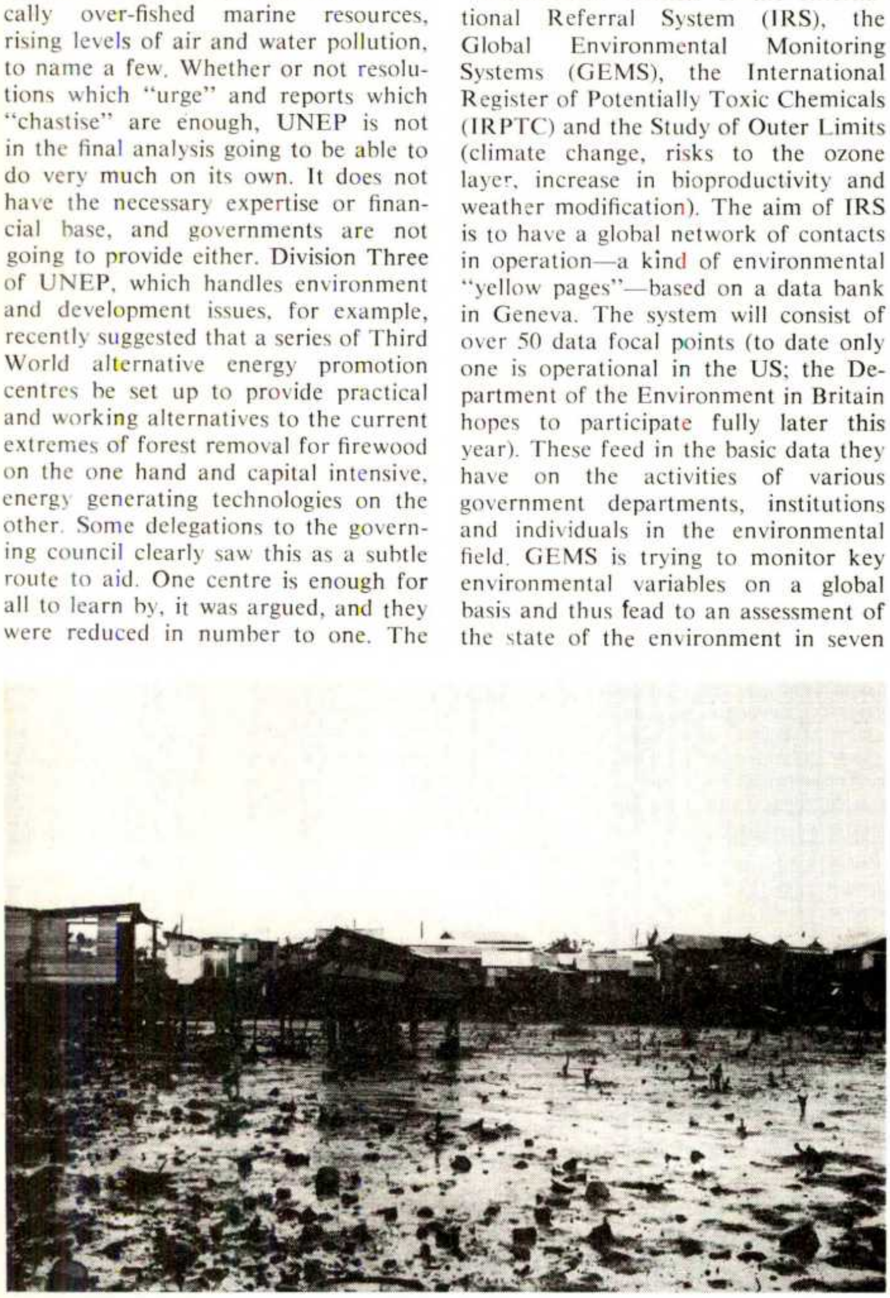
Conference (March 7, 1977, Argentina), the UN Deserts Conference (August 29, 1977, Nairobi), and the imminent UN Human Settlements Conference (May 31 to June 14, Vancouver). Much credit must go to UNEP for causing the latter two events to happen at all. All these conferences will help establish priorities and routes for aid and technical assistance in the coming years on pressing development fronts.

Tasks remain

But UN conferences can only assist in the evolution of "global environmental management"; all too often they seem to result in little more than high sounding cliches. Substantive tasks remain: the world's disappearing rainforests, the protection of the ever-growing number of threatened species, the chronically over-fished marine resources, rising levels of air and water pollution, to name a few. Whether or not resolutions which "urge" and reports which "chastise" are enough, UNEP is not in the final analysis going to be able to do very much on its own. It does not have the necessary expertise or financial base, and governments are not going to provide either. Division Three of UNEP, which handles environment and development issues, for example, recently suggested that a series of Third World alternative energy promotion centres be set up to provide practical and working alternatives to the current extremes of forest removal for firewood on the one hand and capital intensive, energy generating technologies on the other. Some delegations to the governing council clearly saw this as a subtle route to aid. One centre is enough for all to learn by, it was argued, and they were reduced in number to one. The idea of doing it regionally was ruled out.

Earthwatch is, in fact, the only significant functional task that UNEP is involved in apart from its conference support work. The remainder consists of overscanning some 150 projects to be carried out by other UN agencies, governments and institutions. These are organised into some eight priority areas, as follows: Human settlements and human health (1976 Budget $6.3 million), Ecosystems research (1976 $8.19 million), Environment and development ($3.6 million), Oceans ($3.6 million), Energy ($550,000), Natural disasters ($200,000), Environmental management ($450.000), Environmental law ($300,000) and support functions ($5.91 million). Earthwatch takes $3.4 million this year.

Earthwatch consists of the International Referral System (IRS), the Global Environmental Monitoring Systems (GEMS), the International Register of Potentially Toxic Chemicals (IRPTC) and the Study of Outer Limits (climate change, risks to the ozone layer, increase in bioproductivity and weather modification). The aim of IRS is to have a global network of contacts in operation—a kind of environmental "yellow pages"—based on a data bank in Geneva. The system will consist of over 50 data focal points (to date only one is operational in the US; the Department of the Environment in Britain hopes to participate fully later this year). These feed in the basic data they have on the activities of various government departments, institutions and individuals in the environmental field. GEMS is trying to monitor key environmental variables on a global basis and thus fead to an assessment of the state of the environment in seven distinct areas. These include atmosphere monitoring in relation to climate, ocean monitoring, the depletion of renewable resources, natural disasters and human health. Throughout there is much emphasis on the concept of baseline studies.



More than just an environmental problem: the litter and decay of a forgotten community (WHO photo)

Coordination only

UNEP is the first to point out that much of this monitoring is already done by other agencies and that its role is one of coordination only. There is, for example, UNESCO's Man and the Biosphere Programme; the work of the World Meteorological Organisation on climate; the FAO's work on land use, fisheries and soil structure; and, of course, many governments have their own monitoring programmes. It is hoped that variables will be monitored around the globe in a uniform and comparable way, and the data collated into central locations. But the problems in practice are going to be considerable. So-called baseline studies in the marine environment, for example, are notoriously difficult to carry out, and to many are of dubious scientific value anyway. To determine the quantities of various pollutant involved from atmospheric and land sources and their effect on the biological system is an almost impossible task; the state of the initial biological system is usually not known, is probably inherently variable, and the pathways of the pollutant far from clear.

It is thus apparent that UNEP structures are again in a state of wait and see. Until the financial and leadership questions are cleared up its future direction and style are unclear. At present, it is prevented from being the radical outfit that the Third World want by the priorities of its powerful western backers. Any confrontation with the real forces that lead to environmental degradation — inequality between nations and over-indulgent living as Mr Strong once put it—must wait. As the executive director stated in April, four years after Stockholm every country has come to grips with the fact that sustained development and meaningful growth were impossible without a commitment to preserve the environment and promote the rational use of resources. But if the Secretariat has adopted the principles of the brave new world, its major funding source has not. And yet, leaving the development issue aside, there is a clear need for UNEP simply to coordinate the significant effort being made toward the protection of the biosphere at a national, regional and international level. It has gone a long way in convincing governments and international agencies that this should be done. It would be a great pity if it were now denied the wherewithal to do it. ☐

When enough is not enough

Howard Rush, Pauline Marstrand, John Gribbin and Gordon MacKerron look at what is sometimes called the world food paradox

WITHIN the past few months a series of publications* has again focused attention on the complex of problems underlying the "world food crisis". These analyses aim at different audiences, but all have a message in common: our inability to feed the world's population is not due to physical factors placing limitations on total world food production. They also recognise that the causal factors in world hunger and malnutrition are the enormous economic, social and political problems associated with poverty.

The key physical factor, of course, is availability of land. Most recent estimates are based on calculations published in 1967 by the US President's Science Advisory Committee (PSAC), suggesting that the maximum area which would be cropped is 6,600 million hectares, of which about half has been cultivated at some time and about 1,400 million hectares harvested in any one year. Although other estimates—such as those by FAO and the US Department of Agriculture—have produced a broad spread of figures, the PSAC estimates are roughly in the middle of the range, and all investigators agree that only about half of the potential area is now used. The estimates differ partly because of different assumptions about the feasibility of obtaining water, but they all show that apart from competing uses of land, existing world food production could be roughly doubled without improved technology.

Lester Brown and others have postulated that increasing costs of development will preclude utilisation of much of this land—an assumption also built into the *Limits to Growth* model—but there is room to query this assumption. Although it is true that the tendency is for the range of available technologies to move towards the very capital intensive (and expensive) end of the spectrum, in principle developing countries can still select from alternatives ranging down to such labour intensive projects as the human muscle used to build the Yangtse dam. There is certainly room here for further debate, partly because future cost assumptions depend so heavily on the nature and pace of future technological change.

Using the PSAC estimates, the maximum population supportable has been taken as 7,200 million at existing standards of nutrition, or 157,000 million on a 1967 "Japanese" diet. Although it is commonly stated that 400–500 million people are starving in the world today, it seems unlikely on the basis of WHO estimates that more than 60–70 million are currently so severely undernourished that they are using bodily protein reserves (muscles, including heart muscle) as a source of metabolic energy.

The important factors

This represents less than 2% of the present world population, and is probably a smaller proportion than ever before, but it is nothing to be proud of; the efforts made over the past three decades to improve food supply to the hungry have beeen successful in part and are worth sustaining. But if physical factors are not critical in determining the availability of food to the world's population now and in the immediate future, what are the important factors—and are they really so enormous as to provide insurmountable difficulties?

The key to the world food "problem" is now seen to be poverty, not population. Poverty within nations means that poor people receive a smaller share of the food available nationally, while poverty between nations means that the poorer nations have less food per head to share in the first place. And the inequalities are greatest in the poorest nations, so that the smallest slices of the cake are themselves divided the most unfairly.

Between 1951 and 1971 the global production of cereals more than doubled, while the world's population "only" increased by 50%. More than half of the increase in food, however, was absorbed by the richest 30% of mankind, so that the extra food was shared almost equally between 1,000 million people in the developed countries (DCs) and the 2,500 million people in the less developed countries (LDCs). This pattern emphasises that the food is there—or can be produced—for those who can afford it. It is because they are poor that the hungry—whether they be nations or individuals—are unable to buy sufficient food, or to develop their farming sufficiently to provide for their own needs. Under the present world economic system, their hunger, as such, is largely irrelevant; "demand", in the food market as in other markets, means ability (or willingness) to pay. As in other free markets, the rich have a dominant influence: their power in the market distorts demand patterns, and allows them to obtain the greatest benefits for themselves. One important result is that in the poor nations—as well as the rich—increasing demand for meat prevents the most effective use of available land by diverting large areas of cereal from human to (inefficient) animal consumption.

It was a reduction in this market demand that led to a reduction in planted cereal acreage in the developed countries during the 1960s, at a time when there was clearly an increasing need for food among the hungry poor who had no financial access to, or influence on, the market. Between 1960 and 1970 the LDCs were increasing food production at least as fast as the developed countries, but the increasing market demand for "luxury" food—beef, dairy produce and so on—forced prices upwards, including the prices of cereals used for feeding animals as well as people. Together with the emphasis at government level in many LDCs on cash crops that could be sold to developed countries to boost exports (coffee, sugar and so on) this had serious effects on the poor in the LDCs, where even if luxury foods were being exported essential foods had still to be imported in bulk (as represented in Table 1).

The shortages of the early 1970s and high prices have been blamed on many natural factors, not least the weather

(which, in fact, was not so much bad as simply worse than the previous, exceptionally good, years of the 1960s). But these shortages, although real, were not physically necessary; they resulted from the control of the market by producers in the developed countries.

LDCs can only pay for the food they import with the foreign exchange earned by their exports; ironically, agricultural produce makes up three-quarters of those exports, but the LDCs' share of the world market in these products is falling as the developed countries produce more and increase their domination of the market. According to War on Want, "In 1966, prices for exports from the DCs were 13% higher than in 1958 while prices for exports from the LDCs fell by 11% . . . more and more has to be exported to buy the same goods from the DCs". The resulting imbalance, with the developing nations' debts to foreign countries increasing substantially faster than their GNP, means that in the majority of cases the gap between debts contracted and the means of repaying them is widening every year. As this gap increases so do the inequalities between developed and developing nations.

Internal factors

The responsibility for this, however, does not lie solely with the developed nations' control over world markets. Their market control does place the poor of developing nations at a severe disadvantage, but the inequalities are heavily reinforced by agricultural policies and local price factors within the developing nations themselves, where agriculture accounts for more than a third of total production and rural regions provide about three-quarters of the total population.

These regions and most of their impoverished population have little say or control over their economy. The majority are landless or own less than a single hectare of land. What little agricultural policy there is in many LDCs, including investment programmes, is heavily biased in favour of the prosperous minority. The result of this imbalance is clearly seen in the example of India, where 7.7% of the population own more than 50% of the head. More often than not the situation is made worse by national development policies which stress industrialisation of urban areas dependent on the agricultural sector for resources.

As Keith Griffin has pointed out, the outstanding feature of the agricultural sector in almost all LDCs is the bias in access to factors of production (that is, land, credit, water, fertilizers, technical knowledge, etc.) towards the prosperous landowners. Government policies supported by the economic and political influence of this minority virtually control the market structure and allocation of resources—thus assuring no shift in the *status quo* detrimental to their interests.

Technical change, once heralded in the form of the "green revolution" as the solution to man's hunger, becomes a further aid to the rich because of their dominance of the world system. Technical change which relies on easy access to credit and often substantial inputs of water, fertilizer and pesticides, may well increase production—but only for the minority of landowers in whose favour the market is biased. Any innovation under the control of the *status quo* tends to strengthen the *status quo*. Agricultural innovation has become widespread, but the result has not only been increases in productivity but also increases in inequality; the rich get richer, but the poor get poorer.

In recent years the world's food supply has increased faster than the rate of population growth. As suggested by nearly all recent analysis, physical factors are not critical to feeding the world's population. But the fact that fewer people need face starvation than previously believed does not reduce the seriousness of the difficulties which remain: the problems are now recognised as those of poverty and politics. It might seem that these are no less insurmountable than the physical restrictions often assumed—although we could feed a much larger population, it may require a social revolution to remove the inequalities at the root of poverty. As the UK Select Committee on Overseas Development stressed in its report, "the main answer to the world food problem is to give those who are hungry the means to feed themselves, or the income to buy food". ☐

USA

Antidisestablishmentarianism

Arrangements by which the US President receives advice on science matters have now been institutionalised. Colin Norman reports from Washington.

N.E.W.S. photo

President Ford signs the science policy bill, watched by (left) Senator Frank Moss, chairman of the Senate Space Committee, and Representative Olin Teague, chairman of the House Committee on Science and Technology.

WITH storm clouds hovering overhead, and with many elder statesmen of the scientific community in attendance, President Ford last week held a small ceremony in the White House rose garden to mark the signing into law of a bill re-establishing a science policy office in the White House.

The event was pure ceremony. Contrary to rumours flying around beforehand, Mr Ford did not nominate anybody to head the office—the director will also be the President's Science Adviser—nor did he indicate how he intends to use the office when it is eventually set up. Instead, he simply took the opportunity to make a few obligatory remarks about the importance of science and technology in helping to meet "the challenges and opportunities which lie ahead for this nation and the world", and signed the bill with "great pleasure". Fortunately, the rain held off.

The ceremony nevertheless marked an important event in the annals of science policy. The bill, which had been championed by numerous prominent scientists and also by Vice-President Nelson Rockefeller, essentially reinstates the science policy apparatus dismantled three years ago by Mr Nixon. Moreover, since the office has now been established by an Act of Congress—rather than an act of Presidential pique—to remove it.

Though scientists, of course, played a prominent role in shaping national policy during the Second World War, they didn't have a permanent place in the White House until 1957, when President Eisenhower acquired a full-time science adviser during the post-Sputnik panic which swept the country. The adviser was made chairman of the President's Science Advisory Committee, a panel of scientists drawn from academic and industry. President Kennedy established the Office of Science and Technology (OST) five years later, as a small White House operation headed by his science adviser, and that apparatus remained intact until 1973. President Nixon then suddenly scrapped it, largely because he disagreed with much of the advice it was offering him, particularly on such matters as the need for an anti-ballistic missile system and the SST programme. When Mr Nixon abolished OST, he gave the head of the National Science Foundation the extra job of being science adviser to the White House.

The bill signed by Mr Ford last week will establish a small Office of Science and Technology Policy (OSTP) to advise the President and other White House bodies on matters involving science and technology. It also establishes a committee of scientists to conduct a two-year review of the federal government's science and technology programmes, after which the committee can be kept in business as an advisory unit if the President so desires. White House officials say that President Ford hopes soon to nominate somebody as his science adviser, but it will take several weeks to get the office under way.

It should be noted that the establishment of the office couldn't have come at a much worse time. Having suffered a series of staggering defeats in primary elections these past two weeks, Mr Ford's tenure in the White House must be considered precarious, at best. Thus, with a change of Administration at least on the cards a few months after OSTP is established, nothing dramatic should be expected from the office for some time. ☐

THE Senate last week followed the lead of the House of Representatives by voting to cut off federal support for a controversial research project designed to assess the effects, if any, of marijuana on human sexual behaviour. The Senate's action will ensure that the project will be aborted, and thus for the first time Congress has reached deep into the scientific peer review process and cut off a research project for political reasons.

The project, a $121,000 two-year investigation which was to have been conducted by Dr Harris Rubin at Southern Illinois University, had been approved as scientifically meritorious by a committee of behavioural scientists, endorsed by a top level government advisory committee, and supported by a panel consisting of the federal government's most senior health officials. Congress voted to stop the project, however, because some powerful members have labelled it morally unacceptable and scientifically trivial.

The Senate, at least, held a short debate on the matter before deciding to shut the project off. Senator William D. Hathaway, Democrat from Maine, offered an amendment to restore the funds, arguing that "the real issue is the integrity of a carefully constructed government-wide mechanism for awarding research grants and contracts". He argued that by voting to deny the funds, "possibly the least expert group of federal employees to gather in one building—the US Congress—seems now to have taken upon itself the role of grand inquisitor with regard to scientific research". Hathaway's amendment was easily defeated, however, on a voice vote.

It's not too surprising that, once the issue was raised, Congress should vote to eliminate Harris's project. It is, after all, an election year, and Congressmen would be reluctant to defend a vote in favour of spending tax payers' money on a project involving marijuana and sex. But, as the Federation of American Scientists (FAS) noted in a statement last week, the votes set a worrying precedent. "'Every controversial project that finds its anti-champion can now be expected to be raised" in Congress, FAS suggests.

● After months of debate by several committees of scientists and a week of conflicting rumours, the Food and Drug Administration (FDA) formally announced last week that it has no intention of lifting its controversial ban on the artificial sweetener cyclamate. Citing a number of "unresolved safety questions", FDA Commissioner Dr Alexander Schmidt said that he has asked Abbott Laboratories, the manufacturer of cyclamate, to withdraw its petition seeking to restore the sweetener to the market. If the petition is not withdrawn, Schmidt said he would simply reject it.

Cyclamate was banned in 1969, on the basis of studies which suggested that it increased the incidence of bladder tumours in rats when fed to them in high doses over prolonged periods. The FDA ban initiated a chain of similar actions in other countries.

The FDA's decision to keep cyclamate off the market is, however, based more on questions of general toxicity than on the shaky evidence that cyclamate is a carcinogen. A panel of scientific experts, assembled by the National Cancer Institute, reported last February that "although the present evidence does not establish the carcinogenicity of cyclamate", a number of studies have raised worrying questions. In short, the evidence for carcinogenicity is equivocal.

Schmidt said last week that he is worried about "unanswered questions" concerning cyclamate's potential for causing damage to reproductive organs, causing chromosomal damage, and elevating blood pressure.

A spokesman for Abbott has said that it is unlikely that more safety tests will be conducted to resolve those questions, and it is therefore unlikely that Abbott will renew its petition. FDA's decision thus could be the final word in the long battle over the sweetener.

● Mr Jimmy Carter, the leading candidate to be the Democratic Party's Presidential nominee, last week called for a voluntary, worldwide moratorium on the sale of uranium enrichment and nuclear fuel reprocessing plants, including those sales already negotiated. Speaking at a conference at the United Nations Centre, Carter said that the threat of nuclear weapons proliferation from such sales is too great for "business as usual". He called for an un-sponsored world energy conference to discuss worldwide energy problems, and he said that "there is a moral imperative that demands a worldwide effort to ensure that if we travel down the nuclear road we do so with our eyes open".

The nuclear powers, he suggested, should provide more leadership in preventing the spread of nuclear weapons. For a start, he suggested that the United States and the Soviet Union should agree on a five-year moratorium on weapons tests, during which they should negotiate a complete nuclear test ban. The recently negotiated threshold test ban, he said, is "wholly inadequate".

As for the US nuclear power programme, Carter suggested that it should be kept to "the minimum necessary to meet our needs", and it should have to meet "much stronger safety standards".

CANADA

Spraying controversy revived

A link is suspected between the use of certain tree sprays and the condition known as Reye's syndrome. David Spurgeon reports from Ottawa

THE spraying of forests in the Maritime provinces to prevent infestation by the spruce budworm has created a sharper controversy than ever this spring because of the deaths of five children from a disease suspected of being linked to the insecticides used. It is not the first time arguments have arisen over the spraying programme: DDT was used as an insecticide in the 1950s and 1960s until it was found to have caused severe fish kills in surface waters. But it is the first time human deaths have been linked to the programme.

A number of children, mostly from areas that have been heavily sprayed in the past, have died from Reye's syndrome, a condition first described in 1963 following the US Air Force's aerial defoliation in Vietnam and Thailand. The disease causes increased susceptibility to viral infection, and it is the spray dispersal emulsifiers which are suspect; the sprays used are Fenitrothion and Phospamidon.

The current budworm outbreak, which now covers about a third of the province of Nova Scotia, was first reported in 1969. The budworm (*Choristoneura fumiferana*) is a moth that lays its eggs in firs and spruces in July. The eggs hatch in about 10 days, and the larvae spread through the trees. They remain dormant for the winter, emerging in late April and early May to begin feeding on new shoots. In June they enter the pupal stage, and the moths which emerge in June or July can defoliate and kill trees to the extent of causing their death.

Massive increases in population can occur when there is a large incidence of host trees and favourable weather. This has happened in the Maritime provinces six times since the early 1700s. Predictions for this year were bad from the point of view of the forest industries, particularly in Cape Breton Island, so Novia Scotia Pulp Ltd and Nova Scotia Forest Industries—a branch of Stora Kopparbergs Bergslags AB of Sweden—applied to the Nova Scotia government for permission to spray with Fentrothion or Phospamidon.

The Nova Scotia department of lands and forests recommended against it, but the Cabinet gave approval in February. Seven weeks later, on April 2, Cabinet approval was withdrawn as a result of a story that appeared first in the *Cape Breton Post* and subsequently in other newspapers. The story summarised the work of a research team at Dalhousie University begun in 1974 which indicated that a link was possible between the spraying programme and the deaths from Reye's syndrome. It was based on material given to the *Post's* editor by a PhD student who was a member of an environmentalist group.

The research group had published a preliminary report on their work in *The Lancet* in 1974, and has a further paper in press now. Its members applied spray chemicals topically to the abdomens of about 13,000 mice in the same concentrations used in the spraying programme, and then exposed the animals to a virus. They found that the mice died, not as a result of the virus or of toxin but of some third entity. At the time they published in 1974, they had applied only the insecticides as sprayed, to the animals. Later they purchased the carrier substances separately and concluded that one of the emulsifiers used in the sprays was probably the substance linked to Reye's syndrome.

Dr J. F. S. Crocker, one of the research group and an assistant professor of paediatrics, emphasises that the research has been strictly with animals and indicates only that a link between the spraying programme and the deaths from Reye's syndrome "is possible theoretically." The group is now planning *in vitro* experiments and work with primates, and has proposed identifying chemicals in the tissues of children struck by Reye's syndrome—if possible before they succumb. Dr Crocker himself finds it extraordinary that so little research has been done in this field. He says that if the companies that do the spraying make up their own spray formulation, they do not even require a licence for the emulsifiers, whereas the spray mixture must be licenced if it is packaged as a ready-made formulation. Yet the chemical structure of the emulsifiers is unknown—and of course the effects on humans are unknown.

The budworm problem has been worst in New Brunswick in past years, and has only recently spread to Nova Scotia. No spraying has actually been carried out in Nova Scotia, but in New Brunswick it has always been carried out by Forest Protection Ltd, a Crown corporation representing the provinces and its major pulp and paper industries. Decisions about whether to spray or not in a given area have been made by the corporation's board of directors and approved by federal and provincial governments. Costs have been shared equally by the federal government, provincial government and industry. Fenitrothion has been the chief insecticide used since 1968: it is claimed to be non-persistent, non-cumulative and not subject to concentration in the food chain. There is also evidence it is less harmful to fish than is DDT.

This year's spraying programme in New Brunswick will cover 10.2 million acres. The federal government has opted out of the programme, but the federal department of regional eco-

Canadian cutbacks

THE Royal Society of Canada has joined in the general clamour of protest by Canadian scientists against a federal freeze on research funds. The Prime Minister, M Pierre Trudeau, recently received a brief signed by W. Bennett Lewis, president of the council of the Society's Academy of Science, which said the 1975–76 level of federal support for government laboratories was only 83.3% of the 1969 level in terms of the fraction of federal budgetary expenditures. Research in Canadian universities is in an even worse position, with support in 1975 reduced to 67% of the 1969 level—and although the decline was arrested last year, the freezing of grants this year will cause support to decline to about 60% of the 1969 level.

Although it was recognised in 1969 that government support of industrial research and development was already too small, it is now even smaller, the brief said. In terms of the fraction of federal budgetary expenditures it had fallen by 1975 to 68% of the 1969 level. To make matters worse, the Department of Industry, Trade and Commerce had abolished one of its aid-to-industry research and development programmes and had cut back another.

Tables and graphs accompanying the brief showed that Canada was alone among advanced nations in its reductions in support for science and technology. Organisation in other industrialised countries with functions similar to those of the National Research Council of Canada (supporting in-house research and development and university grants and scholarships) had been treated almost as well, and in some cases better, than they were in 1969.

nomic expansion will contribute. As a result of the controversy in Nova Scotia, questions have been asked in the New Brunswick house about the advisability of carrying on with the programme. In an article to be published in the June issue of *Science Forum*, Neal Benneworth and Chris Bailey contend that spraying should be prohibited because it is "an energy-intensive attempt to bend nature to conform with the forest industry's narrow concepts of how a forest should behave".

They say the operation only increases in the long term the chances of occurrence of what it was originally intended to prevent, because preservation of the host trees by spraying "simply improves the environment for the budworm and increases the likelihood of further population expansion." This is so because the forest and the budworm are a self-regulatory system: the budworm destroys the forest and ensures a new development of host species favourable for future budworm generations. The present composition of the forest, they say, has evolved as a result of budworm predation removing mature balsam fir preferentially, which allows less competitive species of trees to survive. Budworm spraying merely protects the host trees, which are economically significant to the forest industry, and this in turn improves the environment for the budworm, thus increasing the likelihood of further population expansion. ☐

USSR

One of the obstacles to communication between Soviet geologists and their foreign colleagues in recent years has been the unwillingness of Soviet geologists officially to admit the possibility of continental drift. This block was not due to any political considerations—unlike those imposed in Stalin's time on genetics and cybernetics—but seems to have been due to personal opposition from certain leading geologists, notably Professor V. V. Belousov of the Institute of Earth Physics in Moscow. Recently there has been a discernible relaxation in this attitude: the popular science magazine *Priroda* has carried an article dealing with this "hypothesis", and even Professor Belousov himself has somewhat half-heartedly discussed the subject in his latest book.

Now, however, a TASS radio bulletin, transmitted in English and hence clearly for international consumption, has given even greater approval to this concept, stating that Australian rock samples, collected by M. Ravich of the Institute of Arctic Geology in Leningrad, have proved to be "completely identical" to samples from the Antarctic opposite Australia, thereby giving added proof of the "so-called theory of Gondwanaland". According to Professor Ravich, the samples match not only in chemical composition and age (2,000 million years), but also in the size of the deposits, and give credence to predictions of mineral wealth in the Antarctic similar to deposits in Australia, South Africa and South America. A number of Soviet geologists have privately supported the concept of continental drift for some time. The TASS broadcast indicates a possible reversal of the official view of the Soviet geological establishment.

- The chance a private individual in the USSR has to participate in a major scientific research project nowadays is extremely limited. But it was granted to the citizens of Byelorussia, the Baltic States and the Leningrad-Novgorod region of the Russian Republic by the flight, on February 11 this year, of what has been named the "Baltic bolide".

This large meteorite, which appeared in the twilight over the Gulf of Finland, crossed the gulf moving in the general direction of Moscow before burning up. Its flight time of more than 100 seconds, instead of the normal one second or so, is a record for any meteor, and is attributed to a velocity comparable with that of the Earth and a trajectory virtually tangential to it. Before the bolide finally broke up with a fine display of natural pyrotechnics, some 600 people following it along its path had observed it closely enough for their letters and sketches to help astronomers at the Pulkovo observatory plot its course. According to V. Kratt, the observatory's Director, the bolide ceased glowing only at a height of 25 km, and there is reason to hope that some fragments may have penetrated the atmosphere to ground level. The Soviet Academy of Sciences has therefore appealed to all persons living along the route to survey the area for fragments.

Cam & Pen Int.

- The State Committee for Science and Technology of the USSR's Council of Ministers has signed an agreement on technical cooperation with British Petroleum, to run for an initial period of five years. It provides for broad-based reciprocal scientific and technical cooperation on a long term basis, and is the result of some two years of negotiation, since Academician Vladimir A. Kirillin, the committee's Chairman, visited Britain in 1974.

The agreement envisages exchanges of scientific and technical information and of specialist staff, joint research and development, the organisation of symposia on topics of mutual interest, and the joint implementation of research programmes and projects—on the production of unicellular proteins from petroleum wastes, for example. The State Committee has shown considerable interest in purchasing the expertise for deep-water drilling developed by BP in connection with the Forties field in the North Sea.

One new Soviet development in anti-pollution measures, however, is unlikely to form part of any exchange agreement. According to Moscow radio a new agent for cleaning up oil spills in the Caspian has been discovered: the cockle *Cerastoderma*, which, although only some 2.5 cm long, filters up to 15 litres of water through its body in its feeding process. Any oil contained in this water is coated with slime and eliminated, forming a sludge which falls to the sea-bed, where, it is thought, it is later rendered harmless biologically.

- The latest volume of the Large Soviet Encyclopedia carries a brief, 75-word biography of Andrei Sakharov, complete with photograph, describing him as a "Soviet physicist and Academician" and recording that he was thrice awarded the title of Hero of Socialist Labour (the highest Soviet civilian award). Sakharov's human rights work is nowhere mentioned: his recent activity is dismissed with the remark that "in recent years he departed from scientific activity". Sakharov himself commented that he was "very pleased" with the entry.

UK ENERGY

BRITAIN'S "Save It" energy conservation campaign clearly doesn't apply to the increasingly protracted debates on the subject itself. Not that the energy spent discussing the issues is entirely wasted, even though it certainly looked that way three weeks ago when the latest rush of events was about to start.

What research and development was in hand, a backbench MP asked, and what new technology developed, so that alternative sources of energy could, if economic, be rapidly exploited? Mr Anthony Wedgwood Benn, Secretary of State for Energy and Britain's principal advocate of open government, was simply uninformative:

> Considerable research and development is in hand on indigenous raw materials which are or might be sources of energy. Much of this work is carried out by the nationalised energy industries, the United Kingdom Atomic Energy Authority (UKAEA), the nuclear industry and the oil companies. In the field of new non-nuclear energy sources, my Energy Technology Support Unit has carried out assessment studies. Research and development programmes are being drawn up for those areas which show most promise of making a significant contribution to the country's energy needs. The United Kingdom agencies also participate in international energy research programmes, such as those of the European Communities and the International Energy Agency.

Just three days later Mr Benn's department launched a major research programme on wave power.

It was an unjustifiably inauspicious start to a period of great activity on the alternative energy front. Whether the MP was anticipating the announcement is not known. If he hoped to probe behind the veil shielding the department's Energy Technology Support Unit (ETSU), he did not have too long to wait before another attempt was made. Three top men from ETSU gave evidence the following week to the Energy Resources Sub-committee of the House of Commons Select Committee on Science and Technology. They offered little hint of the content of the Department of Energy's proposed research and development programme for existing and new sources of energy—that had to wait another week, until the Department of Energy's Chief Scientist, Dr Walter Marshall, appeared before the committee on behalf of the Advisory Council on Research and Development for Fuel and Power (ACORD). ACORD has now passed on that programme to Mr Benn.

But ETSU was not totally unforthcoming. It confirmed that it was placing contracts on behalf of the department and was thus playing a supervisory, monitoring role as well as performing its specified tasks on energy sources and energy conservation. ETSU also revealed its preferential ordering of alternative energy sources: wave power offered the "best potential contribution" and looked the most promising; solar came next, ahead of geothermal; wind and tidal power together took up the rear.

Without some sort of weighting, it all seemed rather crude. The subsequent ACORD hearing indicated that ETSU's chief concerns have been solar, geothermal and wind power; wave power studies were the province of the National Engineering Laboratory, while the Central Electricity Generating Board investigated tidal power. Obviously there is close collaboration, not least through the ubiquitous Dr Marshall and a plethora of committees. ACORD, in particular, is crucial. With members drawn from the nationalised fuel and power industries (coal, gas and electricity), from the oil industry, from research bodies (the SRC and the UKAEA) and from the academic world, it considers the results of ETSU's technical studies and advises Mr Benn on both research and development needs and the size of appropriate programmes drawn up by steering committees.

Thus it was able to confirm ETSU's preference to the select committee: it had considered tidal power (April–May 1975), and ordered a limited study of technical issues relating to the Severn Barrage; wave power (June 1975), which produced the £1 million feasibility study launched at the end of last month; geothermal energy (October 1975), any research programme on which needs to be integrable with the EEC's work in the area; wind energy (December 1975), about which a decision was deferred pending further study of costs; and solar energy (February 1976).

It was, in fact, solar energy's turn to capture some attention by this time, thanks to the publication of a massive document by the UK section of ISES, the International Solar Energy Society (see page 177). The bullish tone it adopts about solar energy prospects contrasts with the apparent view of ACORD. ACORD "accepts in principle the need for a national R & D programme" and wants a more detailed study, backed by research and development, "to define the options more precisely"—in other words, the case for solar energy, at least as presented to it by ETSU, is not yet absolutely proven.

Whether all this reflects a genuine clash of views over priorities will probably only emerge after the one-day "national energy conference" organised by Mr Benn for June 22; ACORD's recommendations to Mr Benn are to be made public the same day. The 50 organisations invited to this more obvious example of open government include representatives of industry, the unions, consumer, conservation and environmental interests, and professional, academic and research bodies. In the meantime, the ISES document is an attempt to reinforce the case for solar energy. Clearly the circle of interests that the subject of energy now covers is widening fast.

So fast, in fact, that the issues involved in alternative energy seem to be growing increasingly political—partly thanks to Mr Benn, but principally because the potential of the various energy sources under scrutiny turns less on the well documented scientific evidence that can be brought to bear than on the impenetrable economic factors involved. The ISES document provides just one example: the case it puts for solar energy is based on more than mere scientific feasibility, but it is not really couched in the propagandist terms typical of a document urging policy changes. As one environmentalist privately pointed out, though, it does provide excellent ammunition.

Alternative energy, however, is but the tip of the iceberg, as any table of comparative expenditures on energy in Britain would quickly show. And as if to add to the recent excitement, the Energy Research Group at the Open University has churned out its own critique of the electricity industry, advocating a national fuel policy and suggesting that sheer overestimation of demand has produced a large measure of overcapacity. It can't be long before the fact that power is consumed to such a large extent in the form of electricity also becomes a legitimate area of enquiry.

Back in the committee rooms of the House of Commons, however, was the poor Science Research Council (SRC), also giving a view on alternative energy resources—the beleaguered Sir Sam Edwards was in the chair. He took the opportunity to cock a snook at the Treasury: in an obvious reference to the condition of "big" science under the SRC, he indicated that even if it was available extra money would not be devoted to alternative energy.

IN BRIEF

Explosions treaty delay

Work has been completed on the final draft of a US–USSR treaty limiting the size of so-called peaceful nuclear explosions, but President Ford has delayed signing the treaty to keep it from becoming an issue in some key Republican primary elections. Formal signing ceremonies, which were to have been held last week in Washington and Moscow, were dropped when Mr Ford suffered a string of defeats at the hands of Ronald Reagan, his right-wing challenger. Anxious not to give Reagan yet another foreign policy issue to snipe at, Ford decided to delay the signing until after the crucial May 18 Michigan primary. The irony in all this, however, is that so far the treaty has been attacked almost solely by liberals who regard it as a sham in terms of arms control.

Nuclear trade moves

US pressure for the severest curbs on the sale of nuclear reprocessing and enrichment technology is expected when the "Group of Seven" (now swollen to ten) nuclear powers meets secretly in London next month. Reports indicate that US delegates will move to dissuade West Germany and France from going ahead with plans to export to Iran and Pakistan. They may also press for a cancellation of the West German–Brazilian deal agreed last year. Meanwhile, Congress is expected to approve a request from the American General Electric Company to export two nuclear installations to South Africa.

New USSR group

A new dissident group, headed by physicist Yurii Orlov, has been formed in Moscow. The group aims to monitor the implementation in the Soviet Union of the Helsinki pledges on human rights. Dr Orlov was quickly arrested and informed that he and the other members of the group would be liable to legal action if they persisted with this "unconstitutional activity". Released after an hour, Dr Orlov stated that the group would continue to function.

Shooting the rabids

KENNETH MELLANBY

Our authorities are right to be concerned about the risk of rabies being introduced into Britain. In recent years the disease has spread rapidly over Europe, and has now reached the coast of France just across the English Channel. All dogs entering the country have to spend 6 months in quarantine so those already infected may be detected; the main risk, however, is thought to be that a pet dog incubating rabies might be smuggled into England, either on a small boat which eluded the customs or, tranquillised, in the boot of a car. Our officials are increasingly alert to the danger, and heavier penalties are being given to those caught trying to evade the law, but the risk cannot be completely eliminated. It is also possible that rabies could reach Britain by other means. We do not have vampires, which are notorious carriers in Central America, but even the apparently harmless insectivorous bats, which are known to fly across the channel, are able to carry the virus. It would even be possible for a fox to swim the channel.

In France foxes have been the main carriers of rabies, and would probably be the greatest danger in Britain. There are therefore plans to kill all the foxes living in an area around any focus of rabies which might occur. Now that the fox is becoming a common suburban denizen in Britain, its potential as a disease carrier is increasing. So is the task of control if this becomes necessary. Foxes likely to endanger city dwellers live in overgrown cemeteries and disused railway embankments, and their elimination will be very difficult. On the other hand in rural areas, where foxhunting is popular, there should be less trouble. Contrary to the view put out by supporters of foxhunting, there would be little difficulty in killing off every fox in their territories in a few days using gas, shooting and poison. Foxhunting is only a method of culling the surplus population, and mainly serves to conserve the species in many areas. The sport would have to be stopped if rabies appeared in the countryside, as the hounds and, in turn, the hunters, would be at risk if they chased a rabid fox.

Wildlife conservation would suffer greatly if rabies became a serious problem in Britain. Not only foxes but many other animals, particularly carnivores like stoats and weasels, might be a danger, and there would be attempts to exterminate them. As there is already considerable pressure on these species in Britain, further persecution would probably be effective, and the whole balance between predators and their prey would be upset. The result might well be an unwelcome population explosion in undesirable species like the rat. The effect on the countryside might be serious.

So far our preparations in Britain have been to stockpile vaccine and serum, to protect animals and to treat humans should rabies appear, and to make plans to try to wipe out foxes and other wild animals. Surely we should immediately devote our attention to our domestic pets? Although an infected fox might appear unnaturally tame, and infect a child (particularly one interested in wildlife) who played with it, a rabid dog would clearly be a much greater danger. While I would not wish to interfere with the right of the responsible pet lover to keep a dog, I think that we should take immediate action to eliminate the large numbers of uncared for, stray and feral dogs which are already a real danger to children and even adults in many parts of the country.

It is estimated that less than half the six million dogs in Britain are licenced, even though the fee remains ludicrously low at 37½ pence. These dogs will be more difficult to eliminate than foxes, so we should start at once. At present there is no requirement to licence a puppy under six months old, so many pets are bought for children only to be turned out when they become larger, hungrier and less attractive. Hundreds of thousands of animals are abandoned when their owners go on holiday. A vigorous campaign to destroy all unlicenced dogs, and a much more expensive licence, required even before a puppy could be acquired, would go far to solve the problem Even without the risk of rabies a reduction in the number of unwanted dogs would make our cities cleaner, more hygienic and safer—and would cut down the need for expensive imports of high protein dog foods which might reduce hunger in other parts of the world.

Class structure in science

SIR,—To be castigated in a leader column is for me a unique and not entirely pleasant experience, but one which, given the choice, I would rather have had for something I did say than for something I did not say.

In talking to the Research and Development Society on April 27 I was careful to say that I did not believe simple direction was the right way to harness the resources of university science to our national objectives. I made no suggestion that (to quote your leader) "research funding in universities should be approved only if the research has clear economic benefit". Nor did I say that "individual universities should be designated as centres of expertise for certain industrial research purposes".

I emphasized that to benefit more directly from university science was essentially a matter of changing the traditional attitudes towards research of other than the very pure kind, and said in this connection that it "would help, perhaps, as a conditioning mechanism, if all applications for funds for academic research were required to state what would come from its successful completion, with the words 'a better understanding of' or any paraphrase of those words banned". No question here of "clear economic benefit" or approval based on such a concept—just a suggestion that clear thinking about where a project fits into the scheme of things would help the attitude-changing process. My mention of banning the phrase "a better understanding of" was a half-humorous reference (well understood by the audience, in which research management was fairly strongly represented) to the fact that such a phrase is the resort of nearly all woolly proposal writers.

In suggesting that we might consider allocating a major interest area to each academic institution I was not thinking of industrial research and made no mention of it. The examples I gave of the kind of theme institutions might tackle were very broad divisions of our national life and the objects of the suggestion were

- to ensure that all aspects of our communal existence were being thought about
- to generate groups of people of different disciplines sharing a common interest in an important national theme.

A journal like *Nature* which is looked upon as the epitome of scientific accuracy has a special duty to be certain of its facts. If there is a class war in science (which I doubt), your role, Sir, is that of *agent provocateur*.

I presented my talk not as a means of expounding specific proposals but to help in generating serious discussion on a vital topic. Your handling of it will almost certainly be prejudicial to that objective, but if any of your readers would like to know what I actually said I shall be happy to send them a copy. I will even send one to you, Sir, if you are interested in fact rather than fiction.

Frozen mineral waters

SIR,—In his article (March 18, page 182) Allan Piper makes it clear that, as soon as the exploitation of the mineral wealth of Antarctica becomes a commercial proposition there will be a major political conflict. Surely the way to handle this situation is to tackle the problem now, while the commercial issues are still relatively remote. Yet I am very much afraid that the temptation will be to postpone any resolution of the situation until the problem arises, by which time it will, of course, be too late to avoid direct confrontation and very probably military intervention.

I believe that action is necessary now to defuse this situation; for example by an agreement to sign over all mineral rights on the continent to the United Nations Organisation It is to be hoped that signatories to the Antarctic Treaty will not sidestep the issue at their meetings this year and next.

Allergic reactions

SIR,—Reports that animal handlers are allergic to laboratory strains of rats, mice and rabbits are becoming increasingly prevalent (Correspondence, March 25, page 280). In the pages of *Nature* and *Science*, the problem has been considered only from the human point of view; we bemoan the fact that many of our colleagues must either walk around with gauze masks or gulp antihistamines in order to survive their experimental subjects. We suggest that the time has come to view the increased number of allergic reactions from the murine rather than human perspective. The rat is evolving; we are the catalysts speeding its evolution.

Consider an animal handler approaching a colony of rats, to some of whom he or she is allergic. Is it not natural for the handler to select for experimentation only those animals who do not cause an allergic reaction? Faced with a roomful of rats, who of us would willingly choose the rat which caused our eyes to tear, our nose to drip or our bronchi to constrict. We are selectively destroying non-allergenic animals leaving behind the allergenic to act as breeders. One can see additional problems arising in the future. Rats and mice are usually picked up by the tail. Just as selection for super-allergenic strains increases the rat's chances of survival, so does selection for the short-tailed or tailless rat.

If we must root around in the rats' cage for five minutes just to find his tail, we suspect that we'll either move to the next cage or suffer a bitten finger. In short, the super-allergenic, tailless rat is a problem only for the experimenter; from inside the cage it will undoubtedly be greeted with chuckles or cheers.

Human anatomy

SIR,—Your correspondent Anthony B. Harris (May 6th, page 10) describes his "experiments" on young ladies purporting to determine a functional basis for structural asymmetry. His results, which suggest to him a positive correlation between handedness and asymmetry, are at complete variance with our observations on a thousand normal individuals, although asymmetry is certainly the rule rather than the exception.

Since Anthony Harris' measurements are all of circumference or volume, this may account for his inability to detect equivalent asymmetries in the two-dimensional representations of the human form to be found in the National Gallery; these asymmetries, however, are observable in sculpture of many centuries and cultures.

H-2 and HLA sequences

from J. C. Howard

ONE of the most important and illuminating observations in the convoluted history of the major histocompatibility complex (MHC) was the demonstration by Snell, Klein and Shreffler that the highly complex antigens of the H-2 system of the mouse could be largely resolved into two allelic series, one at each of two closely linked loci in the K and D regions of the chromosome 17. This observation emphasised the remarkable formal similarity between the principal leukocyte antigen series of man and mouse, and led to the hypothesis that the two allelic series represented products of related genes that had arisen as a result of ancestral duplication. This simplification in turn led to attention being concentrated on the products of these loci—the best defined genetically and serologically in the MHC—as appropriate subjects for biochemical characterisations. In the past few years progressively more detailed analyses of these antigens have led finally, in the past few months, to the first amino acid sequences, the most recent study of which appears in this issue of *Nature*[1].

There is now general agreement that both the H-2D and H-2K products of the mouse, and the HLA-A and HLA-B products of the human MHC are cell surface glycoproteins of total molecular weight approximately 60,000 daltons. They carry about 3,000 daltons of carbohydrate on a heavy chain of approximately 45,000 daltons, and a non-covalently linked light chain of about 12,000 daltons which is known to be β_2-microglobulin. The molecule is inserted into the membrane at the C-terminus, and the whole molecule is soluble only in detergent. A papain fragment of about 36,000 daltons carries all the antigenic activity (as well as the light chain), however, and is water soluble. It is likely that the native molecule exists in the membrane as a monomer, although a free sulphydryl group is available near the C-terminus and may normally participate in some dimerisation. A lymphocyte carries approximately 5×10^5 antigen molecules on its surface.

It has required considerable ingenuity to obtain amino acid sequences from H-2 and HLA antigens because of the minute quantities of material available. By using internal isotopic labelling with individual or small groups of amino acids, four American groups have obtained partial N-terminal sequences of three K end alleles and two D end alleles (Henning *et al.*[2]: Vitetta *et al.*[3]; Silver and Hood[4]; Ewenstein *et al.*[5]). Dissociated immunoprecipitates from detergent-solubilised membrane preparations of normal lymphoid cells were sequenced in the Beckman automatic Sequenator, and the labelled residues identified with appropriate controls. Strominger and colleagues (Terhorst *et al.*[6]) and now Bridgen *et al.*[1] in this issue of *Nature* have obtained partial N-terminal sequences of HLA-A and HLA-B products from lymphoid cell lines. Bridgen and colleagues have adapted solid phase sequencing techniques of whole protein molecules, using a sensitive post-labelling method to identify consecutive residues autoradiographically on two-dimensional thin layer chromatography.

The sequences obtained by these various techniques are summarised in Fig. 1. They demonstrate beyond all dispute the common evolutionary origin of the D and K loci in H-2, and of the A and B loci in HLA. From the substantial numbers of shared residues between H-2 and HLA sequences, a common evolutionary origin for the genes determining both H-2 and HLA is also apparent. The existence of marked species specificity inside the H-2 and HLA sequences seems to

Fig. 1 Collated H-2 and HLA sequences derived from the following sources: H-2, Henning *et al.*[2], Silver and Hood[4], Vitetta *et al.*[3], Silver and Hood[7], Capra, personal communication; HLA, Terhorst *et al.*[6], Bridgen *et al.*[1], Bridgen *et al.* sequenced a mixture of four HLA molecules giving rise to the alternative residue allocations in positions 8, 9, 10, 11 and 13. Residues in parentheses represent either preliminary or disputed results, dashes indicate that the residue present is not any of the other residues known at that position except in position 9 of H-2D where the residue is not valine but may still be histidine. Residues shared between different H-2 sequences are indicated by the vertical blocks, while residues shared between H-2 and HLA are similarly marked in the HLA sequences.

imply that the postulated duplication must have followed the evolutionary divergence of man and mouse, and yet the existence of paired serological loci in many species of mammal suggests the reverse. A resolution of this paradox may be that the genes specifying these antigens show a recurrent tendency to duplicate during evolution. This view might be supported by the existence of a third serological locus, HLA-C, in the human, although the homology of this locus with the A and B loci remains to be demonstrated. The allotypic differences between H-2 specificities at the D and K loci, and between HLA specificities at the A and B loci seem to be reflected in several sequence non-identities between different alleles, for instance at residues 2, 5 and 19 for the three H-2K sequences and residues 3, 5, 8, 9, 17 and 19 for the two H-2D sequences. The frequency of these allotypic substitutions is unprecedented in known allelic systems, and if it is sustained throughout the length of the molecules will pose considerable theoretical problems in accounting for their origin. The conventional models for origin of simple (that is, single substitution) allotypes impose intolerable genetic load on the species when multiple substitutions are to be obtained. Alternative mechanisms to account for the observed differences have been elegantly discussed by Silver and Hood in a recent review (*Contemporary Topics in Molec. Immunol.*, in the press)[7].

It is curious that the sequences reveal no tendency for D products to resemble each other more than they do K sequences, or *vice versa,* since from serological studies the products of the two loci can be shown to differ by locus-specific public antigens. It seems likely however that further sequence data will ultimately confirm the serological results, since in all other respects the implications of serological data have been confirmed by the sequences.

For some time now the notion has been in the air that the remarkable polymorphism in histocompatibility antigens may reflect the specificity of some kind of recognition system, and hence the possibility that H-2 and HLA antigens may show sequence homology with immunoglobulin has been widely canvassed. The association of β_2-microglobulin with these antigens as a "light chain" has reinforced this suggestion in view of the homology of this molecule with an immunoglobulin domain. In the event the sequences of H-2 and HLA antigens so far available do not support the immunoglobulin homology theory, and the absence of a half-cystine anywhere in the first 40 residues also argues strongly against homology. Nevertheless it is possible that sequence homology with immunoglobulin will emerge later on, or alternatively, if the two genetic systems are very distantly related, sequence homology may be absent, but a three-dimensional homology sufficient to account for β_2-microglobulin binding as a light chain homologue may preserved (Hood, personal communication).

There is no doubt that the preliminary sequence data now available for H-2 and HLA antigens have raised as many intriguing problems about the organisation and evolution of these remarkable chromosome regions as they have resolved. It seems certain that as sophisticated microsequencing techniques are further developed there will continue to be a flood of new information about these and other molecules such as Ia or HLA-D in the MHC that will prove as fascinating and intellectually demanding in their interpretation as the immunoglobulin sequences have been.

Ineffective nerve terminals

from Shin-Ho Chung

SEVERAL recent studies by Patrick Wall and his colleagues indicate that a class of synapses in the central nervous system is normally inactive but becomes effective if the target cells are deprived of their main inputs. If this notion is correct, it will have an enormous impact in neurobiology. The new concept will not only have a direct bearing on our understanding of how the brain adjusts to injury or altered environment, but may also shed new light on the handling of incoming sensory messages by the brain and the developmental strategies it adopts for forming intricate neuronal networks

For many decades, anatomists and physiologists have explored the projection of sensory afferents onto the mammalian spinal cord Together they have slowly compiled a story of almost incredible complexity. Cutaneous fibres originating from a circumscribed region of the skin (a dermatome) bundle together to form a dorsal root and enter the cord at the appropriate spinal segment. Once these fibres enter the cord, they branch out explosively to synapse with thousands of neurones in the grey matter. A fibre initially divides into a T-shaped junction, and the two main stems, traversing several segments in the rostral and caudal directions, drop their numerous collaterals onto the cell layers beneath. It has been estimated that major collaterals are given off from the stems at intervals of 100 to 200 μm. Since the radiation of sensory fibres continues over a region covering many segments, several hundred, major collaterals can stem from any one fibre.

In apparent contradiction to these complicated, diffuse patterns of interconnections between sensory afferents and spinal neurones, physiologists have revealed a strict somatotopic map of the skin in the spinal cord. Each dermatome is represented by one or at most two segments of the spinal cord. Cells located medially in the dorsal horn synapse with fibres representing the distal part of the dermatome, whereas those located more laterally represent the proximal part of it. For example, each large cell in lamina IV (to which the large myelinated fibres carrying cutaneous information project) subserves a small patch of the skin, usually less than the size of one toe, and gentle pressure or movement of hair within this receptive field causes a vigorous discharge on that cell (Wall, *J. Neurophysiol.*, **23,** 197; 1960; Brown and Fuchs, *J. Neurophysiol.*, **38,** 1; 1975). Stimuli applied to areas outside this skin region fail to show any effect on the cell, despite the anatomical evidence for a widespread dissemination of sensory information within the cord.

This discrepancy between anatomical and physiological descriptions of the spinal cord has been a persistent worry to Wall. For if a single fibre spreads its terminals over 10 spinal segments, it is not immediately apparent how cells in one segment can have a restricted dermatome and maintain a strict somatotopic order within themselves. Wall and Werman (*J. Physiol., Lond ,* **255,** 321; 1976) have recently re-examined the central projection of spinal afferents and have confirmed the earlier anatomical descriptions. Using the technique of antidromic stimulation, they have traced the trajectory of single axons in the spinal cord of the cat. Some myelinated fibres invading the cord at Lumbar 2 segment, for example, have their terminals extended as far caudally as Sacral 1, which is 6 segments away from their zone of entry. Stated conversely, cells in a given segment receive not only fibres from their nearest dorsal root but also distant arborisations radiating from many neighbouring dorsal root fibres.

According to Wall (*Phil. Trans. R. Soc. Lond.,* in the press), the synapses formed by distant branches normally remain dormant, but become active as a result of changes triggered by de-afferentation. This assertion is based on several related observations on lamina IV cells after cutting the appropriate dorsal roots. All fibres which form effective synapses with the cells are contained in the dorsal root nearest to them; if this root is cut, the cells become unresponsive to tactile stimulation, and the dermatome which is subserved by it becomes insensate. Merrill and Wall (*J Physiol., Lond.*, **226**, 825; 1972) first discovered that within a few hours after surgery, de-afferented cells begin to respond to electrical stimulation delivered to neighbouring dorsal roots, although natural stimulation anywhere on the skin cannot excite them. One week after de-afferentation, the cells can be excited by light brushing, touch or presure on regions of the skin which they normally would not represent (Basbaum and Wall, *Brain Res.*, in the press). Some of these cells are connected to two disparate parts of the body, for example, abdomen and leg. Hints of a similar phenomenon exist elsewhere in the mammalian brain. Cells in the thalamic nucleus of the rat (Wall and Egger, *Nature*, **232**, 542; 1971) and in the gracile nucleus of the cat (Millar *et al.*, *Expl Neurol.*, **50**, 658; 1976) change their receptive fields from leg to arm or trunk when the pathways connecting the leg to these nuclei are destroyed. These findings, taken together, do indeed suggest that axons in the brain form many more synaptic contacts than are apparently needed in normal circumstances. It should be noted, however, that various other interpretations, of which sprouting of neuronal terminals into vacated territory is one, have not been conclusively eliminated.

There are several possible ways in which a synaptic terminal could be rendered ineffective. Nerve impulses travelling down an axon may invade only a few proximal branches and fail to invade the remaining terminals of the axon. Alternatively, the distant terminals may terminate at distant segments of the dendrites of their target cells, thereby making the contacts less effective in bringing the target cells to the threshold of firing. Finally, the distant terminals may terminate on their target cells not directly but through small interneurones. In any of these cases, changed conditions in the tissue induced by de-afferentation could conceivably cause the presence of such distant terminals to be more apparent.

Whatever the mechanism ultimately turns out to be, Wall's findings pose the intriguing possibility that during development a growing axon forms diffuse contacts with a large number of target cells, and through use and disuse some of these contacts remain effective whereas the others become ineffective. The ineffective terminals would remain, in Merrill and Wall's phrase, as "ghosts of the cell's childhood" and become functional again if the neuronal circuitry needed to be modified. This line of speculation leads to testable predictions about early developmental processes of somatotopic organisation. For example, a lamina IV cell in a young kitten could be excited by sensory fibres stemming from disparate regions of the skin, and ordered representation of cutaneous receptive fields onto spinal neurones could evolve gradually as the animal matures. Now and for the next few years, as more direct approaches are used to reveal the mechanisms governing development and plasticity of the nervous system, the observations of Wall, and the interpretations he has drawn from them, will remain as a valuable guide. ☐

Brightness variations of Saturn's Rings

from David W. Hughes

ASTRONOMERS, since 1921, have occasionally reported that the brightness of Saturn's rings varies with azimuthal angle (the angle θ in Fig. 1). The degree of variation is a matter of considerable debate, however, and papers have been published claiming that the eastern ansa of the inner ring B is brighter than the western one, fainter than the western one, and that each ansa is fainter than the ring position directly in front of Saturn (that is $\theta=90°$). The outer ring A is also found to vary in brightness, but in a more complicated way.

Hoping to solve this ambiguity Karl Lumme and William Irvine of the Department of Physics and Astronomy, University of Massachusetts, have made careful photometric studies of some 100 good-quality Saturn plates from the New Mexico State University and Lowell Observatory collections. The preliminary results are reported in a recent edition of the *Astrophysical Journal* (**204**, L55; 1976). The brightness of each ring as a function of θ has been examined for each of six wavelengths in the band 3,600 to 8,000 Å and also for phase angles, α, (the angle Earth–Saturn–Sun) larger or smaller than 1° and for ring tilt angles, B, larger or smaller than 20°. Results show that at 5,500 Å, $\alpha > 1°$ and $B > 20°$, the outer ring A has a maximum of brightness at $\theta=45°$ and 225° and a minimum (about 10% lower) at $\theta=135°$ and 315°. The effects seem to be less pronounced at shorter wavelengths.

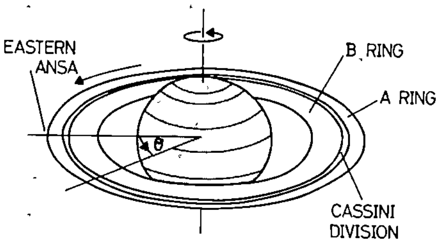

Fig. 1 Saturn and its rings. The brightness of the A ring varies with θ, the azimuthal angle, whereas the B ring seems to have a constant brightness.

For the inner B ring Lumme and Irvine find small maxima in brightness for $\theta=0°$ and 180°. This is caused by the image spreading on the photographic plate due to the finite resolving power of the telescope, atmospheric effects and photographic irradiation on the plate. When corrections are made for this spreading, the resulting brightness is found to be independent of θ.

The authors conclude from their results that the particles in ring A may have rotation periods locked to their period of revolution about Saturn. So just like the Moon they always point the same face to the central planet. The above data also indicate for the first time that the average properties of the particles in ring A may differ from those in ring B.

Morrison (*Icarus*, **22**, 57; 1974), who studied the rings by infrared radiometry, found that the particles at the western ansa had a higher brightness temperature than those at the eastern ansa. He proposed that the particles have uneven albedoes, the brighter sides being orientated towards their direction of orbital motion.

The nature and size of the particles in the rings are still poorly understood. Pollack (*Space Sci. Rev.* **18**, 3; 1975) reviewed recent visual, infrared, radio and radar data and concluded tentatively that the mean particle size is around 10 cm, the bulk composition being, in the main, water ice. These particles occupy between 0.5 and 1% of the total volume of the rings. The physical thickness of the rings is about 100 m but the rings do bulge slightly at some of the period resonances with satellites Mimas and Titan. The total mass of material in the rings is small, Pollack's figures leading to a value in the region of 10^{18} g, which is about the mass of a large comet and is over a million times less massive than the Moon.

It is hoped that this picture will be greatly clarified in the next decade when the data from the Pioneer and Mariner Jupiter/Saturn space probes have been received and analysed. ☐

Sexual selection and the handicap principle

from John Krebs

DARWIN developed his theory of sexual selection to account for the extravagant secondary sex characters possessed by males of many species. Peacock tails, deer antlers, and bird of paradise plumes are classic examples of characters which hamper survival, but which may increase mating success. Darwin's theory was neatly formalised by R A. Fisher 36 years ago in his book *The Genetical Theory of Natural Selection* and later developed as a genetic model by O'Donald (*Heredity*, **17**, 541; 1962); briefly, the argument goes like this. Females on the whole tend to be fussier in their choice of mates than are males (the female has more to loose if she makes a bad choice because eggs are more expensive than sperm), so that males end up vying with one another for the attention of a female. Females will always try to choose partners of 'good quality'—those which make good parents, or which have good genes to pass on to their children—and in the course of evolution females will develop a preference for external indicators of these qualities. Now suppose that females have begun to evolve a liking for males with green heads, an indicator of good quality: immediately a new selective force comes into play. Males with green heads will now be at an advantage because they are popular with females, and therefore females which choose green-headed males will have sexually attractive sons (assuming inheritance of the green colour), regardless of the quality of these sons in any other respect. The female preference itself generates a selective advantage for green heads, which in turn favours a stronger female preference. It is this positive feedback loop which has led to the extraordinary elaboration of many male sex characters

Recently, Zahavi (*J theor. Biol.*, **53**, 205–214; 1975) has come up with an audacious alternative theory of sexual selection. He argues that the females' taste for males with costly, survival-reducing adornments evolves precisely because these features are a handicap. A male which has survived to breeding age in spite of dragging around a huge tail since birth has overtly demonstrated his superior fitness, just as if two athletes ran a mile in four minutes, but one carried a sack of coal, we would conclude that this individual was stronger than his rival. The handicap principle, as Zahavi calls it, has an immediate intuitive appeal. A female benefits by preferring the most handicapped male, because he will pass on good genes to her children, and the handicapped male benefits because the heavy cost of his adornments prevents easy copying by other males. Unfortunately, however, the handicap principle does not work. Maynard Smith (*J theor. Biol.*, **57**, 345–354; 1976) and Davis and O'Donald (*J. theor. Biol.*, **57**, 239–242; 1976) have both analysed Zahavi's idea in more detail, and they show (as many people had suspected) that the verbal argument has serious flaws when translated into strict genetic terms.

Both critiques point to an obvious problem. Even if a handicapped male passes on good genes to his children, he unfortunately also passes on his handicap, which must, according to Zahavi's hypothesis, reduce their survival chances. Perhaps the idea can be salvaged by assuming that the good genes are passed to male and female offspring, but the handicap only goes to the male? Davis and O'Donald point to two difficulties with this argument. First, it is unlikely that genes which are good for a highly adorned male will also be optimal for a cryptic female, and second even if one assumed that the same genes were optimal for both sexes, selection would soon bring females to near their optimum genotype, at which point the advantage of choosing a handicapped male would fade away.

Maynard Smith puts Zahavi's verbal argument into the form of a simulation model, using three loci, one for fitness (high and low), one for a handicap such as tail length, and one for female choosiness—the choosy allele only mates with handicapped males. The fitness of a 'high fitness–no handicap' male is set at 1, and the other fitnesses are calculated by subtracting a cost of the long tail, and a cost of the 'low fitness' allele. In order to eliminate the effect of female preference (Fisher's idea) the simulation was started with a very low frequency of the 'choosy' allele, the other loci being represented by equal frequencies of their two alleles. The results of the simulation were unambiguous: choosy females and handicapped males declined in frequency, and this was true for a wide range of fitness values. The handicap itself does not favour the evolution of elaborate male sex displays.

Interferon deglycosylated

from David Metz

INTERFERON is the cellular protein, synthesised by virus-infected animal cells, which effects the protection of other as yet uninfected cells against subsequent virus infection. Interferon has long been believed to be a glycoprotein. The carbohydrate substitution is to be expected of a secreted protein though the experimental evidence for its occurrence has hitherto been somewhat indirect. The principal impediment to the full biochemical characterisation of the various molecular species of interferon has been the difficulty of purifying the material to demonstrable homogeneity. The reason for this difficulty lies in the very high specific activity of interferon which means that large volumes of crude preparations (necessarily from tissue culture) yield tiny amounts of pure interferon.

Progress in purifying interferon has been steady if unspectacular in recent years. The current state of the art is well illustrated by two recent papers from Knight on the purification and characterisation of mouse and human interferons. Using basically similar purification procedures, both mouse L cell interferon and human diploid fibroblast interferon were purified to specific activities of 2×10^8 units per mg protein. The human interferon preparation, when characterised by polyacrylamide gel electrophoresis, displayed a single peak containing essentially all the interferon activity, protein staining capacity and carbohydrate staining capacity of the preparation (Knight, *Proc. natn Acad. Sci. U.S.A.*, **73**, 520; 1976). This preparation, containing a single polypeptide of apparent molecular weight 20,000, would seem to be the first homogeneous preparation of human interferon.

In contrast, the mouse interferon yielded some dozen discrete bands of activity, following polyacrylamide gel electrophoresis, spanning an apparent molecular weight range of 20,000 to 32,000. About half of these components were demonstrated to contain carbohydrates, as judged by the periodic acid-Schiff base staining procedure (Knight, *J. biol. Chem.*, **250**, 4139; 1975). The reason for this heterogeneity of mouse interferon is as yet undetermined. Variation in the carbohydrate content, as opposed to the primary amino acid sequence, is clearly one possibility.

A second type of heterogeneity in which a variable degree of glycosylation appears to be implicated is the charge heterogeneity of interferon which may be examined by isoelectric focusing. Dorner *et al.* (*Proc. natn. Acad. Sci. U.S.A.*, **70**, 1981; 1973), confirming the earlier work of Schonne, Billiau and De Somer, demonstrated that treatment of rabbit interferon with neuraminidase converted the native heterodisperse charge distribution to a single component with no loss of biological activity. Since neuraminidase would be expected to cleave a terminal sialic acid residue from a penultimate galactose in a carbohydrate side chain it was inferred that native rabbit interferon contained variable amounts of sialic acid as the terminal sugar which, moreover, was not involved in the antiviral function of the molecule.

This type of investigation has recently been extended to human interferon by Anfinsen and his colleagues (Bose *et al.*, *J. biol. Chem.*, **251**, 1659; 1976) who have shown that 80% of the sugar moieties may be removed from a partially purified interferon preparation using a mixture of glycosidases, again without any loss of biological activity. Unfortunately, since the interferon preparation used was of undefined purity one cannot estimate how much of the carbohydrate of the interferon molecule itself was removed in this experiment. Nevertheless, the demonstration of both size and charge changes of the interferon activity following enzymic digestion do support the notion that at least some of the sugar residues may be removed from human interferon without loss of biological activity.

If it turns out that all the carbohydrate is dispensable without loss of activity the eventual chemical synthesis of interferon would be facilitated. But whether such a synthetic molecule free of carbohydrate side chains would be therapeutically useful is uncertain. One general feature of studies in which interferon has been used to attempt the protection of man and animals against virus challenge has been the relatively large quantities of interferon required for efficacy This may well be a consequence of the common finding that interferon has a short half-life in the circulation. It is known that a variety of glycoproteins are rapidly cleared from the circulation when even a limited number of the normal terminal sialic acid residues are removed (Ashwell and Morell, *Advances in Enzymology*, **41**, 99; 1974). Thus Dorner *et al.*, (*op. cit.*) have suggested that the half-life, and consequently the therapeutic usefulness, of interferon might be enhanced if the native heterogeneity were diminished by the additional incorporation of sialic acid residues. So reglycosylation of synthetic or natural interferons might in fact enhance their therapeutic value. ☐

Cross section for nuclear fusion

from P. E. Hodgson

When two nuclei collide, there is a certain probability, depending on the energy and on the nuclei, that they will fuse to form a compound nucleus, which subsequently decays by the emission of neutrons, charged particles and gamma rays. In recent years there have been many studies of the cross section for nuclear fusion, and some features of the process are now understood (*Nature*, **256**, 261; 1975).

The probability that two nuclei fuse depends on the impact parameter, the shortest distance between their initial directions of motion. If the collision is a glancing one (large impact parameter), a few nucleons may be transferred from one nucleus to the other, or knocked out entirely, but the nuclei will go essentially unchanged. If the collision is more or less head-on (small impact parameter), the nuclei will interact strongly and are likely to fuse.

The probability of fusion also depends on the energy of the collision: at low energies the nuclei are kept apart by the electrostatic repulsion and no reactions can occur. As the energy increases, so does the fusion probability, until at very high energies it begins to decrease because the nuclei are more likely to be shattered by the violence of the impact.

These collisions are far too complicated to be treated in detail by quantum mechanics, but substantial progress has been made towards understanding the fusion cross section by using classical ideas (*Nature*, **256**, 261; 1975). If R is the impact parameter, then the angular momentum of the lighter ion about the heaver is

$$L\hbar=mvR=k\hbar R\ .$$

If all collisions with impact parameters less than R lead to fusion, then the total fusion cross section

$$\sigma_f=\pi R^2=\pi^2L^2/k^2$$

As the energy increases, the peripheral collisions bring in more angular momentum than the compound nucleus can accept, so fusion can only occur for angular momenta less than some limiting value $L_F<L$ and then

$$\sigma_F=\pi^2L_F^2/k^2$$

Very many experimental studies of the fusion of nuclei have now been made, and it is found that the fusion cross sections behave in a systematic way. In particular, measurements have been made of the fusion cross section for several different pairs of nuclei giving the same compound nucleus at the same energy, and also of the same reaction at a series of energies. These have shown that fusion is not a static phenomenon; it depends on the dynamics of the interaction process.

Conditions required

A careful analysis of a wide range of fusion cross sections by Galin and colleagues (*Phys. Rev.*, **C9**, 1018; 1974) led to the remarkably simple conclusion that all the data could be accounted for by assuming that fusion takes place as soon as the interacting nuclei come closer than a distance 1.1 $(A_1^{\frac{1}{3}}+A_2^{\frac{1}{3}})$ fm where A_1 and A_2 are the atomic weights of the two ions. A similar analysis of data on other nuclei was made by Gutbrod and colleagues (*Nucl. Phys.*, **A213**, 267; 1973) and they came to a similar conclusion, but with the difference that the distance that fitted their data was 1.4 $(A_1^{\frac{1}{3}}+A_2^{\frac{1}{3}})$ fm. These two results are significantly different and it is important that they be reconciled.

A theory that does this has been developed by Glas and Mosel (*Nucl. Phys.*, **237**, 429; 1975). It provides a simple model of the fusion process by assuming that the potential in the region of interest has a parabolic form with depth $V_B+\hbar^2L(L+1)/2\mathscr{J}_B$ where L is the orbital angular momentum and $\mathscr{J}_B$ the nuclear moment of inertia. This enables the fusion cross section to be calculated analytically, and the formula obtained fits all the experimental values. At low and high energies, it gives to a good approximation the values found by Gutbrod *et al.* and Galin *et al.*, and thus unifies them coherently.

The reason for the change of slope is connected with the upper limit to the relative angular momentum of the two nuclei for which fusion can occur. This upper limit is set in two ways, and since both limits must be obeyed it is the lower of the two that actually

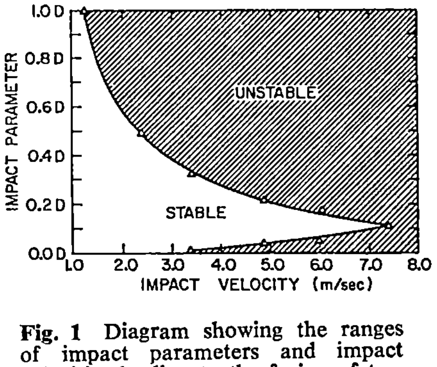

Fig. 1 Diagram showing the ranges of impact parameters and impact velocities leading to the fusion of two equal drops of water (unshaded). The impact parameters are expressed as fractions of the drop diameter $D=300\ \mu\text{m}$. The power limit to fusion at $3.4\ \text{m s}^{-1}$ has a counterpart in nuclear collisions.

determines the fusion cross section. The first limit is set by the nuclear radius R; the angular momentum cannot exceed mvR, where m and v are the mass and velocity of the lighter of the two ions. In practice glancing collisions do not lead to fusion so the limit is somewhat less than this and allowance must also be made for the reduction of the velocity of the incident nucleus by the Coulomb repulsion.

The other limit is set by the maximum angular momentum that can be given to the nucleus without causing it to fly apart. This is fixed by the internal structure of the nucleus and can be estimated by the liquid drop model. At low energies this limit is not important, and the fusion cross section is limited by the nuclear radius. As the energy increases, the angular momentum mvR increases until it reaches the critical value set by the limit of nuclear stability, and thereafter the fusion cross section is limited by the latter criterion.

These two limits correspond to the two different formulae for the separation between the nuclei for fusion to take place, and the transition region to the value of the angular momentum for which the two limits are approximately the same.

The theory of Glas and Mosel thus very neatly accounts for the variation with energy and with interacting nuclei of all the fusion cross sections available when they completed their work. Since then, however, further results have become available that cannot be accounted for by their theory, at least in its original form. The reason seems to be quite well understood in one case, but not in the other.

The first set of anomalous results was obtained by Gauvin and collaborators (*Phys. Rev.*, **C10**, 722; 1974). In the collision of two quite heavy nuclei, ^{74}Ge and ^{84}Kr, fusion takes place at a higher energy than is expected from the results for the collision of ^{40}A with ^{118}Sn, which leads to the same compound nucleus. This energy shift is as high as 15 MeV and was totally unexpected and quite outside the uncertainties of the experiment.

A possible explanation of this anomaly is that there is a lower as well as an upper limit to the impact parameter for fusion. It is then easy to adjust the lower limit to give the observed threshold shift, but then one wants to understand why fusion cannot take place for low impact parameters and how this varies with energy and from one nucleus to another.

Liquid drop model

A way of doing this has recently been suggested by Natowitz and Namboodiri (*Phys. Rev.*, **C12**, 1678: 1975), making use of the analogy with the collision of two liquid drops. This has been studied by Adam and colleagues (*J. appl. Phys.*, **39**, 5173; 1968), and they did indeed find that at some energies there is a lower as well as an upper limit to the impact parameter for the fusion of the two drops.

Some of their results are shown in Fig 1, which gives the impact parameters (expressed as fractions of the drop diameter D) for fusion as a function of the impact velocity in m s^{-1}. This diagram is easily understood: fusion takes place for low velocities and impact parameters but if either or both are large the drops either brush past each other or shatter.

The most interesting region occurs for low impact parameters and impact velocities greater than 3.4 m s^{-1}: even though the impact parameter is small fusion cannot take place, and this is just the effect that we want to explain in the collisions of heavy nuclei.

This effect can be understood by considering the collision in more detail. When fusion takes place, the kinetic energy of the colliding drops is transformed into the rotational and vibrational energy of the combined system. Now the kinetic energy can only go into rotational energy if the impact parameter is greater than zero, and the higher the impact parameter the more rotational energy can be given to the compound system.

For the extreme case of a head-on collision (zero impact parameter) the incident energy can be entirely transformed into vibrational energy for low impact velocities, but at the critical velocity of 3.4 m s^{-1} this is no longer possible. This corresponds to the maximum energy that can go into vibrations of the compound system without breaking it up.

If now the impact parameter is increased, some of the energy can go into rotational energy, so fusion can again take place. Thus for impact velocities above the critical value there is a lower limit to the impact parameter for fusion; below this impact parameter the system cannot be given enough rotational energy to absorb the energy remaining from the incident kinetic energy after as much as possible has been put into vibrations. At still higher impact parameters the rotational energy is so large that the two nuclei cannot stick together and fusion again cannot take place. There is thus a limited range of impact parameters for which fusion can occur.

As the energy increases, so does the rotational energy for a particular impact parameter, so that the lower limit to the impact parameter for fusion rises and the upper limit falls. Eventually at 7.4 m s^{-1} they coincide, and for higher velocities fusion cannot take place at all.

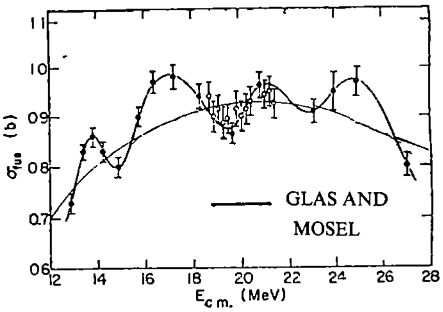

Fig. 2 Fusion cross section for the interaction of ^{12}C and ^{16}O showing the unexplained oscillatory structure superposed on the dependence given by the theory of Glas and Mosel.

The lower limit to the impact parameter for nuclear fusion can thus easily be understood by considering the behaviour of liquid drops. One important difference is the charge on the nuclei which prevents fusion at smaller impact velocities. For light nuclei the fusion threshold is below the critical impact velocity and so all impact parameters are allowed. The earlier experiments were all in this region and it was here that the systematic behaviour already mentioned was established.

For heavier nuclei, however, the fusion threshold is above the critical impact velocity and so only a limited range of impact parameters leads to fusion. There is thus an energy shift in the curve of fusion cross section as a function of energy compared with the curve that would have been obtained if the lower impact parameters also led to fusion. This higher fusion threshold is just what is observed experimentally for collisions between heavy nuclei.

The second set of data that cannot be understood by the theory of Glas and Mosel is the fusion cross sections of the interaction ^{12}C+^{16}O from 13 to 27 MeV measured by Sperr and colleagues. (*Phys. Rev. Lett.*, **36**, 405; 1976). As shown in Fig 2, the experimental fusion cross sections oscillate around the mean value given by the theory of Glas and Mosel, and it is not at all clear how this behaviour can be explained. One possible explanation, that it is due to the effect of successive partial waves as they come in turn to dominate the reaction, is ruled out because it gives oscillations that have too small a period and too small an amplitude.

Other explanations are that it is due to the effect of resonances in other channels, or to a resonant transfer process (*Nature*, **246**, 14; 1973) According to this explanation, a nucleon can be transferred back and forth between the two approaching nuclei, and this could produce a periodic modulation of the fusion cross sections. This mechanism gives a very characteristic variation of the fusion cross section with energy, and this is approximately in accord with the experimental data. □

review article

Short term screening tests for carcinogens

Bryn A. Bridges*

There are now short term tests with a high predictive value for mammalian carcinogens. Many of them are based on the ability to detect damage to DNA in bacteria or mammalian cells after metabolic activation by microsomal enzymes. Their introduction will enable provisional safety assessments to be made for the many thousands of industrial and environmental chemicals for which long-term animal testing cannot at present be considered.

It has been estimated[1] that if one could totally abolish human cancer it would add a mere two years to the average lifespan. Most cancer sufferers are past retiring age so that industrial production would be little affected by the abolition of cancer. The fight against cancer must instead be justified in terms of the cost of hospital services and of basic humanity; treatment of cancer, even when it is successful, is a miserable process. When it fails, as it so often does, one feels guilty of a double offence, not only the loss of the patient, but the imposition of heroic measures that themselves may cause considerable physical and mental suffering.

The International Agency for Research on Cancer holds it as a rule of thumb that around 80% of cancer has an environmental cause[2,3]; others would give a higher figure[4]. The evidence is indirect, being based on differences in tumour incidence between genetically similar populations in different environments[2,3,5]. Even if this estimate is only approximately correct it leads ineluctably to the conclusion that a substantial proportion of cancers, possibly a majority, are in principle preventable. In past decades those responsible for the disbursement of cancer research funds have tended either to look for a breakthrough in the area of curative treatments or to make a long term investment in basic biology in an attempt to understand the disease (or more properly diseases since "cancer" is but a general term for hundreds of different malignant conditions). Recently, however, these two essential approaches have been complemented by a third, the search for the specific environmental factors involved in carcinogenesis.

The nature of these environmental factors is not known in detail, but it seems likely that many of them are man-made or natural chemicals. Even factors such as diet or stress may act indirectly by altering the metabolism of chemicals in the gut or in the body itself. Of course, identification of environmental carcinogens does not necessarily lead to their removal but it does open the way to control so that the risk that they present is no more than is necessary when weighed against any benefits that they may give.

The most direct method of identifying environmental carcinogens for man is based on population studies, but unfortunately it is expensive and seems to have rather low resolving power. Only a handful of chemicals are known to be carcinogenic to man and most of these have been detected following the study of workers occupationally exposed to chemicals capable of giving rise to specific and rather rare neoplasms. The classic case is soot which has been known for 200 years to produce scrotal cancer in young chimney sweeps[6]. More recent examples are 2-naphthylamine, vinyl chloride and asbestos which produce, respectively, rare cancers of the bladder, angiosarcomas of the liver, and mesotheliomas of the lung cavity. The problems involved in identifying two populations differing only in their exposure to one chemical are formidable and are further compounded if the chemical gives rise not to specific and otherwise rare tumours, but to a variety of common cancers. Population studies are thus likely to be of limited value in identifying environmental (as distinct from occupational) carcinogens but they will be indispensable in providing the basis for risk evaluation, particularly where dose–response data can be obtained.

The alternative is to screen chemicals to which man is exposed. The generally accepted method of doing this is to carry out long term carcinogenicity tests with laboratory mammals. Not only are those tests very demanding of resources but any extension of animal testing on such a wide scale would be vigorously opposed by a number of animal welfare lobbies. In practice, it is inconceivable that resources could be made available (either men, money or mice) on the necessary scale to screen all the tens of thousands of substances to which humans are exposed. Of necessity, therefore, testing with whole mammals will be restricted to certain groups of suspect substances, for example those suspect but already in use on a large scale, or those substances which it is proposed to administer on a large scale, as food additives or cosmetics, for instance.

If one is to screen for carcinogenic chemicals, therefore, one must use short term tests with a high predictive value. I propose to review a number of possible systems which have been suggested in recent years. As will become apparent, many of them are in fact systems for the detection of agents causing damage to DNA. Damage to DNA leading to heritable changes may be important to man not only because of carcinogenicity but because it may cause hereditary disease[7–9]. Moreover, DNA damage may conceivably be involved in ageing and diseases associated with ageing[1]. I take it as self-evident that any agent likely to damage the DNA of man, whether in somatic or germ cells, is potentially hazardous.

Screening systems

The induction of cancer is but one aspect of long term toxicity and for the evaluation of such hazards a three-tier

---

* Address: MRC Cell Mutation Unit, University of Sussex, Falmer, Brighton BN1 9QG, Sussex, UK

approach has been proposed[10,11] The first tier would consist of simple short term sub-mammalian tests with a high predictive value for the human effect ultimately of interest. As many substances as possible should be screened with these tests. Second-tier tests would be both short and long term, on mammals. Only selected, high priority substances would be screened by these tests in addition to the first-tier tests. Tests in the third tier are designed not to detect toxic agents but to evaluate as quantitatively as possible the hazards to man from agents shown to be potentially toxic. Only substances whose use or presence seems inescapable would be subject to the third tier of evaluation, the object of which would be to make a risk–benefit assessment and institute appropriate regulatory action. Tests in successive tiers show in principle increasing relevance to man but this is often accompanied by decreasing sensitivity and practicability.

Not all of the sub-mammalian tests depend upon the postulated electrophilic nature of the active forms of carcinogens and in particular on their ability to react with DNA. Williams and Rabin[12], for example, have proposed that substances might be screened using a test based on membrane–polysome association. They found that a number of carcinogens caused degranulation of rough endoplasmic reticulum (microsomal membranes) from male rat liver. This test has been further developed by Purchase and Lefèvre[13] who have measured the loss of radioactive RNA from rough endoplasmic reticulum. Preliminary results (D Anderson *et al.*, unpublished) with a large number of carcinogens and non-carcinogens indicate that the method predicts the activity of arylamines rather well (85% correct) although it is less successful with polycyclic hydrocarbons and direct acting alkylating agents.

The necessity for metabolic activation of many carcinogens by microsomal enzymes prompted the suggestion of McPherson *et al.*[14] that the specific *in vitro* enhancement of biphenyl 2-hydroxylation activity in rat liver microsome preparation might be used as a screening test. They found that of eight known carcinogens, all caused an increase of around 100% in such activity; four compounds whose carcinogenicity is in doubt gave lower but significant increases, and eleven non-carcinogenic compounds gave no significant increase. This test system, like that of degranulation of ribosomes, is obviously promising and in need of a much more exhaustive validation on a scale similar to that used with some other systems.

Metabolic activation

There is a widespread belief among cancer workers that DNA damage is involved in the induction of cancer. That is the basis for the supposition that carcinogens might be detected by the consequences of DNA damage in simple systems. Two recent developments have enabled this possibility to be realised. First, it has become clear that many carcinogens are the products of metabolism of inactive chemicals by mixed function oxidases in the animal[15], and that preparations of liver microsomes can be used *in vitro* to carry out this metabolic activation[16–18]. Second, ultra-sensitive bacterial systems, usually involving strains deficient in DNA repair, have been developed for the detection and characterisation of agents causing damage to DNA[19–23].

The first published work in which the mutagenic activity of metabolites was detected after metabolic activation of carcinogens was by Malling[17]. The methodology of his quantitative liquid assay system has been recently described[24]. Later, Ames *et al.*[25] showed that microsomes could be added to the semi-solid agar overlay in a plate test, a procedure that is in some ways rather better for routine screening although it fails with a few compounds, for example, dimethylnitrosamine, possibly because the agar interferes with the diffusion of short-lived active metabolites.

Bacteria deficient in repair of DNA are killed more easily by DNA-damaging agents than are wild type bacteria, and this is the basis for several simple tests. Bacteria deficient in excision repair have been used[18] but these are sensitive only to certain types of DNA damage. Much more useful have been bacteria lacking DNA polymerase I (Pol$^-$)[26], or deficient in genetic recombination (Rec$^-$)[27]. These tests are usually conducted on the surface of agar plates but are also amenable to rather more quantitative procedures with liquid-phase treatment[28,29].

Another way of revealing the existence of DNA damage is to look for the repair that it usually initiates and this is the basis of a very useful test developed by Stich and his colleagues. It depends on estimating the amount of DNA synthesis involved in repair by measuring autoradiographically the uptake of tritiated thymine during the period immediately following exposure to the test chemical. The method has the advantage that it can be used with cultured human skin fibroblasts. To prevent normal DNA synthesis the cells are kept in an arginine deficient medium for 3 d before exposure.

In a report on 64 substances tested, Han and Stich[30] found that all directly acting carcinogens elicited unscheduled DNA synthesis whereas no repair synthesis was observed after treatment with 16 non-carcinogens. Most carcinogens known to need metabolic activation gave negative results although a few were active after prolonged exposure to high concentrations. More recent results[31] indicate that metabolic activation systems can be incorporated in this assay and make possible the detection of procarcinogens.

Mutation induction

Perhaps the most sensitive assay for DNA damage is the induction of mutations in bacteria, particularly if the bacterial strain carries a mutation rendering it unable to excise damage from DNA (Uvr$^-$). Excision-proficient strains should always be included in any assay, however, because certain agents able to cross-link DNA are only mutagenic in such strains[32]; presumably the mutational event occurs as an error during excision-initiated repair. Reversion to prototrophy is generally regarded as the most sensitive type of assay and the methodology has recently been reviewed[33,34]. *Escherichia coli* WP2 is a tryptophan-requiring strain that responds to mutagens causing base-pair substitution mutations at both adenine : thymine and guanine : cytosine sites.

A more complete set of tester strains has been developed in *Salmonella typhimurium* by Ames and collaborators[21]. Individual strains respond to base-pair substitution mutagens or to compounds causing various types of frameshift. The permeability of these *Salmonella* strains to some chemicals has been increased by the incorporation of a cell wall mutation ("deep rough")[22]. From recent data one can calculate that these strains are capable of detecting mutagenic activity of between 61%[35] and 90% (D. Anderson, unpublished) of known carcinogens. In an attempt to detect the "false negatives" obtained with the deep rough strains, Ames's group developed a fourth generation set of strains containing the drug resistance plasmid pKM101[23]. As suggested by MacPhee certain plasmids confer a mutator activity on their host cell which becomes more sensitive to many mutagens and carcinogens[36]. The ability of these plasmid-containing strains to detect carcinogens as mutagens is impressive (see below). A word of caution is in order, however, since although the mechanism by which the plasmids act is still unknown, it is clear that they convert into mutations damage which would not be mutagenic in a normal cell. They may even act as amplifying systems and produce mutations at sites where no damage exists. The value of such strains lies in the correlation they show with carcinogenicity but there is at least a theoretical possibility of real "false positives".

It is possible to improve sensitivity by altering the methodology, and a modified fluctuation test has been proposed which achieves between ten and one hundredfold greater sensitivity than the conventional assay without the need for plasmid-containing strains[37]. There is also the possibility of developing a single tester strain that can be used to detect many different types of mutational events[38]. Although bacterial screening systems have proved very useful, there is still scope for further improvement.

As well as the bacterial tests that have now been extensively studied, a large number of other techniques can be used to detect DNA damaging activity and may perform a useful supplementary role, probing ambiguous or suspect results and characterising more fully the nature of the genetic damage. One may, for example, study the induction of mutations in cultured mammalian cells[39–41]. Mammalian cells may also be used for cytogenetic study of visible chromosome aberrations[42]. Recently developed staining techniques for demonstrating sister-chromatid exchanges show a greatly enhanced sensitivity[43] and their role in screening has been recently discussed[44]. Sister-chromatid exchanges may now be detected in spermatogonia[45] and bone marrow cells[46] following exposure of the whole animal to carcinogens. It is already clear, however, that although the induction of sister-chromatid exchanges is a very sensitive response to some carcinogens it occurs hardly at all with others[43]. Other eukaryotic mutation systems include fungi, yeasts and insects. All of these have their own advantages and disadvantages.

Malignant transformation in cultured cells

Rather than develop a model system depending on mutation or DNA repair, others have worked towards a screening method by which transformation to the malignant condition could be brought about and detected in cell culture. The only really valid criterion for malignant transformation is the ability of a cell to produce a tumour when inoculated into an appropriate host. There are, nevertheless, several secondary criteria (discussed by Freeman and Huebner[47], of which the most commonly used is the ability of cells to grow into clones in soft agar or, in the case of fibroblast cultures, to produce clones of piled-up cells when growing on a solid surface.

Most human cancers are carcinomas which are derived from epithelial cells Relatively little work has, however, been done on the transformation *in vitro* of epithelial cells. Such cells are usually obtained from rat liver and are not easy to retain in culture in the differentiated state. Nevertheless they have been successfully transformed by 4-nitroquinoline-1-oxide[48], aflatoxin B_1, *N*-hydroxy-2-acetylaminofluorene, and 7,12-dimethylbenz[*a*]anthracene[49], dimethylnitrosamine and *N*-methyl-*N'*-nitro-*N*-nitrosoguanidine[50], and *N*-acetoxy-2-acetylaminofluorene[51]. Epithelial cells transformed *in vitro* usually show no altered morphology although they may grow in soft agar.

Work on fibroblasts is considerably more advanced. Fibroblasts, when transformed, give rise to sarcomas, responsible for a minority of human malignant disease. They show, nevertheless, great promise as the basis of a potential screening system for chemical carcinogens. As with bacterial mutation systems, it has often been found necessary to supplement the fibroblast's relatively poor ability to metabolise carcinogens into their active form. This has been achieved, either by cocultivation with other cells capable of carrying out metabolic activation[58], or by isolating the cells from hamster embryos after treatment of the pregnant mother[53].

Much of the work on transformation has been carried out with treatment of mass cultures often for long periods of time and has been subject to some criticism. Transformation has, however, been reported with short treatments followed by cloning[54] and this would seem to be a better approach to adopt in future. A noteworthy feature of much work with both fibroblast and epithelial systems has been the high spontaneous rates of transformation, sometimes considerably higher than one would expect for a gene mutation. Many workers regard this as the result of the artificial environment in which the cells are cultured, and have looked (often successfully) for conditions in which the spontaneous rate is lower. Nevertheless it is likely that the rate of transformation *in vivo* is higher than has been thought and that the body is normally able to deal effectively with the aberrant cells. If this were true the role of DNA-damaging carcinogens might be seen as increasing the already high spontaneous rate and thus overloading the ability of the natural defences of the body to cope with malignant cells.

Most of the work on transformation *in vitro* has concentrated on the development of systems that can be used as models for the study of carcinogenesis (for reviews see refs 55 and 56). To the uninvolved observer, a certain amount of contradiction and inconsistency is apparent. There is, notwithstanding, an impression that this technique may soon be a valued constituent of the battery of techniques for detecting carcinogenic and DNA-damaging substances. Two recent studies have shown successful prediction of carcinogenicity almost as good as that of the bacterial mutagenicity tests[57,14].

Validation

Some of the test procedures described above are very sensitive, but how good are they as predictors of carcinogenicity? Recent reports have presented[35] and discussed[58] carcinogenicity and mutagenicity data obtained for more than 300 chemicals. All the results come from the use of *Salmonella* strains developed by Ames. Where negative mutation results had been obtained with now-obsolete strains, the test was repeated with the latest plasmid-containing strains. Testing was done both without metabolic activation and (generally) with microsomes embedded together with the bacteria in soft agar. With some nitrosamines incubation was carried out with microsomes before plating. A summary of the results is given in Table 1. Since publication, one of the non-carcinogens, 5-hydroxy 2-acetylamino-fluorene, has been shown to be mutagenic because of the presence of an impurity and has now been reclassified as non-mutagenic.

It can be seen that of 179 compounds whose carcinogenic effect on animals is well documented, 157 (or 87.7%) were detected as positive in the bacterial test. This level of confirmation was obtained with essentially all types of compound and was also evident for the small group of compounds for which evidence exists for carcinogenicity in man. The proportion of compounds believed to be non-carcinogenic which gave negative results in the mutagenicity tests was also high: 101 out of 117 (or 86.3%). These included 46 common biochemicals all of which were negative. Seventeen compounds were tested for which carcinogenicity data are uncertain; of these 11 were positive in the mutagenicity test.

The apparent "false" positives and negatives have been discussed elsewhere[58]. It is apparent that many of the latter damage DNA or cause mutations in other systems, or have mutagenic metabolites. Furthermore there is a very obvious limitation to the use of liver microsomes for activation: some chemicals may need reductive activation, or may be metabolised by the gut flora, by organs other than the liver, or by cell components other than microsomes. Indeed it is surprising that liver microsomes are as effective as they seem to be; certainly the method is capable of further improvement.

When one considers the "false" positives, that is the supposed non-carcinogens that register as mutagenic with bacteria, certain difficulties become apparent. Any correla-

Table 1 Correlation of animal carcinogenicity and bacterial mutagenicity with and without metabolic activation (from McCann *et al.*[35])

Group of compounds	Carcinogens detected as bacterial mutagens	Non-carcinogens not mutagenic to bacteria	Compounds of uncertain carcinogenicity detected as mutagens
A Aromatic amines etc.	23/25	10/12	5/7

tion is only as good as the confidence one has in the reliability of both parameters. Whereas positive and negative mutagenicity results can be both unambiguous and reproducible, the same is not true of carcinogenicity results where, as will be discussed below, there are several factors which could result in a failure to detect relatively weak carcinogens. As discussed by McCann and Ames[58], there is good reason to believe that many of the "false" positive chemicals will eventually be shown to be carcinogenic. This has already happened with the food additive furyl furamide which had been used for many years in Japan and had given negative results in two carcinogenicity trials[59]. After positive results had been obtained in *Bacillus subtilis* and *E coli* systems for detecting DNA damage, it was re-examined and shown to produce a low but significant yield for tumours when given to foetal and young mice[60]. There is also the real possibility that some of the "false" negatives are genuine, that metabolism *in vivo* is different from that with isolated microsome preparations. Only further studies in depth can resolve this.

It is worth analysing the data of McCann *et al.*, further to see whether there is any particular type of mutational event (as detected by the *Salmonella*) that is correlated with carcinogenicity. It has been postulated[61] that carcinogenicity is associated with the ability to produce specific types of frameshift mutation This hypothesis does not hold up in any general application. As can be seen from Table 2, whereas most members of some groups of carcinogens (for example, amoratic amines, polycyclic aromatics and nitroaromatics) gave rise to both frameshifts and base-pair substitutions, others (for example, esters, epoxides and carbamates, nitrosamines, miscellaneous nitrogen compounds) gave rise exclusively to base-pair substitutions. There was no group that gave rise exclusively to frameshifts. Taken together, 45.2% of mutagenic carcinogens gave rise solely to base-pair substitutions, 14.8% solely to frameshifts, and 40% gave rise to both.

Rosenkranz (cited in ref. 62) using a Pol⁻ strain of *E. coli* together with the *Salmonella* .set without plasmids, has obtained results as encouraging as those of McCann *et al.* with the plasmid-containing salmonellas. Of about 100 compounds tested, 85% of the known carcinogens were detected (91% of direct acting carcinogens, 72% of procarcinogens). The proportion of non-carcinogens detected as positive was rather high, 30%, but the figure is not comparable with the lower value derived from the data of McCann *et al.*[35] since it did not include the 46 common laboratory biochemicals tested by the latter workers, none of which was positive.

A comparison of the efficiency of various microbial systems for detecting DNA damaging agents has been carried out by Shirasu *et al.*[63]. They found that the hypersensitivity of repair-deficient bacteria (Rec⁻ *B. subtilis*) was the most sensitive. Of 166 pesticides studied, 23 were positive in the Rec-assay (carried out without microsomal activation) Of the 143 negatives, none proved to be positive when tested with *E. coli* or *Salmonella* reverse mutation systems. Of the 23 positives 9 were positive in reverse mutation systems, and of these 9, 1 was not detected by the *E. coli* strains and 1 by the *Salmonella* strains. As far as base-pair substitution mutations are concerned, the non-plasmid *E. coli* strains were found to be preferable to the non-plasmid *Salmonella* strains at least with some groups such as nitrofurans. With other groups such as the organic phosphates a similar small proportion of mutagens was missed by both *S. typhimurium* and *E. coli* strains[64].

The only study in which a single laboratory has compared a number of different tests for predicting carcinogenicity appears to have been carried out by the Central Toxicology Laboratory of ICI (D. Anderson *et al.*, unpublished). The preliminary results with 120 chemicals point to the value of the bacterial mutation tests when metabolic activation is incorporated. The carcinogenicity, or non-carcinogenicity was accurately predicted for 90% of the chemicals by this test. Cell transformation *in vitro* came close with 83% accuracy. Rather less accurate was degranulation of endoplasmic reticulum, 72%, and morphological changes following subcutaneous implantation, 70% correctly predicted Sebaceous gland suppression[65] was good for polycyclic hydrocarbons (90%) but little better than random for other substances (52–62%). Tetrazolium reduction in mouse skin was also poor (62% overall). The authors conclude that some of these rapid tests are capable of distinguishing between carcinogens and non-carcinogens with sufficient accuracy to enable them to be used for selecting potential carcinogens. They also make the point that figures for successful prediction must be treated with

Table 2 Number of carcinogens detected as bacterial mutagens (with or without metabolic activation) classified as to type of mutation induced.

	Base-pair substitutions only	Frameshifts only	Both base-pair substitution and frameshift mutations

Key for chemical groups as for Table 1 (From McCann *et al.*[35])

some caution since they can be manipulated within wide limits by the choice of substances tested. As their substances include a large number of non-carcinogenic chemicals closely related to known carcinogens they feel that their results give a reasonably good indication of the likely value of the tests in practice.

DNA damage and human cancer

The correlation between mutagenicity and carcinogenicity is satisfying to those who believe in the somatic mutation theory of cancer[66] and distressing to those who do not[67]. I think the correlation can be more correctly described as being between DNA damaging ability and carcinogenicity. Gene mutation is but one consequence of DNA damage; others such as chromosomal structural rearrangements, virus integration and excision, and changes in gene expression, may well be important in the carcinogenic process. Non-genetic effects are also probably involved.

One could argue that detecting DNA damage is merely a very sensitive way of detecting electrophilic reagents, and that the actual target(s) may well be in other molecules as well as or instead of DNA. This is quite possible; but there is other evidence strongly implicating DNA damage as the rate-limiting step in many carcinogenic processes.

In man, for example, mutations in five complementation groups are known to reduce or abolish the ability of cells to remove ultraviolet photoproducts from their DNA[68]. In all cases they enormously increase sensitivity to the carcinogenic effect of sunlight (resulting in the hereditary disease xeroderma pigmentosum). A further mutation causing the same symptoms has been shown to be associated with a deficiency in another DNA repair pathway active on newly synthesised DNA[69]. Another human mutation responsible for the disease ataxia telangiectasia has been shown to block repair of ionising radiation damage[70] and also results in proneness to develop malignant disease[71]. Thus, the human data strengthen our confidence in the reality of the observed correlation between DNA damaging ability and carcinogenicity. It must be emphasised, however, that even an empirical "litmus paper test", with no known theoretical basis, which gave an 80 to 90% predictiveness for carcinogenicity would be a powerful tool in the screening of chemicals for human toxicity.

The place of tests with mammals

No single test is adequate for a first-tier (sub-mammalian) screen; most authorities agree that a battery of tests must be used as false negatives may occur with any one test. The results of these tests would be used to assign priorities for further testing using mammalian systems. At one extreme, a substance with no apparent effect on sub-mammalian systems might be given a priority so low that no further tests would be considered unless a large human population exposure were to occur or be contemplated. At the other extreme a strongly active substance might well be regarded as hazardous without further testing if the population exposed were small. If it were, say, an industrial chemical, then production workers and users ought to treat it as if it were a known toxic agent or carcinogen, at least until such time as it became possible to carry out full scale animal tests.

The greatest problem in testing for carcinogenicity or mutagenicity with mammals is the insensitivity of most of the tests. This has led, for example, to difficulties in validating microbial carcinogenicity screening systems since many of the "false" positives obtained with these are based on animal experiments that may be inadequate[58]. There have been, and still are, too many carcinogenicity tests with 20 or 30 animals per group.

Provided that the number of animals in each group is kept small, even a large increase in the frequency of neoplasms can fail to be statistically significant and enable a conclusion of "non-carcinogenic" to be drawn (see for example a recent study on the carcinogenicity of hair dyes[72]). As long ago as 1954, Barnes and Denz[73] pointed out that to detect with a probability of 0.01 an effect occurring in 1% of the animals, one would need a group of at least 455 animals. If the effect also occurred spontaneously then the number of animals per group would have to be increased manyfold. Today, notwithstanding, carcinogenicity experiments with 100 animals per group are often regarded as "good" and those with 200 animals per group are extremely rare. But although "kilomouse" experiments are theoretically attractive there may be little to be gained from them in practice. Logistical problems dictate that such experiments be phased over many weeks and involve slightly varying conditions. "Spontaneous" rates of tumour occurrence unfortunately often vary in time and place, perhaps reflecting slight differences in diet, and it is often difficult to run an adequate control group. Errors in handling are also more likely in very large experiments.

Whereas a significant reproducible positive result in a mammalian test may be taken as indicating the existence of a potential hazard for man, a negative result taken should not necessarily be taken to indicate the absence of hazard, particularly if the human population to be exposed is very large, and the number of animals in the test small. We may take some comfort where the disparity in dose between the animal and human exposure is great. This is not always so. Anaesthetic gases, for example, are given to an appreciable fraction of the population in Western society at concentrations which are not far from the lethal level. One might well feel that a negative result in a screening test with a few dozen mice would be of little value.

It can be seen that mammalian tests are not wholly appropriate for the validation of sub-mammalian tests, and it is perhaps remarkable that they should show such good agreement Validation of one type of test against another must not blind one to the real objective, which is to predict long term toxic effects in man. There are few proven human carcinogens and most of these can be detected by both mammalian and sub-mammalian tests. In man, carcinogens tend to be recognised only when the tumour is of a rare type and there is a sufficient cluster of cases to enable association with a particular occupation to be seen by an alert clinician. Genetic effects in man are even harder to detect retrospectively. There are several examples of somatic chromosome damage in lymphocytes of persons exposed to known mutagenic and carcinogenic substances (for example, vinyl chloride[74], ozone[75], benzene[76], toluene[77], cadmium[78,79] and methyl mercury[80]. Recent evidence for the possibility of dominant lethal damage in man by vinyl chloride (P. Infante, unpublished) and anaesthetic gases[81] is ominous but needs closer examination.

Ultimately quantitative risk assessments must be attempted, for we must face the unpalatable fact that man will almost certainly have to be exposed to some carcinogens and mutagens whose benefits cannot be dispensed with and others which it is impracticable to eliminate from the environment. Risk evaluations at the present time almost always require information which is not available, such as the nature of the dose–effect response at low doses. Nevertheless, approaches must be found that will lead eventually to risk–benefit evaluations based less on guesswork and more upon knowledge. In the meantime the use of short term tests would enable potentially carcinogenic substances to be identified among the many thousands for which long term animal testing cannot at present be contemplated. This in turn would open the door to provisional regulatory action to minimise human exposure. Taken seriously and on a large enough scale, there is good reason to believe that this approach would ultimately result in a reduction in the incidence of chemically induced cancer.

I thank Drs D. Anderson, E. J. Ashby, P. A. Lefèvre, E. Longstaff, I. F. H. Purchase, J. A. Styles and F. R. Westwood of ICI Central Toxicology Laboratory, and Dr Bruce Ames for allowing me to see their data before publication.

Isolation and N-terminal amino acid sequence of membrane-bound human HLA-A and HLA-B antigens

John Bridgen
Laboratory of Molecular Biology, Hills Road, Cambridge CB2 2QH, UK
David Snary & Michael J. Crumpton*
National Institute for Medical Research, Mill Hill, London NW7 1AA, UK
Colin Barnstable, Peter Goodfellow & Walter F. Bodmer
Genetics Laboratory, Department of Biochemistry, University of Oxford, Oxford OX1 3QU, UK

Membrane-bound HLA-A and HLA-B antigens have been extensively purified in good yield. The sequences of the N-terminal 16 amino acids have been determined using about 1 nmol of protein eluted from polyacrylamide gel after electrophoresis in sodium dodecyl sulphate.

THE major histocompatibility region of man (HLA) occupies at least 1 to 2 recombination units on chromosome 6 and probably contains a large number of genes involved in diverse immune and possibly other functions[1]. The gene products that have so far been identified with this region comprise various

Table 1 Purification of HLA-A2 antigen from BRI 8 cells

Fraction	Protein (% recovery)	HLA-A2 activity (% recovery)	Degree of purification of HLA-A2
BRI 8 cells	100	100	1
Plasma membrane	1.0	46	45
Na deoxycholate-soluble	0.95	38.8	41
Gel-filtration	0.26	36.1	136
Glycoprotein	0.026	32.5	1,240

BRI 8 cells grown by Searle Diagnostic were used as the antigen source. The cells (about 80% viable; 5×10^7 cells ml^{-1} of 10 mM Tris-HCl buffer-0.15 M NaCl, *p*H 7.4) were broken using the Stansted cell disruptor (model A0 612; disrupting valve 516; air pressure applied to disrupting valve 12 p.s.i.). The plasma membrane fraction was separated, as previously described[15], by differential centrifugation and discontinuous sucrose density gradient centrifugation (36% (w/v) against 25 (w/v) sucrose as judged by refractive index measurement), and was washed by homogenising twice in 10 mM Tris–HCl buffer, *p*H 7.3. The membrane (4 mg of protein ml^{-1}) was solubilised at 0 °C by addition of sodium deoxycholate (10% (w/v) in 10 mM Tris–HCl buffer, *p*H 8.2) to a final concentration of 2% and was immediately centrifuged at 100,000*g* for 1 h. The supernatant (7 ml) was subject to gel filtration on a column (55 × 5.0 cm) of Ultragel AcA 34 (LKB Instruments) in 0.5% deoxycholate at a flow rate of 70 ml h^{-1}. The fractions corresponding to the A and B antigens (see Fig. 2, ref. 16) were pooled (about 60 ml) and added to a column (16 × 1.6 cm) of *L. culinaris* lectin–Sepharose 4B (1 mg of lectin per ml of gel sediment) in 0.5% Na deoxycholate. The bound glycoproteins were subsequently eluted with 2% methyl-α-D-mannopyranoside in 0.5% Na deoxycholate (see Fig. 2, ref. 15). The results shown were obtained using lectin isolated from lentils purchased from Whitworths. Similar results have been consistently obtained using lentils from this source, but a few batches of lentils from other sources have given lectin that bound a portion of the HLA-A and -B activities only. A, B and C antigen activities were measured by inhibition of cytotoxicity[18] using antisera which have been previously described[16]. The purification of the A1, B8 and B13 antigens was similar to that illustrated for the A2 antigen.

cell surface antigenic determinants as well as the C2 (ref. 2), C′3 proactivator[3], C4 (ref. 4) and C8 (ref. 5) components of complement. The most extensively characterised cell surface antigens are those of the three highly polymorphic segregant series of the HLA-A, -B and -C loci [1,6]. The HLA region also codes for a set of serological specificities, called Ia (immune-associated) antigens[7]. These probably represent the products of several loci (refs 7–10 and J. G. Bodmer, personal communication), some of which show a close association with the HLA-D locus that controls the expression of the major determinants involved in mixed lymphocyte responses[11]. The functions of these loci have yet to be delineated but they seem to be connected with the ability to generate immune responses against foreign substances[12], tumours and virus-infected cells[13] as well as other phenomena related to cell–cell recognition. A complete understanding of the biological relevance of these gene products relies ultimately upon their isolation in a highly purified state and the determination of their structure.

The choice of tissue for the isolation and subsequent structural studies of the HLA-A, -B, -C and Ia antigens has been dictated by several considerations. HLA-A, -B and probably -C locus antigens are expressed on the surface of almost all cell types except erythrocytes. Ia antigens, however, show a much more restricted tissue distribution, being found on B lymphocytes, monocytes and possibly some endothelial and epithelial cells, but not T lymphocytes and fibroblasts[14]. Our choice of cultured human lymphoblastoid B cell lines as the tissue source has not only enabled the simultaneous purification of the HLA-A, -B and Ia antigens, but has also permitted the purification of antigen of restricted and reproducible specificity in amounts sufficient for structural studies.

The selection of purification procedure was influenced by various factors such as HLA-A and -B; Ia antigens are integral plasma membrane glycoproteins and being insoluble in conventional aqueous solvents need to be solubilised in detergents[15]. In particular, the fractionation techniques were selected because they gave a high yield coupled with considerable discrimination. This was necessary because of the high cost of cultured cells and because the HLA-A and -B antigens comprise <0.1% of the total cell protein. The separation of the cell surface (plasma) membrane was chosen as the initial purification step in preference to either the preparation of a crude membrane fraction or the extraction of whole cells with detergent. The reasons for choosing this approach were that it greatly reduced the possibility of degradation and of the generation of structural artefacts, such as dimerisation through disulphide interchange[16], as well as giving a significant degree of purification. The success of this approach depends, however, on being able to prepare highly purified plasma membrane in good yield (preferably better than 50%).

The structural analysis was facilitated by the availability of a new microtechnique for determining N-terminal amino acid sequences (J. B. unpublished). This technique combines high sensitivity with the considerable resolving power of SDS–polyacrylamide gel electrophoresis, and is applicable to less than 1 nmol of protein eluted from polyacrylamide gels.

Purification of HLA-A and -B antigens

The purification of HLA-A2 antigen from the lymphoblastoid B cell line BRI 8 (HLA specificities: A1, A2, B8, B13 and CW2) is summarised in Table 1. The A1, B8 and B13 antigens co-fractionated with the A2 antigen and were purified to

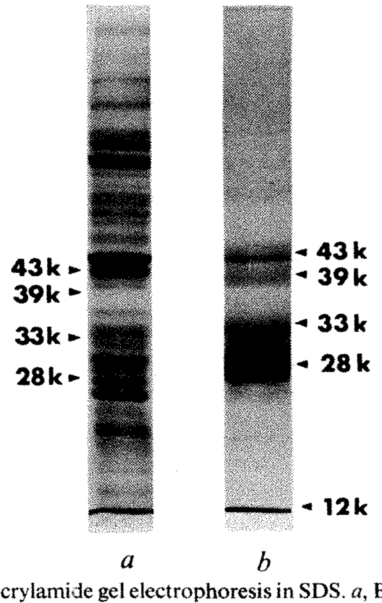

Fig. 1 Polyacrylamide gel electrophoresis in SDS. *a*, BRI 8 plasma membrane; *b*, glycoprotein fraction (Table 1). Electrophoresis was performed in 10% (w/v) polyacrylamide slab gels using the Tris–glycine discontinuous buffer system of Laemmli[21]. Samples were dissolved by heating at 100 °C for 2 min in 2% (w/v) SDS, 0.1 M dithiothreitol, 10% (w/v) glycerol and 0.02% bromophenol blue. Gels were stained with 0.1% Coomassie blue in methanol, water, acetic acid (41:52:7, by volume) and destained with the same solvent. Molecular weights were calculated by reference to the mobilities of standard proteins: transferrin (78,000), bovine serum albumin (69,000), ovalbumin (45,000), immunoglobulin L chain (25,000), soybean trypsin inhibitor (21,000) and cytochrome *c* (12,500). In the above conditions β_2-microglobulin was coincident with the bromophenol blue band at the gel front. The presence in the glycoprotein fraction of a band with a molecular weight of 12,000 was revealed by using 12% (w/v) polyacrylamide gels.

similar extents. The yield and purity of the purified plasma membrane is intimately related to the method used for cellular disruption[17]. In this study the cells were broken using a commercial model of the cell-disrupting pump (Stansted Fluid Power). The plasma membrane was separated by differential centrifugation and discontinuous sucrose density gradient centrifugation[16] and was washed by homogenising under hypotonic conditions. Under these conditions yields of purified plasma membrane in excess of 50% are often achieved. The purified membrane was solubilised in sodium deoxycholate before purifying the A and B antigens by conventional separation techniques such as gel filtration and affinity chromatography. Sodium deoxycholate (final concentration 2%) proved superior as the solubilising agent to other weakly anionic detergents such as Ammonyx Lo, and the non-ionic detergents Nonidet P-40 and Triton X-100. It was selected in preference to the strongly ionic detergents such as SDS because, in contrast to these detergents, it had a negligible effect on antigenicity and did not interfere with specific molecular interactions[19]. The solubilised membrane was fractionated by gel filtration on Ultragel AcA 34 in sodium deoxycholate. Ultragel AcA 34 was used in preference to Sephadex G-200 and Bio-Gel P-150 because of its superior column stability and flow rate. The glycoproteins of the gel filtration fraction were next separated from the non-glycosylated proteins by selective adsorption to *Lens culinaris* lectin–Sepharose 4B in sodium deoxycholate and subsequent elution with methyl-α-D-mannopyranoside. Gel filtration was selected to precede affinity chromatography since adsorption to and elution from *L. culinaris* lectin–Sepharose provided a very convenient concentration step. As shown in Table 1 the overall purification procedure gave a 1,240-fold increase in the specific activity of the A2 antigen relative to BRI 8 cells with a recovery of 33%.

The CW2 antigenic activity of BRI 8 cells co-fractionated with the A and B antigens up to the gel filtration step but was not detected in the glycoprotein fraction. The results suggest that it was not adsorbed to *L. culinaris* lectin–Sepharose due either to a different carbohydrate composition (compare the behaviour of rat thymocyte Thy-1 antigen in ref. 20) or to the absence of carbohydrate.

The glycoprotein fraction was recovered by precipitation at −20 °C for 48 h with 66% (v/v) ethanol in which deoxycholate and sugar are soluble, and was analysed by polyacrylamide gel electrophoresis in SDS. Figure 1 shows that the glycoprotein fraction has a very restricted polypeptide composition compared with that of the original plasma membrane preparation. Only five bands whose position corresponded to molecular weights of 43,000, 39,000, 33,000, 28,000 and 12,000 were detected. Various results indicate that the 43,000 and 12,000 molecular weight chains are derived from the HLA-A and -B antigens. This conclusion is based on the reports[22–24] that the A and B antigens are composed of two non-covalently-bound polypeptide chains with molecular weights of about 43,000 and 12,000, and that the smaller chain is identical with β_2-microglobulin. It is also supported by the observation that only these two chains were specifically adsorbed when the glycoprotein fraction (Table 1) was added to a column of antibody to β_2-microglobulin attached to Sepharose and were subsequently eluted by 3 M potassium thiocyanate in 0.5% sodium deoxycholate, *p*H 8.5 (ref. 25).

The remaining polypeptide chains are of unknown function, although the following evidence suggests that those of molecular weight 33,000 and 28,000 represent the human counterparts of the mouse Ia antigens. First, the polypeptide chains of mouse Ia antigens possess similar molecular weights of about 30,000 (ref. 26). Second, the Ia allogeneic activity expressed on the surface of BRI 8 cells co-fractionated with the A and B antigens on gel filtration and *L. culinaris* lectin–Sepharose[27]. Third,

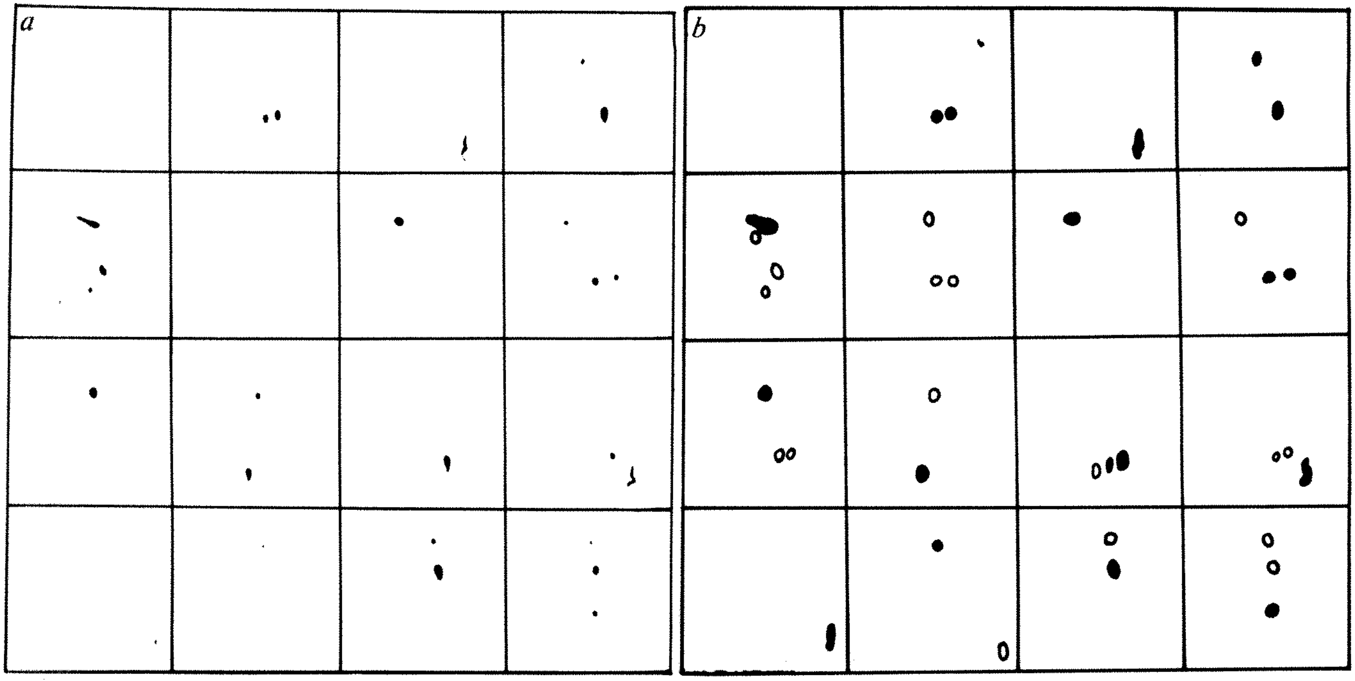

Fig. 2 *a*, Autoradiograph of thin-layer chromatograms resulting from sequence analysis of the 12,000 molecular weight polypeptide chain recovered after polyacrylamide gel electrophoresis of the glycoprotein fraction in sodium dodecylsulphate (SDS). Phenylthiohydantoin–amino acids were separated on 5×5 cm polyamide layers by 2-dimensional chromatography[33] using 5-*bis* [2(5-*tert*-butylbenzoxazolyl)]-thiophene (0.1%) as fluorescent indicator[34]. The phenylthiohydantoins of histidine and arginine were resolved by redeveloping the chromatograms in the direction of the first solvent using *n*-propanol, formic acid (20:1, v/v). Radioactive spots were revealed by autoradiography using Kodak 'Auto-process' X-ray film and were identified relative to the unlabelled internal markers that were visualised under ultraviolet light. The autoradiograph was exposed for 60 h. The variation in intensity of the spots at successive steps partly reflects the varied amount of cyclised derivatives analysed. The residues are arranged in sequence from left to right. The sequence shown begins at residue no. 2 since residue no. 1 remains attached to the resin and is not identified. The blank at residue no. 6 indicates that no information is available on this residue although, by implication, it is lysine which would remain attached to the resin and consequently would not be identified. The origin of the background of faint spots that increased in intensity with increase in the number of steps is not clear. This background was independent of the protein analysed (see Fig. 3). In the above conditions phenylthiohydantoin–glutamine (residues nos 2 and 8) and phenylthiohydantoin–serine (residue no. 11) give two spots due to decomposition (see also Fig. 3, residues nos 2 and 4). *b*, Drawing of autoradiograph. The filled-in areas correspond to the spot(s) due to the amino acid(s) identified at each step. The open circles represent spots which were detected but which were judged to be due either to overlap from the previous residue(s) or to background.

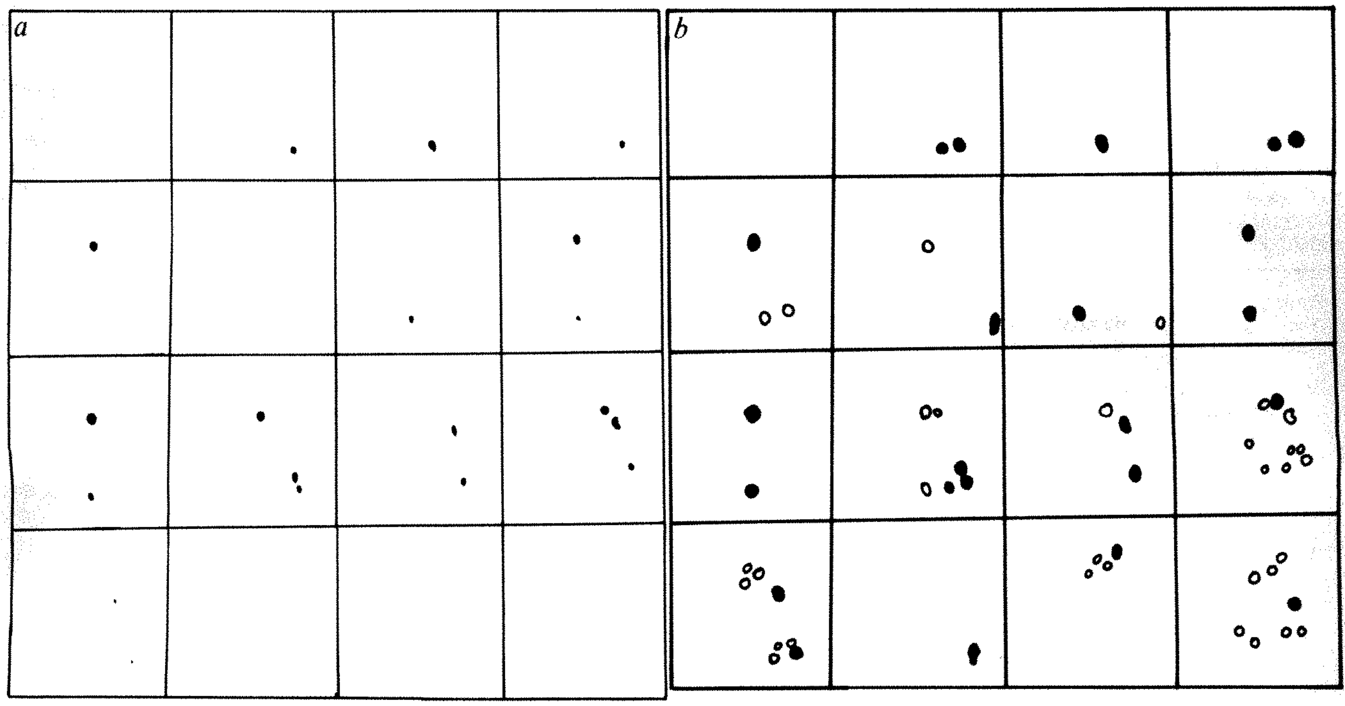

Fig. 3 *a*, Autoradiograph of thin-layer chromatograms resulting from sequence analysis of the 43,000 molecular weight polypeptide chain recovered after polyacrylamide gel electrophoresis of the glycoprotein fraction in SDS. Experimental details were as described in the legend to Fig. 2 except that the autoradiograph of the first twelve residues was exposed for 60 h. and that of residues nos 13–16 for 120 h. The sequence determined from the data is shown in Table 2. *b*, See Fig. 2*b* legend.

antisera produced in rabbits and mice against the 33,000 and 28,000 polypeptide chains of the glycoprotein fraction had many of the properties expected for heterologous anti-Ia sera[27,28]. Thus, they reacted preferentially with human B-lymphoblastoid cell lines, purified peripheral blood B lymphocytes and monocytes, but not T cell lines, peripheral T cells, fibroblasts and erythrocytes. The immunoglobulin fraction of the antisera and its Fab fragments also blocked human mixed lymphocyte cultures[27].

Amino acid sequence of A and B antigens

The N-terminal amino acid sequences of the 43,000 and 12,000 molecular weight chains were determined by the high-sensitivity solid-phase procedure[29] using material extracted from the polyacrylamide gel (J. B., unpublished). As soluble foreign material occluded in the gel, and the glycine of the Laemmli buffer system[21] interfered with the subsequent procedure, the following separation method was adopted. The polyacrylamide gel (15%, w/v) slab (8×7×0.15 cm) was washed overnight in 0.17 M Tris-HCl buffer, *p*H 8.15, containing 0.1% SDS, reinserted into the gel apparatus and cut to size before casting a 3% (w/v) polyacrylamide stacking gel on to the top edge. The glycoprotein fraction (400 µl containing 100 µg of A and B antigens in 2% SDS, 0.1 M dithiothreitol, 10% glycerol and 0.02% bromophenol blue) was added and electrophoresis was carried out using the Trisborate discontinuous buffer system of Neville[30]. The edges of the gel were detached, stained for 30 min with 0.1% Coomassie blue and destained for 90 min in methanol–water–acetic acid (41:52:7, by volume) followed by 10 min in 7% (v/v) acetic acid. Using the stained strips as guides the regions corresponding to the 43,000 and 12,000 molecular weight chains were removed, cut into 2-mm cubes and extracted overnight by shaking at 37 °C in 1 ml of 0.04 M *N,N'*-dimethyl-*N*-allylamine buffer in pyridine, water (3:2, v/v) (Pierce Chemical Co.) containing 0.1% SDS and buffered to *p*H 9.5 with trifluoroacetic acid. The eluted protein was covalently attached to *N*-(2-aminoethyl)-3-aminopropyl glass (120 Å pore diameter) that had been activated by treatment with phenylene diisothiocyanate in dimethylformamide[29].

Amino acid sequences were determined on an Anachem SPA 1200 automatic solid-phase sequencer using high specific activity ^{35}S-labelled phenylisothiocyanate (2% (v/v) solution in acetonitrile containing 1 mCi ml^{-1}; Radiochemical Centre, Amersham) for the coupling. The reaction was completed by a second coupling with unlabelled phenylisothiocyanate (5% solution in acetonitrile). The cleaved thiazolinones were collected into tubes containing all the conventional phenylthiohydantoin-amino acids (1 nmol of each in 10 µg of ethyl acetate) to act as carrier and markers. The thiazolinones were converted to thiohydantoins by heating at 80 °C for 10 min in 200 µl of 20% aqueous heptafluorobutyric acid. The phenylthiohydantoin-amino acids were extracted with ethyl acetate and were identified by two-dimensional thin-layer chromatography.

The applicability of the method is evident from Fig. 2 which shows the autoradiograph obtained for the N-terminal 16 residues of the 12,000 molecular weight polypeptide chain of the glycoprotein fraction. The amino acid sequence is clearly discernible as:

1 5 10
— -Gln–Arg–Thr–Pro– — -Ile–Gln–Val–Tyr–
15
Ser–Arg–His–Pro–Ala–Glu–

This sequence is, apart from the blanks at residues no. 1 and 6, identical with that determined previously by Cunningham and coworkers[33] using conventional techniques, for the N-terminus of human urinary β_2-microglobulin.

The autoradiograph of the N-terminal 16 residues of the 43,000 molecular weight polypeptide chain is shown in Fig. 3. The identification of the spots was straightforward apart from that of residue 3 which could not be related to any known phenylthiohydantoin-amino acid; this residue was also not identified by conventional sequencing methods (Table 2). One possible explanation is that this residue is substituted by carbohydrate. The interpretation of the sequence was less straightforward than that of β_2-microglobulin. This was due to the heterogeneity of the 43,000 molecular weight polypeptide

Table 2 Comparison of N-terminal sequences

Protein	Antigenic specificity	Residue no. 1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16
43,000 molecular weight chain	A1, A2								Phe	Phe	Thr	Ala		Ala			
			Ser		Ser	Met	Arg	Tyr					Val		Arg	Pro	Gly
	B8, B13								Tyr	Tyr	Ser	Ser		Ser			
Papain-solubilised	A2	Gly	Ser		Ser	Met	Arg	Tyr	Phe	Phe	Thr	Ser	Val	Ser			Gly
34,000 molecular							Arg										
weight chain	B7, B12	Gly	Ser		Ser	Met	Val	Tyr	Phe	Tyr	Thr	Ala	Val	Ser	Arg	Pro	Gly

Amino acid sequence of the N-terminal 16 residues of the 43,000 molecular weight polypeptide chain compared with the N-terminal sequences of the larger polypeptide chains of the papain-solubilised HLA-A2, and mixed HLA-B7 and HLA-B12 antigens reported by Terhorst and coworkers[34]. The A and B antigenic specificities of the 43,000 molecular weight polypeptide chain are based on the known specificities of the glycoprotein fraction and on reports that the allogeneic A and B specificities are associated exclusively with a polypeptide of this molecular weight[24]. The sequence of the 43,000 molecular weight chain is based on the results shown in Fig. 3 and begins at residue 2 since residue 1 remains attached to the resin and is not identified. Blank positions indicate that no information is available on the residue at this point. Residue 3 of the 43,000 molecular weight chain gave a detectable spot on thin-layer chromatography (Fig. 3) but this spot could not be identified with any known phenylthiohydantoin-amino acid.

chain (A and B antigens with polymorphic specificities) and to the need to differentiate between the presence of more than one residue at a particular position and overlap from the previous residue, especially when the same amino acid occurred at adjacent positions (residues 8 and 9, for example). Overlap was judged on the basis of experience gained from the analysis of unique sequences (J. B., unpublished). The most probable sequences are presented in Table 2 together with the N-terminal sequence of the papain-solubilised HLA-A2, and mixed HLA-B7 and HLA-B12 antigens determined using conventional methods[34].

It is apparent that the solid-phase sequencing method has much to recommend it. It is applicable to < 1 nmol of protein eluted from polyacrylamide gel after electrophoresis in SDS and is rapid (1 cycle (residue) h^{-1}). As with conventional methods the extent of sequence attainable is limited by decrease in yield, increase in background and overlap from the previous residue. The sequence of β_2-microglobulin could have been extended beyond residue 16, but little further information was obtainable from the 43,000 molecular weight chain.

Polymorphism

Clearly the N-terminal sequence of the 43,000 molecular weight polypeptide chain represents the sum of the sequences of the papain-solubilised A and B antigens, apart from some slight variation at residues 6, 8, 10 and 13. The marked similarity between the N-terminal sequences indicates that papain must cleave the polypeptide chain towards the C-terminus and that the N-terminus is exposed on the cell surface. This means that the portion of the polypeptide chain inserted into the lipid bilayer of the membrane is close to the C-terminus, although it does not rule out the possibility that the actual C-terminus is exposed on the inner or outer face of the membrane. The same conclusions have been drawn for the homologous mouse H-2 antigens[35]. Similarly, it is apparent from the identity of the N-terminal sequences of the membrane-associated and urinary β_2-microglobulins, that if the urinary material has been degraded then cleavage must have occurred towards the C-terminus.

If, as seems likely, the HLA-C locus products were not present in the material used for sequence analysis, then several interesting points emerge from the data in Table 2. First, at least 10 of the N-terminal 16 residues are apparently constant for both the A and B locus antigens, and all of the amino acid variations correspond to single nucleotide base changes. This restricted heterogeneity is consistent with the suggestion that the A and B genes arose from a common ancestral gene by duplication[1,36]. In this context the sequence of the C antigen will be particularly informative since, although its molecular size and shape in deoxycholate resemble more closely those of the A than the B antigens (ref. 16 and C.B., W.F.B., M.J.C., and D.S., unpublished), the strong linkage disequilibrium between the C and B locus determinants suggest that the C gene(s) arose from the B gene(s)[36]. Second, the sequence differences at residues 9 and 11 can be interpreted as A and B locus differences, but those at residues 6, 10 and 13 cannot be interpreted in this way. Thus, the A1, A2, B8 and B13 antigens collectively have arginine at residue 6 whereas the B7 and B12 antigens have arginine and valine. This variation is consistent with the suggestion that the B7 or B12 antigen differs from other A and B antigens in having valine at this position. Similarly, the serine and alanine residues at positions 10 and 13 respectively may represent changes that are directly related to the A1, B8 and/or B13 specificities. If these and other changes do contribute to the serologically defined polymorphism then each allele may represent the sum of a number of changes at positions remote from each other in the unfolded polypeptide chain. The present data are too limited to provide an answer to this proposal or to the postulated common origins of histocompatibility antigens and immunoglobulins[1,37]. Definitive answers will, however, emerge as more sequence data are accumulated. It will, in general, be interesting to delineate the evolutionary relationships between the products of the different alleles and loci of the HLA system, and, in particular, to see whether cross-reacting antigens (A2 and A28, for example) have some common changes that distinguish them from all other antigens as well as additional changes that distinguish them from each other.

Cell-cycle, cell-shape mutant with features of the G_0 state

M. St. J. Crane & D. B. Thomas

Immunology and Experimental Biology Division, National Institute for Medical Research, Mill Hill, London NW7 1AA, UK

A cold-sensitive mutant of CHO cells has features of "reverse transformation" at the non-permissive temperature of 33 °C. Cells accumulate at G_1 with altered morphology and remain viable and quiescent for more than 40 d. Such cultures are synchronised by a temperature shift back to the permissive 39 °C.

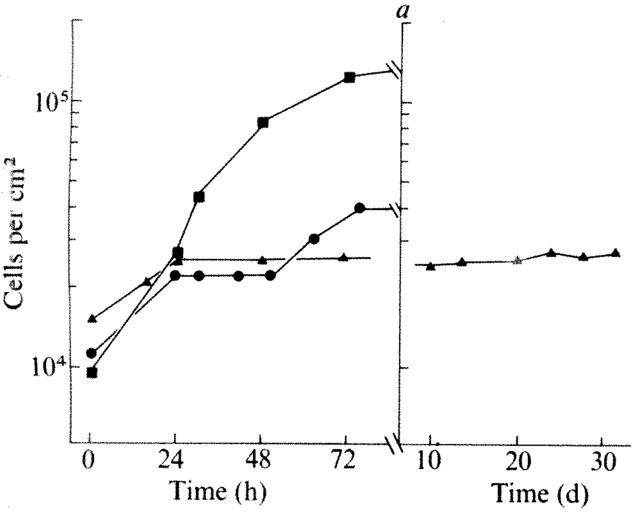
THE selection and isolation of temperature-sensitive mutants of eukaryotic cells defective at a specific phase of the cell division cycle (cdc) provides an attractive model for the study of growth control *in vitro*. Hartwell *et al.*[1,2] have pioneered this approach by isolating 150 *cdc* mutants of the yeast *Saccharomyces cerevisiae* defective in the initiation of DNA synthesis, DNA replication, bud emergence and cytokinesis. More recently, heat-sensitive mutants of mammalian cells have been described including variants defective at metaphase[3], G_1[4–6], DNA replication[7,8], and cytokinesis[9]. Most mammalian *cdc* mutants, however, are disappointing in two important respects: rapid loss of viability at the non-permissive temperature and failure to be synchronised by a temperature shift.

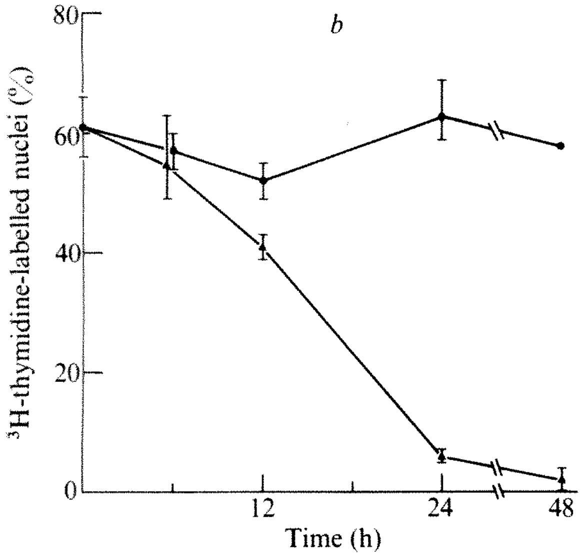
We describe here a cold-sensitive mutant of Chinese hamster ovary cells, clone cs4-D3 initially isolated and provided by Dr Rosann Farber, which has unique features at the non-permissive temperature (33 °C). First, cells accumulate at the G_1 interval and remain viable and quiescent indefinitely. So far, we have maintained the mutant at 33 °C for 40 d without loss of viability or potential for growth at the permissive 39 °C. Second, there is a cell-cycle-dependent change in morphology: cells are transformed from their normal "fibroblast-like" shape to a round, epithelial form. This shape change can be reversed at the non-permissive temperature by addition of dibutyryl (db) cyclic AMP. Finally, cells can be synchronised by a temperature shift (39 °C to 33 °C to 39 °C) and then undergo several rounds of synchronous division. This is the first report of a cell cycle mutant reversibly arrested in a quiescent state. Clone cs4-D3 may provide a useful *in vitro* model for the study of the induction of DNA synthesis and the relationship between cell morphology and cell growth.

Selection and isolation of cold-sensitive mutants were as reported before[10]. Briefly, CHO cells were mutagenised with ethyl methane sulphonate and selected at 33 °C by the BUdR–visible light technique. Stock cultures of cs4-D3 were maintained at 39 °C as monolayers (Falcon culture flasks; 25 cm^2 surface area) in Eagle's basal diploid medium—10% foetal calf serum supplemented with non-essential amino acids and passaged twice weekly at a split ratio of 1:20. Experimental cultures were established in disposable glass scintillation vials (surface area 4.3 cm^2; 2–4×10^4 cells) and maintained at a constant temperature (± 0.1 °C) in a water bath fitted with a contact thermometer (Grant Instruments, Cambridge Ltd).

When exponentially growing cultures of cs4-D3 were stepped down to the non-permissive temperature (39–33 °C) cell numbers increased by about one population doubling to plateau values (Fig. 1*a*; division index, 0.6–0.9) and the number of ^{3}H-thymidine-labelled nuclei fell to base line (<2% at 48 h; Fig. 1*b*), while samples established at a similar density from stationary cultures increased no further in cell number. In contrast, growth of wild-type CHO cells was only marginally reduced at 33 °C (Fig. 1*c*). cs4-D3 remained viable at the non-permissive temperature for a minimum of 40 d, as determined by dye exclusion tests (>95%) and showed no sign of detachment from the glass surface. Moreover, cells retained the ability to grow at the permissive temperature (see below and Fig. 3). In long term experiments (>5 d) this was routinely tested at 2-d intervals by "stepping up" replicate cultures and measuring increases in cell number. The mutant was "leaky" at the slightly higher temperature of 34 °C and, after an initial growth plateau, there was a further increase in cell number by 72 h (Fig. 1*a*). This emphasised a need for strict temperature control (33±0.1 °C) of all experimental cultures.

Change in morphology was perhaps the most striking feature of this mutant. At the permissive temperature, cs4-D3 resembled a fibroblast with an elongate, spindle shape and smooth surface membrane (Fig. 2*a*) whereas at 33 °C most cells (>90% by 24 h) were round and epithelial-like with a rough surface membrane bearing knob-like protrusions (Fig. 2*b*). Moreover, the epithelial form assumed by the mutant at the non-permissive temperature could be reversed by the addition of db cyclic AMP (Fig. 2*c*). This is shown in the following experiment. Coverslip cultures were incubated for 48 h at 33 °C (>90% epithelial-like cells at 48 h) before treatment with 0.5 mM or 1 mM dibutyryl cyclic AMP. Thereafter, replicate samples were fixed at intervals in 0.1% (v/v) glutaraldehyde and examined by light microscopy (Table 1). At 6 h, cells treated with db cyclic AMP (Fig. 2*c*) could not be distinguished from corresponding controls maintained at 39 °C. Cells had reverted to an elongate, spindle shape and showed no further sign of surface "blebbing". In spite of this





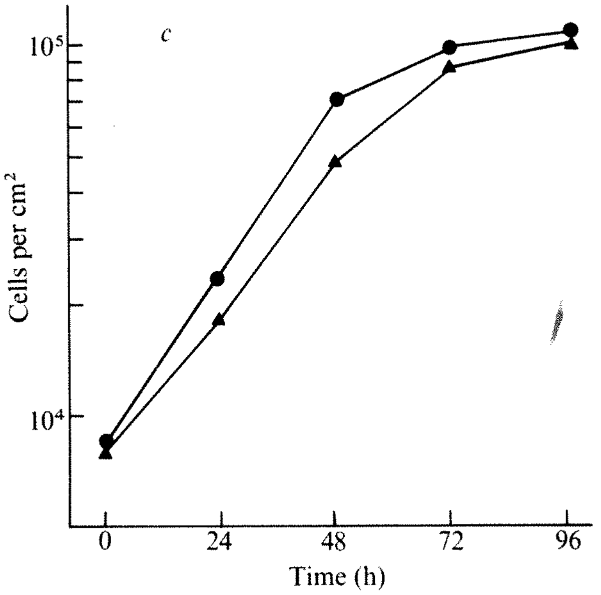


Fig. 1 *a*, Growth of cs4-D3 at different temperatures. Cells (0.5–1 × 10^4; 2 ml) were seeded in screw-top glass vials (surface area, 4.3 cm^2) and incubated for 48 h at 39 °C for exponential growth. Cells were then cultured further at 39 °C (■), 34 °C ± 0.1 °C (●) or 33 °C ± 0.1 °C (▲). At the times indicated, samples were trypsinised and cell numbers were estimated in a Coulter counter, model 2B1; values represent the mean for five determinations. *b*, Percentage of nuclei labelled with ^{3}H-thymidine at 39 °C (●) or 33 °C (▲). Coverslip cultures of cs4-D3, in the exponential phase of growth, were incubated at either the permissive 39 °C or the non-permissive 33 °C. At the times indicated, triplicate samples were exposed to 6-^{3}H-thymidine (0.1 μCi ml^{-1}; 5 Ci mmol^{-1}) for 30 min, washed in EBD medium, and fixed for 10 min in acetic acid–ethanol (1:3, v/v). Air-dried coverslips were mounted on microscope slides and autoradiographs were prepared using Ilford K5 nuclear emulsion. *c*, Growth of wild-type CHO cells, determined as in (*a*) at 33 °C (▲) and 39 °C (●).

dramatic change in shape there was no effect of db cyclic AMP (0.05–1 mM for 24–72 h) on growth and cells remained quiescent at 33 °C.

Recent studies by time-lapse cinematography (our work with J. B. Clarke, in preparation) indicate that change in shape is dependent on the cell cycle: at 33 °C cells maintained their fibroblast appearance throughout the intermitotic period, rounded up for mitosis and divided but then failed to spread out on the substratum. They remained in this rounded shape indefinitely but were still firmly attached to the culture flask. Conversely, when cells were returned to 39 °C, normal morphology was only observed after mitosis. This delay of one cell cycle may be of interest from a development aspect.

A similar change of shape in the reverse direction, from epithelial to fibroblast, has been described by Puck *et al.*[11–13] for a variant of wild-type CHO cells, clone K1, after treatment with db cyclic AMP or certain prostaglandins. An interesting comparison can be made between their published illustrations and those presented here: wild-type CHO-K1 has an identical shape to the mutant at the non-permissive temperature (Fig. 2*b*) while dibutyryl cyclic AMP-treated cultures of CHO-K1 resemble cs4-D3 at 39 °C (Fig. 2*a*). Puck *et al.* have introduced the term "reverse transformation"[13] to describe the sum of effects induced by db cyclic AMP: change in shape, ordered arrangement of confluent cultures, decreased agglutination with plant lectins, increased synthesis of collagen—the changes mirrored those found in neoplastic transformation. Cell morphology, however, was unrelated to growth behaviour and the generation time in either epithelial or fibroblast form was similar. Clone cs4-D3 illustrates a further distinction between cell shape and cell growth by resembling a normal fibroblast at 39 °C and a virally transformed cell at 33 °C.

The effects of db cyclic AMP on cell shape are antagonised by Colcemid and vinblastine, thereby implicating microtubules; this has received some support from ultrastructural studies[14]. We have no evidence for the involvement of microtubules in the cold-labile defect, and preliminary analysis by electron microscopy showed no significant difference in microtubule content of cs4-D3 between 33 and 39 °C.

To determine whether the mutant was defective in a specific phase of the division cycle, "labelled-mitoses

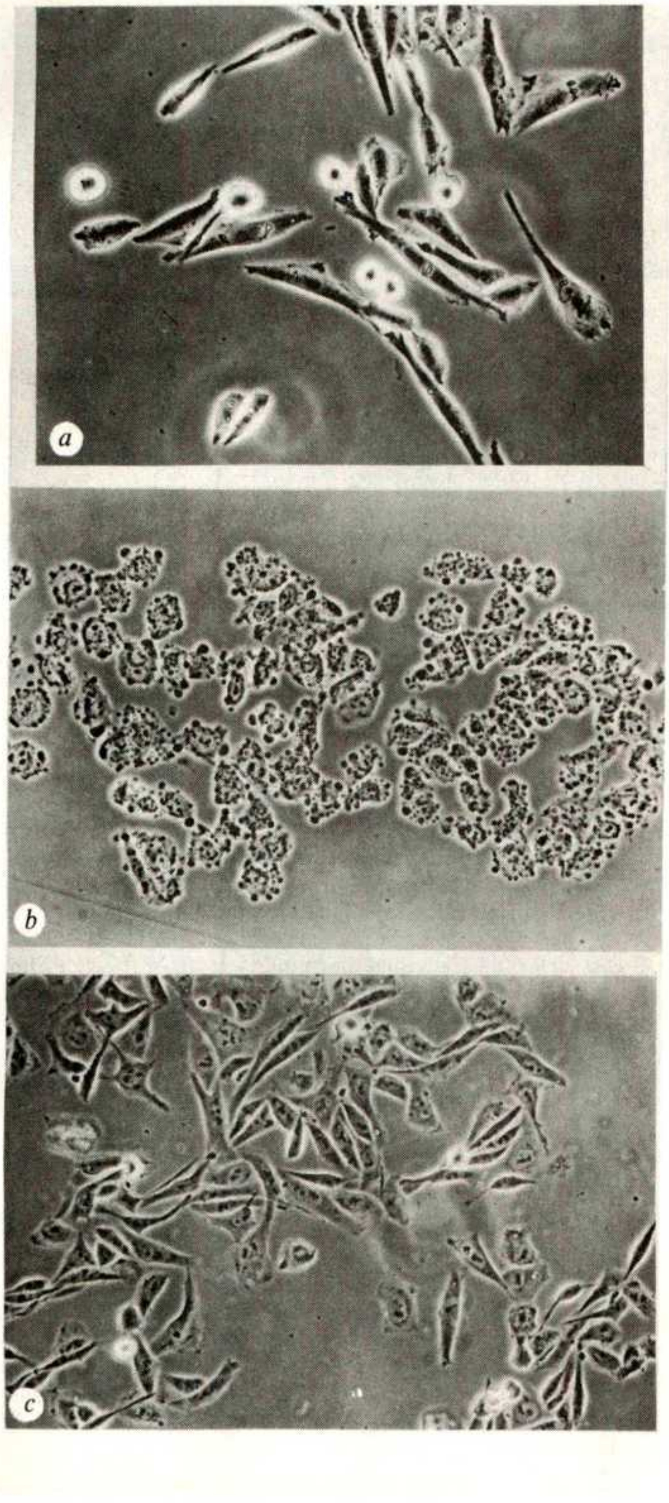
Table 1 Effect of db cyclic AMP on cell shape

Time (h)	0.5 mM db cyclic AMP Epithelial (%)	0.5 mM db cyclic AMP Fibroblast (%)	1.0 mM db cyclic AMP Epithelial (%)	1.0 mM db cyclic AMP Fibroblast (%)
0	93	7	93	7
2	70	30	26	74
4	66	34	20	80
8	35	65	16	84

Coverslip cultures which had been maintained at the non-permissive 33 °C for 48 h were treated with 0.5 mM or 1.0 mM db cyclic AMP. Coverslips were removed at intervals, washed, fixed in 0.1% glutaraldehyde and examined under light microscopy. A minimum of 200 cells was scored for morphology.

curves" were estimated at 39 °C and 33 °C. In this procedure[15], replicate cultures are pulse labelled with ^{3}H-thymidine and the subsequent rate of accumulation of ^{3}H-labelled mitoses is measured, thereby providing an estimate of cell cycle traverse from S to G_2 to M. In spite of an initial low rate at 33 °C, all cells labelled with ^{3}H-thymidine reached mitosis by 10 h (Table 2). These results together with the data in Fig. 1*b* indicate that cs4-D3 is arrested at the G_1 interval. Furthermore, analysis of DNA distribution profiles by flow microfluorometry in a fluorescence activated cell sorter (D. B. T. and D. F. Capellaro, unpublished results) have shown that after 24 h at 33 °C most cells (>75%) had the 2c DNA content characteristic of G_1.

Fig. 2 Morphology of cs4-D3 at the permissive temperature, 39 °C (*a*); at the non-permissive temperature, 33 °C for 48 h (*b*), and at 33 °C for 48 h followed by a 6-h treatment with 1 mM db cyclic AMP (*c*) (see Table 1).



So far no mammalian *cdc* mutant has been synchronised after a temperature block and, in most instances, mutants show loss of viability by 24 h at the non-permissive temperature. In contrast, the cold-labile defect of clone cs4-D3 was reversible at all times tested and cells could be synchronised by a temperature shift (Fig. 3). Cell cultures (100–300 replicate culture vials) in the exponential phase of growth were stepped down to 33 °C for 24 h (Fig. 3*a*) or 48 h (Fig. 3*b*) or 96 h (Fig. 3*c*) or 240 h (Fig. 3*d*) and then returned to 39 °C; samples were monitored at different times for cell number and incorporation of ^{3}H-thymidine into DNA. There was a constant and reproducible lag period followed by a three- to fivefold increase in ^{3}H-thymidine incorporation and a plateau increase in cell number by 30 h (Fig. 3*a*–*c*). Optimum synchrony was obtained after 48 h at 33 °C (or 72 h, data not shown) and, at the first division, increase in cell number was often equal to a theoretical doubling (division index, 0.8–1.0) with respectable synchrony for at least two cell cycles. The length of the prereplicative lag before the onset of DNA synthesis was related to time spent at the non-permissive temperature. After 24 h (Fig. 3*a*) or 48 h (Fig. 3*b*) at 33 °C an 8-h lag preceded the onset of DNA synthesis; this was extended to 12 h in cultures maintained at 33 °C for 240 h (Fig. 3*d*). It should be emphasised that an extended delay of 12 h does not indicate loss of viability or growth potential; autoradiography studies showed that most cells could

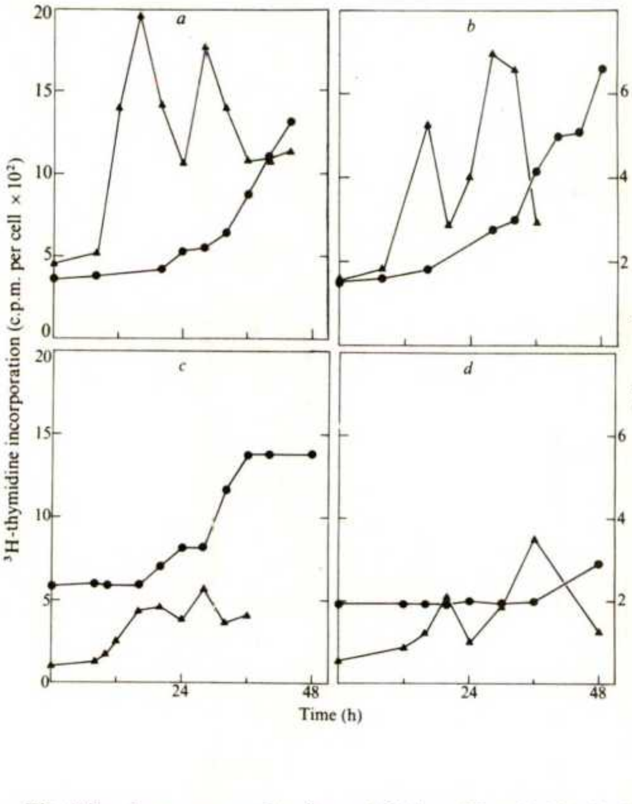


Fig. 3 Synchronous growth, after a shift from 33 to 39 °C, of cell cultures maintained for 24 h (*a*); 48 h (*b*); 96 h (*c*); and 240 h (*d*) at the non-permissive 33 °C. Each experimental group represents a minimum of 100 cultures established in glass scintillation vials. At various times, quintuplicate samples were exposed to 6-^{3}H-thymidine (1 µCi ml^{-1}; 5 Ci mmol^{-1}) for 30 min, washed with EBD medium containing 2 mM thymidine and then ice-cold trichloroacetic acid (10% w/v) and counted directly in a Beckman liquid scintillation counter. Values for cell number represent a mean for three estimations. Cell number (●), ^{3}H-thymidine incorporation into DNA (▲).

Table 2 Estimation of ^{3}H-thymidine-labelled mitoses

Time (h)	Labelled mitoses (%)	
	39 °C	33 °C
0	0	0
2	49	10
3	79	55
4	95	98
5	99	98
6	100	100

Coverslip cultures were established in Leighton tubes (10^4 cells; 2 ml), incubated at 39 °C for 48 h to ensure exponential growth, and then pulse labelled with 6-^{3}H-thymidine (0.2 μCi ml^{-1}; 5 Ci mmol^{-1}) for 30 min. Cells were washed twice with EBD medium and recultured at either 39 or 33 °C. Coverslips were removed at intervals, then fixed in acetic acid–ethanol (1:3; v/v) and autoradiographs were prepared using Ilford nuclear emulsion.

be induced to divide (> 90% at 96 h) after 240 h at 33 °C.

A similar kinetic response has been reported by Augenlicht and Baserga for serum stimulation of quiescent human fibroblasts[16]. The length of the prereplicative phase varied according to the duration of the quiescent period. Initially, a prereplicative period of 8 h was observed before DNA synthesis and this extended to 14 h if cultures were deprived of serum for a further 4 d. Augenlicht and Baserga argued that "cells initially arrest in G_1, subsequently pass into G_0, and continue to go deeper into G_0, as they remain quiescent".

cs4-D3 is remarkable in that, at 33 °C, it expresses the phenotype of normal, differentiated cells—a viable quiescent state. *In vivo* many tissues exist for an indefinite time in a quiescent, G_0 state[17–19], and can be induced to divide by the appropriate stimulus; for example, interaction with antigen for lymphocytes[20] or partial hepatectomy for liver cells[21]. It is doubtful whether the equivalent G_0 state occurs *in vitro*[22,23]. Proliferation of normal fibroblast cultures declines at confluency and cells accumulate at the G_1 (postmitotic) interval of the cell cycle; they can be induced to divide further either by reculture or addition of fresh serum, but stationary cultures lose cloning efficiency after some days. Even this limited period of quiescence is absent on transformation; tumour cells continue to proliferate at low serum concentrations, albeit at a reduced rate, "piling-up" at confluency and eventually detaching from the substratum. This is particularly true for wild-type CHO: cells round up at confluency and detach from the substratum while stationary cultures, induced by isoleucine starvation[24], show rapid loss of cloning efficiency. It might even be argued that G_0 is a feature of the differentiated state, *in vivo*.

We suggest that cs4-D3 reverts at the non-permissive temperature from a neoplastic phenotype of the parental CHO cell to that of a "normal" cell. Phenotypic differences between normal and transformed cells have been described but many were found to be a function of cell division. An important difference between normal and transformed cells might be ability of the former to maintain a viable, quiescent state.

Search for X-ray emission from Nova Cygni 1975

WE have used the SAS-3 X-ray observatory to search for X rays from Nova Cygni 1975 before, during and after the time of optical maximum (1975 August 30–31). No X rays were detected at any time over the spectral range 0.1–50 keV, and from these negative results we can place very low upper limits on the ratio of X-ray to optical luminosity.

The light curve and spectrum of Nova Cygni 1975 show it to be a fast common nova of spectral type around A2 near maximum. (All optical and infrared data are taken from ref. 1.) Figure 1*a* shows the optical growth and decay of the nova, and Fig. 1*b* the 3σ upper limits we obtained for the X-ray intensity (1.5–15 keV) during three periods spanning the optical maximum. The X-ray measurements were taken with argon-filled proportional counters behind large angle slat collimators centred on the satellite *y* axis. During the observations, the spacecraft was being manoeuvred to bring Nova Cygni 1975 closer to the equatorial plane of the satellite, gradually increasing the effective observing area to the maximum of 154 cm^2 and thus lowering the successive upper limits. The upper limits were computed assuming a flat X-ray spectrum.

Two photographic magnitudes[2], $m_{pv} > 9.6$ on August 28.059 and $m_{pv} = 7.5$ on August 29.052, show that the nova was already brightening rapidly at the time of our first observations, August 28.5–28.9. At the time of the second observations, August 29.9–30.5, the visual magnitude was $m_v = 2.0$, implying an intensity of 5.95×10^{-21} erg cm^{-2} s^{-1} Hz^{-1} at 5,500 Å, which gives $[I_x(\sim 4\ \text{keV})]/I_{op}$ (5,500 Å)] $< 2.8 \times 10^{-8}$. We have converted these intensity ratios to luminosity ratios. With little interstellar reddening[3,4] an A2 star has a bolometric correction of −0.3 (ref. 5) giving $m_{bol} = 1.7$ for August 29.9–30.5 and, thus, $L_{op} \simeq L_{bol} = 5.2 \times 10^{-6}$ erg cm^{-2} s^{-1}. This yields $[L_x(1.5\text{–}15\ \text{keV})]/L_{op} < 1.0 \times 10^{-4}$. Bolometric corrections derived for normal stars may, however, not be applicable to nova shells of similar temperatures. This introduces an uncertainty factor of at least 2 into the optical luminosity.

On September 1.64, repeated scans were made back and forth over the object for several minutes, giving a large increase in sensitivity. In addition, Nova Cygni 1975 was now in the circular fields of view of the thin-window, low energy (LE) proportional counters (20 cm^2, 2.9° FWHM) and the xenon-filled proportional counters (101 cm^2, 1.7° FWHM) so that upper limits are available for energies from 0.1 to 50 keV. These are shown in Fig. 2.

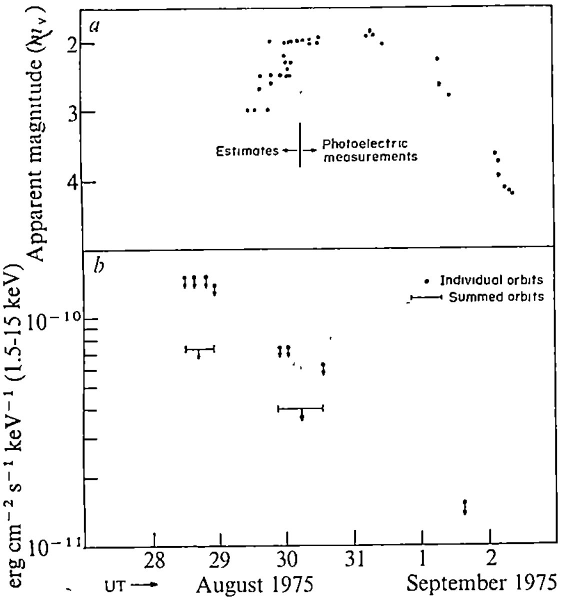

Fig. 1 *a*, Optical light curve for Nova Cygni 1975. *b*, 3σ upper limits on 1.5–15 keV X rays from Nova Cygni 1975 observed by SAS-3 at various times before, during and after optical maximum.

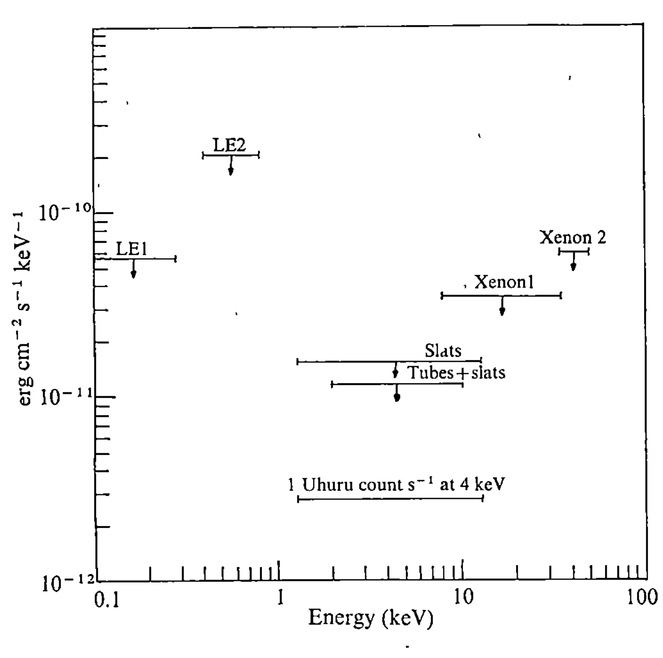
The optical luminosity decreased to $m_v = 3.1$ between our second and third set of observations, when we find $[L_x(1.5\text{–}15\ \text{keV})]/L_{op} < 8.1\times10^{-5}$. In the energy range 0.1–0.3 keV interstellar absorption is important. From the rapid decline after maximum, de Vaucouleurs[6] estimated a distance of ~1.6 kpc. At this distance, even Sco X-1 is essentially invisible at 0.1 keV. Our upper limit of the X-ray energy received at the Earth is

$$[L_x(0.1\text{–}0.3\ \text{keV})]/L_{op} < 5.4\times10^{-6}$$

but this ratio may be higher at the source.

Porton and Clark[7] reported an upper limit of 10 mJy to radio emission at 10.6 GHz near optical maximum. Hjellming[8] reported an upper limit of 4 mJy at 8,085 MHz on September 3, soon after maximum. Three weeks later, at the same frequency, he detected weak emission (6±2 mJy), which had increased to 14 mJy by October 9.

Fig. 2 3σ upper limits to X-ray emission from Nova Cygni 1975 over the spectral range 0.1–50 keV (September 1.64). For comparison, we show the flux level corresponding to 1 Uhuru count per second, adjusted to a 1.5–15-keV energy range.



We continued SAS-3 observations of Nova Cygni 1975 after the optical maximum. The next time that Nova Cygni 1975 was close to the equatorial plane of the satellite was September 20–24, three weeks after optical maximum. No X rays were seen with the following 3σ upper limits (1.5–15 keV)

September 20.46–20.58, 4.4×10^{-11} erg cm^{-2} s^{-1} keV^{-1}

September 22.92, 5.4×10^{-11} erg cm^{-2} s^{-1} keV^{-1}

September 24.9, 4.4×10^{-11} erg cm^{-2} s^{-1} keV^{-1}

The intrinsic properties of Nova Cygni 1975 such as peak luminosity, ejection velocity and mass are typical for common novae (see ref. 3). Because of its high relative optical brightness, we have been able to place a strong upper limit on its X-ray to optical luminosity, $L_x(1.5\text{–}15\ \text{keV})/L_o < 10^{-4}$. For comparison with known X-ray sources, we note that L_x/L_o ranges from 10^{-8} in the quiescent Sun to 10^3 in Sco X-1. Nova Cygni 1975 is the first common optical nova for which a significant X-ray upper limit has been set. What is the significance of this result?

Common optical nova outbursts are thought to result from the explosive burning and ejection of material from a white dwarf which has accreted matter over an extended period from its binary companion star[9,10]. Since the explosion itself is caused by nuclear reactions at the base of a surface layer of material accreted on to the white dwarf, there is no *a priori* reason to believe that significant X-ray emission should directly accompany the explosive event. The spectral types of Nova Cygni 1975 and other common novae near maximum light[11] indicate effective temperatures of $\sim10^4$ K. Such temperatures are entirely consistent with the small upper limit on L_x/L_o that we have obtained.

Brecher and Morrison[12], however, suggested that the subsequent shock heating of any present circumstellar material by the ejected nova shell would give rise to X-ray emission with a flux which depends mainly on the density of the surrounding gas. Wallerstein[13] has also proposed that such a model could account in a natural way for the existence of coronal emission lines seen in novae (which in any case imply the presence of material heated to several million K, a temperature much higher than the colour temperature and absorption line temperature of the nova shell itself). In this picture, only high mass exchange systems (for example, recurrent novae such as WZ Sge, RS Oph, T CrB) should produce X-ray emission at presently detectable levels. If Nova Cygni 1975 is a virgin nova, exploding for the first time (L. Jacchia, private communication), its low mass exchange rate ($dM/dt < 10^{-9}M_\odot$ yr^{-1}) would imply that any associated X-ray emission would be undetectable by present techniques.

Mass loss in early stages of stellar evolution

IT has been known for some time that stars lose mass between their birth on the main sequence and their death as white dwarfs (or as neutron stars or black holes for more massive stars), and the existence of the solar wind shows that not all the mass loss occurs in a last gasp to form a planetary nebula. Mass loss has also been observed in O–B stars (see refs 1–3), and in red giants[4], but the mass loss rates observed in these stages do not seem sufficient to explain all of the mass loss required for stars to become white dwarfs. The question has always been at what stages and in what manner this excess mass was lost. Suggestions have tended to favour helium flashes for stars with $M < 2.25M_{\odot}$ and possibly double shell instability flashes for stars in the range $2.25M_{\odot} < M < 8M_{\odot}$. Although it is possible that a significant mass is lost during these stages, there is no quantitative support for this speculation, and in particular none for the helium flash. We show here that there is increasing evidence for substantial mass loss during the immediate post-main sequence stages when the star is moving from the main sequence to the giant branch on the Hertzsprung–Russell diagram.

Mass loss at these early stages of evolution may have implications on the subsequent evolution of the star and the amount of nuclearly processed material that is ejected into the interstellar medium. Although possible loopholes can be found in all of the arguments we present, it is interesting to note that the naive interpretation of each of these independent arguments points to the same conclusion.

Mäckel *et al.*[5] have estimated the mass of Arcturus to be in the range $0.1M_{\odot} < M < 0.6M_{\odot}$. Arcturus belongs to a moving group with an age comparable to the oldest galactic clusters[6], and to have evolved to a red giant; its original mass was $1–2M_{\odot}$. Thus it seems that Arcturus has lost a significant amount of mass.

The well known post-main sequence relation between luminosity and mass of the core (hydrogen-depleted interior) can be used to help determine the evolutionary stage of Arcturus. Calculations by Kozlowski and Paczynski[7] show that for a star to have the luminosity of Arcturus, $\log (L/L_{\odot}) = 2.36$, the mass must be $\geqslant 0.3M_{\odot}$ to be moving along the giant branch, and $\geqslant 0.9M_{\odot}$ to be burning its helium core. Similar calculations by Paczynski[8] indicate that a core mass of $\sim 0.52M_{\odot}$ is necessary to give this luminosity if the star is on the asymptotic branch. The luminosity is too low for Arcturus to have begun double shell flashes, and the normal composition, except for the CNO isotopes, indicates that there has been no mixing of the products of helium burning with surface layers as one may expect during double shell flashes. If the mass determined by Mäckel *et al.* is accurate, it seems most likely that Arcturus is on the giant branch and has not yet reached a helium flash point.

The composition may give additional clues as to when Arcturus lost its mass. The $^{12}C/^{13}C$ ratio has been shown[9] to be 7.2 ± 1.5. If the $^{12}C/^{13}C$ ratio was initially solar (90), one would expect that simple deep convective mixing while on the giant branch reduces the $^{12}C/^{13}C$ ratio from 90 to 25. Varying the initial $^{12}C/^{13}C$ ratio to 40 changes the final ratio to 20. No further change in the $^{12}C/^{13}C$ ratio is expected until the star begins double shell flashes, after which the $^{12}C/^{13}C$ ratio rapidly goes to 3.5 (ref. 10). If Arcturus has not yet reached the double flash stage, it is difficult to understand its low $^{12}C/^{13}C$ ratio. Dearborn *et al.*[11] have shown that the $^{12}C/^{13}C$ ratio can be reduced below 10 if half the mass of the star was ejected before material reaching the surface convection zone had been CNO processed. (Even if Mäckel *et al.*'s mass estimate should prove low, it is possible that Arcturus started near $2M_{\odot}$ and now has a mass of $1M_{\odot}$.)

The low $^{12}C/^{13}C$ ratios observed in most K and M giants[12–15] are consistent with these stars losing 20–30% of their mass before the convection zone reaches the ^{13}C-rich layer in the star. Some giants have $^{12}C/^{13}C$ ratios in the range 20–30, but are still consistent with some mass loss (10%) at an early stage of post-main sequence evolution. Arcturus cannot be dismissed as a pathological case. Dziembowski and Kozlowski[16] have shown that AI Velorum stars are theoretically consistent only with hydrogen shell burning stars of masses $0.2–0.25M_{\odot}$. Stars of such low mass will never ignite helium. Kinematic studies of these stars imply progenitors with masses $\sim 1M_{\odot}$. Also the masses of the helium core of stars reaching the giant branch would be larger than those of the AI Velorum stars for $M > 2M_{\odot}$. Since the AI Velorum stars were not able to ignite helium, they must have lost mass immediately after depleting the hydrogen in their cores.

It has been known for many years that to form a white dwarf from a star more massive than $1.4M_{\odot}$, substantial mass must be lost. From the number of white dwarfs in the Hyades and from supernovae statistics, it seems that stars up to at least 3 or $4M_{\odot}$ lose sufficient mass to become white dwarfs. A white dwarf of $\sim 0.7M_{\odot}$ has been observed in the Pleiades (see ref. 17) which have a main sequence turnoff mass of $\sim 6M_{\odot}$. Integration of Reimers' formula[4] for mass loss from a $7M_{\odot}$ star implies a mass loss of only $1.6M_{\odot}$ before carbon detonation (most of this is lost at extremely late stages). Estimates of mass ejected in planetary nebulae[18] do not give sufficient leeway to make up this difference, and a $7M_{\odot}$ star must lose another $5M_{\odot}$ somewhere along its evolutionary track to form a $0.7M_{\odot}$ white dwarf. The lack of success of Reimers' formula in yielding a sufficiently large mass loss does not mean that it does not apply at all to luminous red giants, but simply indicates the need to search for an additional mechanism for losing mass.

If stars lose 20–30% (or even 50%) of their mass when subgiants, there are few directly observable consequences. The luminosity and temperature of most field stars are affected more by unknowns such as age and original mass than mass loss. One would expect, however, to see some effect in the Hertzsprung–Russell diagram of clusters if mass is being lost. First, as was shown by Chiosi and Nassi[19], mass loss on or near the end of the main sequence causes a slightly smaller core to form, and stars approach the giant branch with a lower luminosity. Second, if different amounts of mass are lost from stars in the same clusters, there will be a spread in the horizontal branch or clump (for Pop. I stars with $M < 3M_{\odot}$). Rood[20] has shown that Hertzsprung–Russell diagrams of globular clusters are consistent with a mass loss of $25\pm3\%$. Varying masses on the giant branch also seem consistent with Osborn's observations of the old open clusters, M67 and NGC2420 (refs 21, 22), and both of these effects also appear in the observations of Flower[23]; he observed several young clusters with $7M_{\odot}$ turnoff masses where there seem to be giant stars of mass $5M_{\odot}$. Lindhoff[24,25] reported on such effects in several galactic clusters, but uncertainty in the turnoff mass (or age, ref. 26), or small numbers of stars made interpretation difficult.

Table 1 is a chart which summarises all of the arguments presented and strongly indicates the possibility that mass loss occurs as a subgiant or at the base of the giant branch (before the convection zone reaching the ^{13}C layer).

One should remember that none of the above arguments is conclusive. Other explanations may be found for the scatter in young clusters, $^{12}C/^{13}C$ ratios, and the apparent low mass of AI Velorum stars. The arguments stated here may be just a large collection of false leads.

Table 1 Summary of evidence for subgiant mass loss.

	Main sequence	Subgiant	Giant branch	Helium flash	Horizontal branch	Asymptotic branch	Double shell flashes	Supernovae	Planetary nebula	Total fractions of main sequence mass which is lost
O–B Supergiants	*								X	?
Luminous red giants						*	*		*	10%
Globular clusters	X				X	X	X	X		20–30%
White dwarf in Pleiades				X				X		90%
Arcturus	X	*	*				X	X	X	> 50%
$^{12}C/^{13}C$ several K giants	X	*	*			X	X	X	X	20–30%
AI Velorum stars	X			X	X	X	X	X	X	≈ 70%
NGC 2420	X				X	X	X	X	X	≈ 30%
Scatter on H–R-diagrams	X			X	X	X	X	X	X	?

*Requires mass loss in this stage.
X, either this stage did not occur, or only small amount of mass loss allowed.
Blanks indicate possibility of mass loss at that stage but no strong evidence.

Mass loss at an early stage can reduce the number of carbon detonation supernovae (which seem to produce excessive amounts of iron peak elements) and allow stars to arrive at the double shell flash stage with smaller envelopes, making it easier to produce carbon stars and FG Sag like objects. If, however, stars lose mass as subgiants or low luminosity giants, it is necessary to ask why some low mass stars, such as those in globular clusters, lose only 25% of their mass so that they can still undergo a helium flash, whereas AI Vel stars lose too much mass to even ignite helium (if Dziembowski and Kozlowski's models are correct). This question is, of course, entangled in how the mass is lost.

It is possible to estimate the energy constraints on the mass loss. The power per unit volume in a convection zone from acoustic[27] and gravity[28] waves are

$$P_{\mathrm{acc}} = 38\,\frac{\rho V_c^{8}}{l\,V_s^{5}}$$

$$P_{\mathrm{grav}} = 100\,\frac{\rho V_c^{3}}{l}\left(\frac{l}{H}\right)^{5}$$

where ρ is the density, V_c is the convective velocity, V_s the sound velocity, l the mixing length, and H the pressure scale height. Unfortunately, both powers end up being proportional to l^7—an extremely uncertain parameter.

The acoustic energy flux is sufficient to sustain a tremendous corona and could easily provide the required mass loss to produce the $^{12}C/^{13}C$ ratios. If, however, this is the power source of the solar corona, then only a small fraction of the flux emerges to drive the solar wind. Calculations of the emergent flux have been attempted by Whitaker[29] and DeLoore[30], but are extremely uncertain. There is also no theory explaining the possible effects of metal concentrations, magnetic field or rotation to explain the apparent variation of the mass loss.

Those arguments strongly suggest the possibility of substantial mass loss at an early stage of post-main sequence stellar evolution. Further observations are required for some indication of mass loss, such as of coronae, particularly of stars which have recently left the main sequence and are in the process of moving to the giant branch. They also indicate the need to look in detail for a reasonable mechanism to explain the required mass loss.

We would like to thank B. Paczynski for numerous discussions. This research was supported in part by a Smithsonian Foreign Currency grant and by the NSF.

Accretion-disk scenarios of the precursor peak in X-ray transients

ONE of the striking features of a number of the transient X-ray sources is the 'precursor peak', an intensity maximum which precedes the rise to primary maximum and is separated from it by a dip. It is characteristic of A0620−00 (refs 1, 2), A1524−62 (ref. 3), A1118−61 (refs 4, 5), and A0535+26 (refs 6–9). The time scale across the precursor and subsequent dip is ~4–20 d, though for A0620−00 the dip itself spans a time of only ~10 h. Apart from flares, which have a much shorter time scale, there are similar secondary peaks observed during decay for some of the sources—A1524−62 and A0535+26, for instance. Any model of these transients must account for such features along with the concurrent softening of the X-ray spectrum in some cases, the temporal asymmetry of the light curve and, for sources A1118−61 (ref. 5) and A0535+26 (ref. 6), periodicities of 6.755±0.010 min and 104.14±0.16 s, respectively. It is possible to explain qualitatively the precursor and related phenomena on the basis of accretion-disk behaviour with a rising accretion rate $\dot{M}$, followed by its gradual subsidence and the emptying of the disk. In this paper I present three schemes.

I start with two preliminary comments. There are models where a decreasing $\dot{M}$ gradually uncovers the X-ray producing regions buried beneath an optically thick blanket of accreting material[10]. This seems unlikely for a number of reasons (A. P. Willmore, unpublished)—the gradual softening of the spectrum and the skewness of the light curve towards the decay phase.

Second, our reliance on available thin-disk models is, at this stage, not crucial for our work. Except for those of Lightman[11,12], all models are either independent of time[13,14] or time averaged[15], assuming that $\dot{M} = 4\pi rh\Sigma v_r$ is constant; here r is the radius, h the disk half-thickness, $\Sigma = \Sigma(r)$ the surface density and v_r the radial drift velocity. Nevertheless, their use in the present context is rigorously justified as long as the time scale t_M over which $\dot{M}$ varies satisfies[12].

$$t_{\mathrm{M}} > t_{\mathrm{D}} \tag{1}$$

where $t_D \simeq (r/h)^2\,\alpha^{-1}\,t_H$ is the drift time scale, the time it takes Σ to diffuse a distance r. Here α is the 'catch-all' viscosity parameter and t_H is the hydrodynamic time scale; $\alpha \simeq 10^{-3}$–1, $t_H \simeq 10^{-3}$–10^{-2} s. Thus, if $\dot{M}$ is increasing over a period of days, equation (1) will generally be satisfied. Even when it fails, the models probably give us a qualitatively correct picture of the evolution.

In the first scenario, Roche-lobe overflow begins and increases; a disk forms. At first, the very soft X-ray flux from portions of the disk with large radii will dominate. But eventually, as a stable type II (electron-scattering opacity and matter dominated) inner region develops, the luminosity will become significant in the 1–20-keV range, where the Ariel V transients have been detected. The continuing rise in $\dot{M}$ will lead to increasing luminosity, since the flux $F \sim \dot{M}$ throughout the disk[13,14].

For the two sources A1524−62 (ref. 3) and A0620−00 (ref. 2) a significant spectral softening is evident during the luminosity increase, but at different phases of the light curve. In the former it occurs during the rise to the precursor peak; for A0620−00, however, the spectrum remains relatively hard across the precursor, with the softening occurring only afterwards—during the rise to principal maximum. How is this to be interpreted?

The intensity dip is caused, in this scheme, by disk thickening, primarily in the cooler outer regions, which absorb some of the radiation originally destined for the observer. Some of the harder photons from the inner regions of the disk and/or from the surface of the compact object, are reprocessed and re-emitted at lower energies (Cunningham, C. T., unpublished). This mechanism can account for the spectral softening, which in A1524−62 is in proper correspondence with the intensity dip for this picture: thickening (and spectral softening) occurs during the precursor peaking and then reaches a point where the outer region of the disk begins to intercept radiation directed towards the observer. For A0620−00, however, this correspondence fails—and it seems impossible to apply the scenario properly

The absence of spectral softening (as in A1118−61 (ref. 5)) does not necessarily rule out this scheme. Whether it will be observed in a given case depends on the observer's angle of inclination and other factors and can be predicted only on the basis of a detailed quantitative model.

The gradual thickening postulated here would arise primarily from the reabsorption of radiation itself—from the hotter inner regions of the disk and from the surface of the compact object. As the disk thickens, of course, it becomes even more susceptible to such absorption and reheating. Thus it is possible that through this process the outer regions would swell into a cloud shrouding the entire compact object and inner-disk system.

The continuing increase in $\dot{M}$ forces the luminosity of the thick disk or cloud configuration from the dip to the primary maximum. Then, as $\dot{M}$ begins to decrease, the transient enters its decay phase, which has a time scale of months. It is likely that this is just the emptying time t_e of the disk modulated by $\dot{M}$. From both related observational (Bailey, J., unpublished) and theoretical[16] considerations, t_e, for reasonable values of $M/M_{\odot}$, binary period and disk radius, is of the required order. If an extensive quasi-spherical cloud shrouds the disk, its accretion time may also be important. A secondary maximum during decay, such as is seen in A0535+26, can be accounted for in terms of thick disk subsidence to a thin disk.

For sources like A1118−61 and A0535+26, it is important to establish whether their periodic components persist at the same level through the peak and dip and on into the principal maximum, or are characteristic only of certain stages of the transient's evolution. Such information would also help determine whether the precursor phenomenon arises primarily from disk behaviour or from mechanisms associated with, say, funnel accretion on to the polar caps of a neutron star. Though these observed periodicities are not directly explained by the disk behaviour itself in this scheme, they are not inconsistent with it. They may be a characteristic, for example, of the component of radiation emanating from the polar caps of the neutron star in a neutron-star thick-disk system.

The second scheme pertains to non-magnetic situations, black holes or unmagnetised neutron stars, and applies primarily to A0620−00. It begins and ends like the first. But, in the course of the rise to the precursor peak with increasing $\dot{M}$, either an unstable radiation dominated inner region appears[11,12] or thermal instabilities[18] develop from the severe density thinning across the inner edge (W.R.S., unpublished). In either case the inner region of the disk will blow up into a very hot, essentially spherical cloud, and inner disk models like those of Thorne and Price[19], Lightman and Shapiro[20], Eardley *et al.*[21], and Shapiro *et al.*[22] will be applicable. The onset of such instabilities occurs at the precursor peak, and the subsequent dip is formed as the luminosity contributed to the 1–20-keV range by the hotter inner region is lost. The continually increasing $\dot{M}$, however, quickly overcomes the dip and moves the transient towards its maximum.

This sequence would explain why the spectrum remains hard during precursor peaking in a source like A0620−00 and begins softening only afterwards. It would also account for the relatively sudden dip with recovery on a time scale of hours. A crucial test of the model would be significant spectral softening in the narrow dip itself.

It is possible that, corresponding to the occurrence of the dip, hard X-ray emission in the 100–500 keV range from the very hot inner cloud would make its appearance. But, then again, such a source might might not be evident, particularly if this cloud is optically thin. For then the flux $F \sim n^2T^{\frac{1}{2}}$ instead of the much more substantial $F \simeq bT^4$ of black-body radiation. The swollen inner region, however, might still function to boost soft photons into medium hard X-ray range by inverse Compton scattering[21,22]. G. F. Carpenter, M. J. Coe, A. R. Engel and J. J. Quenby (unpublished), in fact, have shown that the spectrum of A0620−00 is similar in many respects to that of Cygnus X-1, where just such a model closely fits the data[21,22].

The third scenario applies only to a black hole in a stellar-wind environment and demands both an increasing $\dot{M}$ and an increasing specific angular momentum L of the accreting material. Modulation of L could be provided by a highly eccentric binary orbit, but this seems somewhat questionable on other grounds[23]. The general picture involves the formation at very small radii of an initial marginal accretion disk[24,25] ($r=4M$ to $r=12M$ in the Schwarzschild case—in units where $G=c=1$), which grows into a stable disk as $\dot{M}$ and L increase.

We can describe the disk evolution in terms of the orbital topography of the Schwarzschild metric[26]. The specific energy (including rest mass) of the infalling material is $E \simeq 1$. As L approaches and then becomes larger than $L_{\rm ms} \simeq 3.464M$(the specific angular momentum for a marginally stable circular orbit at $r_{\rm ms} \equiv 6M$), a chaotic transitional disk will form, heat up and radiate[25]. Such a disk will extend outwards, not from $r_{\rm ms}$, but from $r_{\rm mb} = 4M$ (the marginally bound circular orbit). Since the material has both a large E and $L < 4M$, a large proportion of it will be in unstable circular and elliptical, and stable elliptical, orbits extending from $r_{\rm mb}$ outwards ($E_{\rm mb} = 1$ and $L_{\rm mb} = 4M$). As the material loses some of its energy and angular momentum, a large proportion of that between $4M<r<6M$ will first migrate into stable circular orbits at $r>r_{\rm ms}$ before spiralling on to the secondary.

As L and $\dot{M}$ increase, the disk grows radially, and the inner region between $4M$ and $6M$ disappears, superseded by a stable 'classically' described thin disk with inner edge at $r_{\rm ms}$. The formation of the chaotic inner disk would explain the initially hard spectrum, the precursor peak would arise from the gradual build up of this inner disk with increasing $\dot{M}$ and L, and the dip, along with some of the spectral softening during the rise to primary maximum (as in A0620−00), to the dissipation of the transitional disk as the stable outer disk developed. The rise to primary maximum and the continuing softening of the spectrum would then be the result of both the gradual growth of the stable disk and the increasing $\dot{M}$. The time scale across the precursor peak will depend on how long accretion with a marginal L continues, and that across the dip on the time it takes for the rising accretion rate to recover the ground lost through dissipation of the chaotic disk—for A0620−00 this would have to be ~ 10 h. The time scale of decay, again, is just $t_{\rm e}$ modulated by $\dot{M}$. A marginal-disk stage should be a briefly discernible feature during the decline.

I hope this work will open theoretical avenues of approach to the precursor phenomenon and motivate further investigation of this unexpected feature.

I thank Professor Martin Rees for his help and A. C. Fabian and J. E. Pringle for discussions.

A return to the pre-1971 intensity level and a 5.6-d modulation for Cyg X-1

CYG X-1 exhibited three pronounced X-ray intensity increases during 1975. The last of these, unlike the previous two, has not rapidly decayed back to its pre-increase value. Such a persistently high emission level from Cyg X-1 has not been observed since the source 'transition' in 1971[1].

A 5.6-d modulation synchronised with HDE226868 was observed over the first six months of the Ariel V all-sky monitor (ASM) data accumulation before the April 1975 increase[2], but was not detectable immediately afterwards. We report here the detection of a similar 5.6-d modulation in the 'high-state' data obtained over the 3-month interval November 1975–January 1976.

The Ariel V ASM experiment has monitored Cyg X-1 quasi-continuously since its launch in October 1974. No flare-like increases were observed until April 1975, when the source suddenly increased to an intensity level in excess of that of the Crab Nebula. The rise[3], maximum[4] and decay[5] were marked by considerably more variability on time scales of hours, or more than was the relatively quiescent pre-increase temporal record. A smaller increase was reported in September[6], which displayed the same variability and decay time of ~ 1 week. The third increase in November[7,8] was to the level of the April event, displaying the same variability. It did not, however, decay over the same time scale[9], and has shown no sign of decay after 3 months. Figure 1 displays the daily averages of the Cyg X-1 data accumulated between launch and January 31, 1976 by the ASM.

The folded data from both the six months before the April 1975 flare and the 3-month interval November 1975–January 1976 are displayed in Fig. 2, where we have used the ephemeris of ref. 10 to define the epoch of superior conjunction. The folds are in five bins, with the ordinate for each bin defined as the source intensity relative to the average of the four bins excluding superior conjunction. This average value for the new data is more than twice that of the pre-April 1975 measurements.

The light curve decrement (that fraction of the total source emission over one 5.6-d cycle which is deficient at superior conjunction) is 0.019 ± 0.003 for the lower trace of Fig. 2, compared with 0.029 ± 0.004 for the upper trace. This level of modulation was not detectable in the ASM data between the April and November flares, which may have been the result of uncorrelated source intensity variations masking the effect (the experimental value of the decrement was 0.008 ± 0.009 during this interval). Daily averages for the April, September and November–January increases are displayed in Fig. 3, combined with a 5.6-d grid from the ephemeris of ref. 10. It is obvious that the uncorrelated intensity variations prevent the direct observation of the reported level of 5.6-d modulation over individual cycles in general, and the effect can only be demonstrated convincingly by averaging over many cycles.

In ref. 2 it was suggested that the modulation observed before the April flare might be associated with the build up to the increase, and might be observable only just before such increases. The new results reported here suggest that this level of X-ray modulation may be generally character-

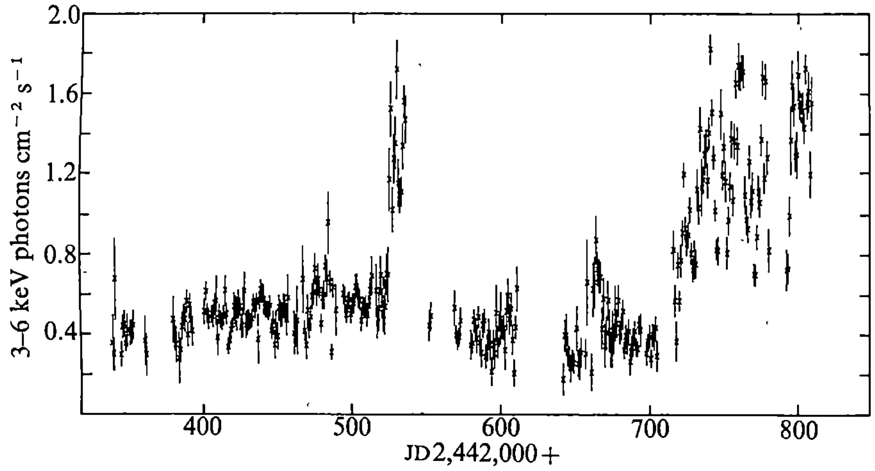

Fig. 1 Daily averages for more than one year of ASM measurements of Cyg X-1. The ordinate is natural for the experiment, with the Crab Nebula giving ~1.2 in the same units.

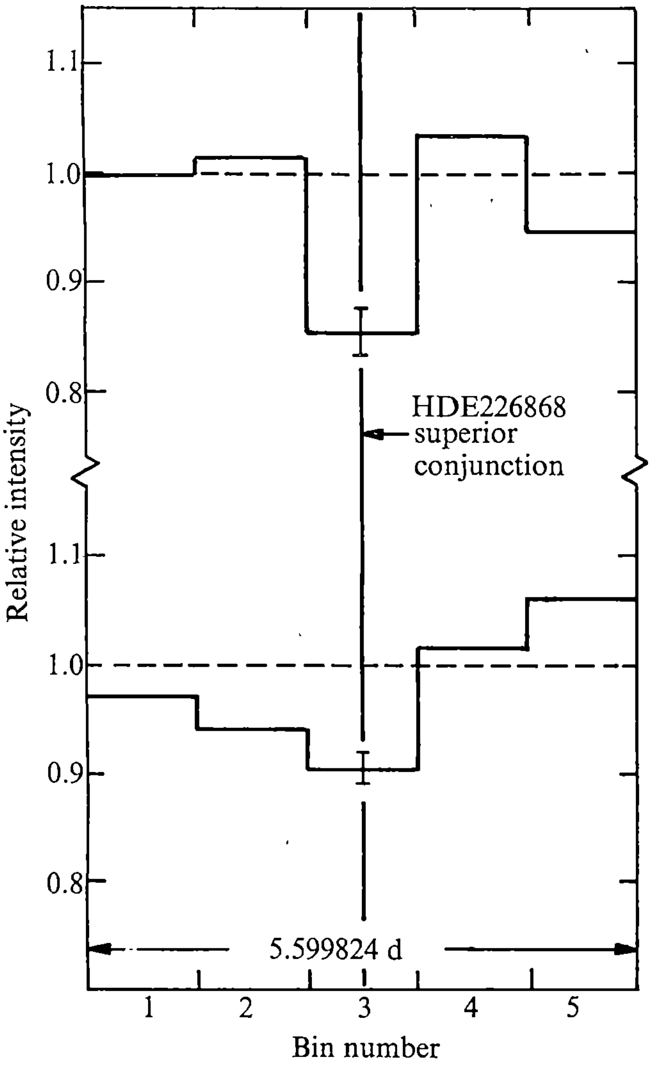
istic of Cyg X-1. The orbital analyses of Hutchings (see ref. 11) and Bolton[10] suggest that an inclination i of ~30° is necessary to reconcile the optical measurements, in contrast to the i ~60° required if the present results represent an eclipse of the source by a completely-filled primary Roche lobe. It would seem, therefore, that our results are most easily explained by scattering from ionised material between the two stellar components which extends outside the orbital plane (see ref. 10). The material must be largely ionised because a much larger effect has not been reported at lower energies. As described in ref. 9, the magnitude of the present level of modulation is approximately an order of magnitude in excess of the expectation from the more sharply defined 'absorption dips' which have been attributed to the effect of neutral material, so that it is not at all clear how these two classes of superior conjunction decrements are related. In any case, the decrement at > 3 keV reported here appears to be consistent with a stable few per cent underlying average periodicity in both the high and low intensity states of Cyg X-1. We cannot ascertain unambiguously whether this effect is present every cycle at the average level, or whether the effect is larger and present only a fraction of the time. Figure 3 does contain a few pronounced minima which are synchronised with superior conjunction, but it also contains many which are not. The final determination of this question must await a detailed analysis of many high state cycles (of which only ~15 are

Fig. 2 Data taken before the April 1975 increase (upper trace, November 1974–April 1975) and after the start of the November 1975 increase (lower trace; November 1975–January 1976) folded in 5 bins using the HDE226868 ephemeris[10].



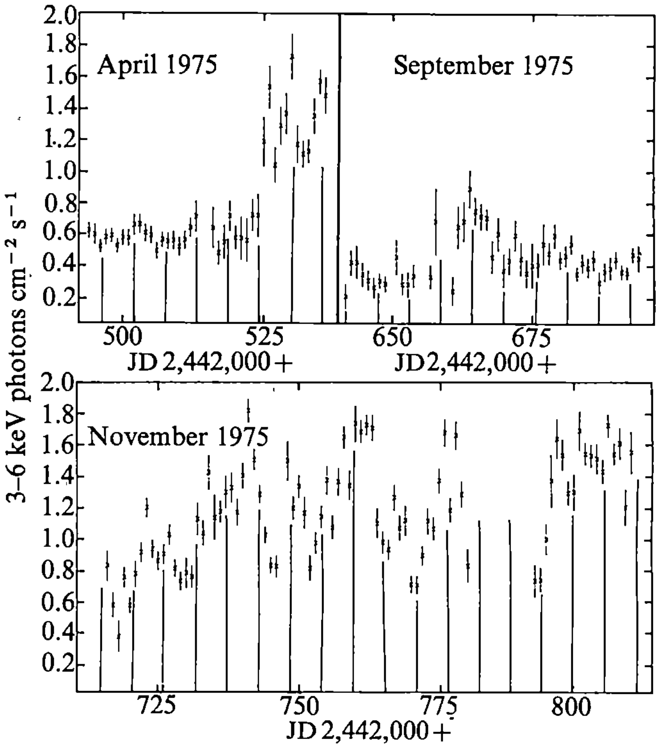


Fig. 3 Daily averages at the times of the three 1975 increases, with a superposed HDE226868 superior conjunction grid. On a finer time scale, the asynchronous intensity variations are even larger than those reflected in the plotted daily averages.

included here). Should the intensity remain high indefinitely, the ASM should be capable of resolving the issue eventually, as it is expected to continue operation for at least another year.

L. J. K. acknowledges support from the University of Maryland.

Note added in proof: Shortly after this manuscript was submitted, Cyg X-1 was observed by the ASM to return sharply to its "low" state[12]. Its average intensity for the week ending on JD 2,442,822 was 1.85±0 04, after which it dropped by a factor of three in one week. The intensity has since been roughly constant at ~0.5 to JD 2,442,851.

Molecular hydrogen formation on interstellar dust grains

EARLY estimates of the maximum temperature, T_M, of interstellar dust grains (IDGs) consistent with efficient H_2 formation on their surface, yielded values near 10 K (refs 1–3). The expression for T_M is

$$T_M = E_H/\ln\left[\frac{1}{Svn_H A\tau_0}\right] \simeq 10\,\mathrm{K} \qquad (1)$$

where E_H is the binding energy of hydrogen to the dust grain $\simeq$ 400 K, S is the sticking coefficient of H on the grain $\simeq$ 0.5, v is the average velocity of H atoms in the dust clouds $\simeq$ 10^5 cm s^{-1}, n_H is the hydrogen density in the cloud $\simeq$ 10^2 cm^{-3}, A is the surface area of a dust grain $\simeq$ 10^{-9} cm^2, and $\tau_0 \simeq 6\times10^{-13}$ s. Observations have shown this T_M to be unacceptably low (see, for example, refs 5 and 4), and have led to proposals of new or revised mechanisms for interstellar H_2 formation[6–9]. Here we point out that for a certain class of gas–solid systems the characteristic desorption lifetime, τ_0, is many orders of magnitude longer than that used in refs 1–3. For grains made of these materials the original "physisorption model"[1–3] will work for grain temperatures up to 30 K.

The τ_0 of 6×10^{-13} s, used in refs 1–3, comes from the Frenkel theory of adsorption[10], in which detailed balance, single particle partition functions, and equilibrium between the gaseous and adsorbed phases are assumed. These assumptions are not necessarily valid in interstellar clouds. A dynamical theory of desorption makes none of the aforementioned assumptions. Ying and Bendow[11] have formulated such a theory by considering phonon-induced desorption. In particular, they performed detailed calculations for the model system, Ne adsorbed on Xe-covered graphite, and found that τ_0 exceeded 10^{-5} s for temperatures below 40 K. This occurs because the low temperature excitation spectrum of the substrate (Xe on graphite) contains few phonons with energies exceeding the binding energy of the adsorbed atoms. Thus multiphonon processes, which are slow when the phonon gas is dilute, are necessary for desorption. A similar situation does not occur for H adsorbed on the graphite basal plane—a commonly proposed form of IDG. The binding energy of H on graphite, E_H, is about 400 K (ref. 12), while the transverse and longitudinal Debye temperatures are T_t = 760 K and T_l = 2,700 K (ref. 13), respectively. Desorption induced by a single phonon can thus occur and a short τ_0 is the result. This can be seen from the following derivation. The flux of phonons, each with sufficient surface normal energy to cause desorption, times the phonon–adatom cross section, gives the desorption rate, R,

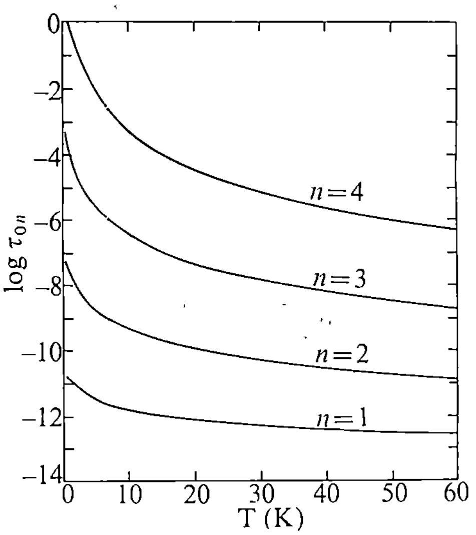

Fig. 1 Log τ_{0n} as a function of T for n = 1,2,3 and 4. τ_{0n} is related to the average lifetime with respect to desorption, τ, by the Frenkel formula[10], $\tau_{0n} = \tau\exp(-E/kT)$, where E is the binding energy of the adsorbed atom and T is the temperature of the substrate.

$$R = \int_{\omega_0}^{kT_D/\hbar}\int_{\theta,\psi} cg(\omega)\sigma(\omega,\theta)\cos^2\theta\,\sin\theta\,d\theta\,d\Psi\,d\omega \qquad (2)$$

where $\omega_0 = E/\hbar$, E is the binding energy of the adsorbed species to the substrate, T_D is the Debye temperature of the substrate (all polarisations are treated equivalently), c is the speed of sound in the substrate, $\sigma(\omega,\theta)$ is the cross section for maximum energy transfer between the phonon and the adsorbed atom $\lesssim \pi(\lambda+d)^2$, $\lambda(\omega)$ is the phonon wavelength, d is the adsorbed atom scale size, $g(\omega)$ is the phonon distribution function in the substrate[14]

$$(g)\omega \simeq V(3/2\pi^2c^3)\{\omega^2/[\exp(\hbar\omega/kT)-1]\}\ \mathrm{s\ for}\ \frac{\hbar\omega}{k} \leqslant T_D$$

and

$$g(\omega) = 0\ \mathrm{for}\ \frac{\hbar\omega}{k} > T_D$$

For the hydrogen–graphite system, $E = E_H \simeq 400$ K, $c \simeq 10^6$ cm s^{-1}, $T_D \simeq 1{,}500$ K, and $d \simeq 3\times10^{-8}$ cm.

Using the facts that $kT \ll E_H < kT_D$ and $\lambda_0 \lesssim d$, equation (2) can be integrated

$$R \lesssim \frac{d^2V}{2\pi^2c^2}\frac{kT}{\hbar}\omega_0^2\exp(-\hbar\omega_0/kT) \qquad (3)$$

This gives a desorption time of the Frenkel form and magnitude,

$$V/R \leqslant \tau_1 = \tau_{01}\exp(\hbar\omega_0/kT) = \tau_{01}\exp(E_H/kT) \qquad (4)$$

where

$$\tau_{01} = \frac{2\pi^2c^2}{d^2}\frac{\hbar}{kT}\frac{1}{\omega_0^2} \simeq 6.0\times10^{-13}\ \mathrm{s}\ (\mathrm{at}\ T{=}100\ \mathrm{K})$$

The inequality in equations (3) and (4) comes from the un-

Table 1 Characteristic desorption times of certain adsorbed gas–substrate systems

Adsorbed species	Substrate	Temperature (K)	Binding energy (K)	τ_0 (s)	Reference
H_2	H_2 covered Cu	1–4	96	4×10^{-9}	23
H_2	CO covered Cu-Ni	10–25		10^{-7}	19
He	He covered Cu-Ni	4–30	30–90	1.5×10^{-7}	21
CO_2	SiO_2	80–130		5×10^{-4}	20
H_2 κ state	CO covered W	300	3,700	1.25×10^{-3}	18
CO	CO covered Co	300–1,000	2,000	2×10^{-3}	22
CO	CO covered Ni	300–1,000	2,000	4×10^{-3}	22
Ar	SiO_2	80–130	250–500	1	20

certainty in the cross section. Specifically, $\sigma(\omega,\theta)$ depends on the phonon polarisation, the availability of final phonon and adatom states, the scattering matrix, and the constraints of energy and momentum conservation.

Graphite is an oddity in that it has a very high Debye temperature. "Softer" materials of low atomic mass constituents such as α-iron, ice, silica or solid carbon monoxide, have Debye temperatures below 200 K (refs 15 and 16). For hydrogen physisorbed on these materials ($E_H \geq 400$ K) two or more phonon impacts are necessary for desorption. For two-phonon desorption to occur, a second phonon must transfer sufficient energy to a hydrogen atom which has been raised to an excited (surface normal) vibrational state by a previous phonon. The second phonon must impact on the excited hydrogen with proper phase and within a time $t \simeq 2\pi/\omega_0 \sim 1.2\times10^{-13}$ s, or else the excitation may decay away by spontaneous phonon emission. The time between successive impacts by energetic phonons is τ_1 (ω), equation (4). Accordingly, the probability that an excited atom will be desorbed by the impact of a second phonon is

$$P(\omega) \simeq \frac{1.2\times10^{-13}\gamma}{[\tau_1(\omega)+1.2\times10^{-13}]} \qquad (5)$$

and the desorption time (at low temperatures) is

$$\tau_2 \simeq \frac{\tau_1(\omega')}{P(\omega)} = \frac{1}{1.2\times10^{-13}\gamma}\left[\frac{2\pi^2c^2}{d^2}\right]^2 \left[\frac{\hbar}{kT}\right]^2 \frac{1}{\omega^2}\frac{1}{\omega'^2} \exp[\hbar(\omega+\omega')/kT] \qquad (6)$$

where γ is a phase coherence factor for the two phonons $\simeq 0.5$ (this corresponds to a $\pi/3$ phase shift between phonons, thus a 50% decrease in energy due to interference effects), $c \simeq 5\times10^5$ cm s^{-1} for iron, ice, silica, and so on, $\hbar\omega$ and $\hbar\omega'$ are the energies of the two phonons, and $\hbar(\omega+\omega') \geq \hbar\omega_0$, the binding energy of the adsorbed hydrogen. The minimum τ_2 occurs for

$$\omega = \omega' = \omega_0/2 \qquad (7)$$

that is, the maximum rate of two phonon desorption occurs when the phonons have equal energy.

This can be generalised to n phonon processes. For n phonon-induced desorption, τ_n is given by

$$\tau_n = \left[\frac{1}{1.2\times10^{-13}\gamma}\right]^{n-1} \left[\frac{2\pi^2c^2}{d^2}\right]^n \left[\frac{\hbar}{kT}\right]^n \frac{1}{(\omega_0/n)^{2n}} \exp(E_H/kT)$$

$$\simeq (n)^{2n}\left(\frac{200}{T}\right)^{n-1} \frac{1.5\times10^{-11}}{T} \exp(E_H/kT)\,\text{s} \qquad (8)$$

which defines a characteristic desorption time

$$\tau_{0n} = (n)^{2n}\left(\frac{200}{T}\right)^{n-1} \frac{1.5\times10^{-11}}{T}\,\text{s} \qquad (9)$$

A graph of τ_{0n} as a function of temperature for n = 1,2,3 and 4 is shown in Fig. 1. It must be stressed that these are lower limits for τ_{0n} because of the uncertainty in $\sigma(\omega,\theta)$. For a four-phonon process, as would be necessary for H desorption from solid CO or to covered surfaces, τ_{04} is 10^{-5} s and T_M (equation (1)) is raised to 30 K.

Long τ_0s have been measured in many experiments. As early as 1928, Cockcroft[17] measured τ_0 of 10^{-9} s at $T = 150$ K. Later experiments showed τ_0 values up to 1 s and several notable examples are listed in Table 1. As can be seen, τ_0 for H_2 on CO covered W[18], for H_2 on CO covered Ni[19] and for CO_2 and Ar on SiO_2 (ref. 20) are greater than 10^{-7} s.

In summary, a dynamical theory of phonon-induced desorption is presented. It is shown that the characteristic desorption time, τ_0, is long at low temperatures if the binding energy of the adsorbed atoms exceeds the Debye temperature of the substrate. This fact has immediate application to the problem of abundant H_2 present in interstellar dust clouds by raising the maximum temperature for efficient H_2 formation to 30 K. From this model we conclude that the basal planes of clean graphite flakes are not effective substrates of H_2 formation, whereas solid CO, H_2O or SiO_2 surfaces are.

I thank E. S. Marmer, J. L. Cecchi, and J. G. King for discussions. This work was supported by the USERDA.

Isotopic fractionation in meteoritic cadmium

ISOTOPE and elemental abundance studies of Cd in this laboratory have led to the discovery of Cd with an isotopic composition which differs significantly from that normally observed in nature. This isotope abundance study was initiated with the primary aim of detecting and measuring neutron irradiation effects in Cd (^{113}Cd (n,γ) ^{114}Cd, σ = 20,000 barn) of similar origin to that observed in Gd (ref. 1), and included a survey of

*The ratios are not corrected for instrumental discrimination. The error associated with each measurement (in parentheses) is two standard errors of the mean of sets of 10 ratios. The — difference between each isotope ratio and that for laboratory standard is given below the error, where — difference is defined for the 116/112 isotopic ratio as

$$[1-(116/112)\text{sample}/(116/112)\text{standard}]\times 1{,}000$$

The "laboratory standard" ratios are based on measurements on Cd from Cd-rich terrestrial minerals as well as repeated measurements of laboratory reagent Cd (Johnson Matthey Spec-pure metal)

†These figures are calculated from a knowledge of the weight of meteorite used and the cadmium concentration. No allowance has been made for the efficiency of the chemical extraction procedure which is ~ 50%. The chemistry blank for the separation is ≃ 3 ng. In the dilution experiment 2 μg of reagent cadmium was added to the meteorite sample before dissolution.

nm, No measurement made

Cd isotope abundance in terrestrial samples[2] and a range of meteorites. The meteorite data will be reported in detail elsewhere. The Brownfield H3 chondrite, included in the survey because of its enhanced Cd content[3], was found to contain anomalous Cd; some results are given in Tables 1 and 2.

Table 1 shows the Cd to be consistently isotopically fractionated relative to the laboratory standard, with an enrichment in the heavier isotopes. Figure 1 shows that a linear trend exists when the ‰ differences between the mean of the Brownfield data and the laboratory standard are plotted. The fractionation decreased by the expected amount when the meteorite Cd was diluted with reagent Cd (see Fig. 1).

Two samples of Brownfield were double spiked[2] with a ^{106}Cd–^{111}Cd tracer. The ratios measured for the mixtures as well as other data needed for the calculation of the fractionation are given in Table 2. Both mixtures yielded a fractionation of 2.3‰ per mass unit relative to laboratory reagent Cd (Johnson Matthey Spec-pure metal). Measurements made in this laboratory[2] have shown that the reagent Cd used for the experiment has the same isotopic composition as Cd from Cd-rich terrestrial minerals. There is excellent agreement between the double-spike result and the unspiked measurements (Fig. 1).

The data presented here so far show that recognised sources of isotopic discrimination such as chemical processing and mass spectrometry could not be the cause of the observed isotope fractionation. The fractionated Cd could still have a terrestrial origin, however, since Brownfield is a "find"[4]. To establish that the anomalous Cd was most probably present in Brownfield when it fell, it was necessary to find isotopically similar Cd in a meteorite known to be a "fall". A sample of the H3 chondrite Tieschitz was obtained for this purpose and the results of the analyses are given in Table 3. The Cd in Tieschitz is also clearly fractionated, although the results of the two measurements differ.

Further double-spike measurements indicate that both the fractionation and the Cd concentration are extremely variable

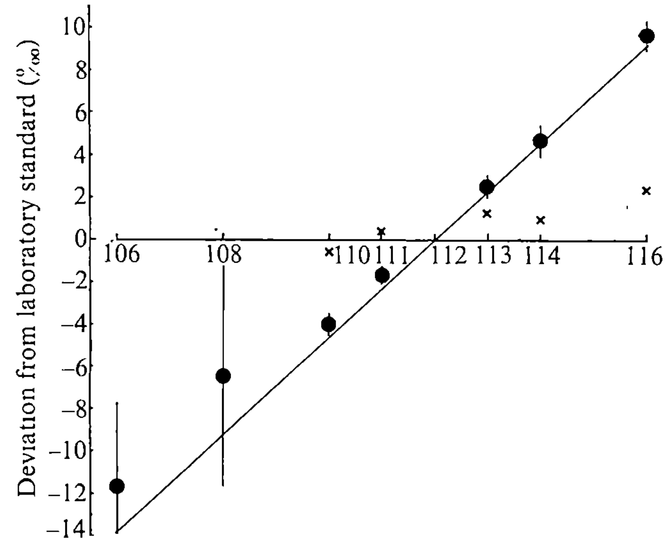
‡The observed enrichment beyond that expected for linear isotope fractionation is probably due to ^{116}Sn contamination Such interferences may be resolved when a double spike is added by selecting 114 instead of 116 for computations

in this meteorite. This may be due to dilution of a fractionated Cd component in the meteorite with an unfractionated component. It is also interesting to note that the Cd content of Tieschitz (values of 75–203 ng g^{-1} have been obtained so far) is substantially lower than that in Brownfield (408 ng g^{-1}) but unusually high when compared with other H chondrites[3]. The chemical inhomogeneity is not unexpected owing to the primitive nature of the H3 chondrites. (Further analyses suggest that the concentration of 408 ng g^{-1} for the bulk meteorite is more representative of Brownfield than that previously reported by us[3].)

Linear isotope fractionation has only been detected in two of the 22 meteorites from various classes examined in this study.

At present we can only speculate on the origin of the anomalous Cd. Arrhenius and Alfvén[5] have indicated several mechanisms which could lead to isotope fractionation during the formation of the Solar System and one of these may account for the observed anomaly. For instance, in chemical species with high re-emission coefficients, such as Hg and the noble gases, efficient isotope separation can be achieved by a multiple desorption process involving impingement, diffusion and desorption from the solid surfaces of a growing condensate. Arrhenius and Alfvén[5] imply that the Hg anomaly observed by Reed and Jovanovic[6] could be attributed to this mechanism. Although Brownfield was not measured by Reed and Jovanovic, it is interesting to note that Tieschitz yielded a 510% enhancement in ^{202}Hg/^{196}Hg ratio. Since Cd has a high ionisation potential and is also volatile, this mechanism may also lead to isotope fractionation of Cd.

Fig. 1 Isotope data for the Brownfield chondrite. ●, Mean of the unspiked analyses shown in Table 1. The error limits indicate two standard errors for the mean. ×, Result of diluting a sample of Brownfield with laboratory reagent Cd. The line represents a fractionation of 2.3‰ per mass unit which is obtained by independent measurements using a double-spiking technique.



Lewis *et al.*[7] have reported the presence of fractionated noble gases in chromite from Allende. Ne, Ar and Kr were enriched in the heavy isotopes whereas Xe was enriched in the lighter isotopes. They suggest that fractionation may have occurred during trapping of the gases from the solar nebula. An examination of Cd in chromite may therefore be profitable.

We thank Dr M. P. Gorton for discussions and Dr G. Kurat for providing the sample of Tieschitz. This research was supported by the Australian Research Grants Committee.

Evidence for two discrete centres in Skye

ONE of the best-developed igneous areas in North-West Britain is on the Isle of Skye: in addition to extensive flood basalt lavas and their feeding dykes there are three adjacent intrusive centres across the south-east of the island[1]. The Eastern and Western Red Hills, usually identified as two almost contemporaneous centres, comprise surface granite outcrops in a mass 10 km across, intruded against the older basic-to-ultrabasic Cuillin centre which is of similar size and lies to the west (Fig. 1*a*). Using aeromagnetic, gravity and isotopic evidence we will argue that there are two structurally discrete centres at depth, which probably were intruded several million years apart.

Bott and Tuson[2] have reported a large gravity anomaly over the Skye centres of ∼50 mgal above the regional value (Fig. 1*b*). They interpreted this as due to a conical mass of gabbro widening down to a depth of 15 km, underlying all three centres and outcropping as the Cuillin, with the granitic Red Hills being no more than a veneer, perhaps 2 km thick. The aeromagnetic map[3] shows, however, a negative anomaly of ∼600 nT over the Cuillin, and a roughly equal but positive one over the Red Hills. Though the former can be accounted for if the Cuillin have a reversed remanent magnetisation (common in the province[4,8,18]) the latter cannot be identified with the Red Hills because the anomaly is no less prominent on the filtered aeromagnetic map[5] (Fig. 1*c*) which only registers bodies deeper than ∼5 km in the Skye area[6]. We therefore propose that there are two basic masses underlying the centres of Skye, having opposite magnetic polarities but sufficiently close together to appear as a single gravity anomaly.

It is inherent in our postulate (twin deep-seated masses which cannot be resolved by gravity) that a detailed interpretation is not possible with the present data. Indeed, simple calculations assuming two deep vertical gabbro 'cylinders' of 16-km radius in contact, as suggested in cross section by the magnetic map (Fig. 1c), have shown that only a single gravity anomaly would be resolved. To satisfy the observed magnetic anomalies we must assume that the induced magnetisation in these cylinders is small compared to their remanence[7]. If the latter has an inclination of 60°N, appropriate for an early Tertiary age[8], a strong positive anomaly would be observed to the south and a weak negative to the north at the Red Hills, conversely for the reversely magnetised Cuillin root. Only the strong anomalies can be identified clearly in Skye, but in spite of this it is clear that the magnetic anomalies can be satisfied only if two opposite magnetised bodies are present.

Comparable strong positive and negative magnetic anomalies are not observed on the filtered maps for the other Tertiary centres, and the question arises in what way Skye differs. One possibility is that Skye contains centres formed at two distinct times. Field evidence shows that the succession commenced with the flood basalts; then followed the Cuillin centre which coincided with the later lavas, and in turn was succeeded by the bulk of the (basic) dyke swarm; last came the Western, then the Eastern, Red Hills, but there is no field evidence to determine the intervals in the succession, which have been assumed to be short[9]. Rb–Sr isochron dates on the Red Hills are 52±3 Myr (ref. 10) and 51±4 Myr (ref. 11), and all the 24 K–Ar dates of Kelly[12] are <55 Myr, except for two (59.2±0.7, 59.3±1.0 Myr). There is no evidence for a detectable difference in age between the Eastern and Western Red Hills. The Cuillin are undated, and the only other relevant dated bodies are the lavas, for which the data are equivocal Kelly[12] found that most of his lava samples also gave K–Ar ages <55 Myr. It is, however, believed from oxygen isotope work[13] that the southern part of Skye was subjected to hydrothermal alteration caused by the heat of the centre or centres, and it may be significant that the one sample which came from a locality where the oxygen isotope ratio was normal, gave an apparent age of 59 Myr. Unpublished data from this laboratory on lava samples from the north of Skye also include some samples of higher ages. Thus a possible interpretation of the radiometric evidence is that the lavas—and therefore the Cuillin centre—were intruded ~59 Myr ago, but were extensively 'overprinted' by the heat and chemical changes associated with the Red Hills centres which were not emplaced until ~53 Myr ago. Such conditions probably would not have remagnetised the adjacent rock[14] and, anyway, the magnetism in question here is deep seated.

This date for the lavas gains support from indirect evidence· the dispositions of the dyke-swarms of Skye, Mull and Arran strongly suggest that they were contemporaneous[15,16]. The dykes of Mull mostly pre-date the Loch Bà centre (60.4±1.9 Myr, Rb–Sr isochron[17]), whereas those of Arran came between the closely contemporaneous centres (Northern Granite 58.8±0.6 Myr : Central Complex 58.3±2.2 Myr, dated by the ^{40}Ar/^{39}Ar method[18]) and Holy Island (54.9 Myr, Beckinsale, unpublished): all these dates are consistent with the Skye dykes—and hence the Cuillin which preceded them—being ~59 Myr old.

It is a basic assumption of this paper that the Cuillin 'cylinder' acquired its remanence during a period of reversed polarity; an age of 59 Myr is consistent with this, for the lavas of Mull are of similar age and are reversed[19,20].

Strontium and lead isotopic evidence[11,21] suggest that the Red Hills granites were mainly derived by partial melting of Lewisian rocks although the possible effects of hydrothermal alteration[13] throws the isotopic evidence into doubt. Whether these granites were derived by partial melting, or by fractional crystallisation of the underlying basic rock mass, a large heat source is implied. This could not be the mass underlying the Cuillin if it were intruded several million years before; therefore, a second source is needed which we have identified from magnetic anomalies to be a second deep-seated basic mass which cooled during a normal polarity period.

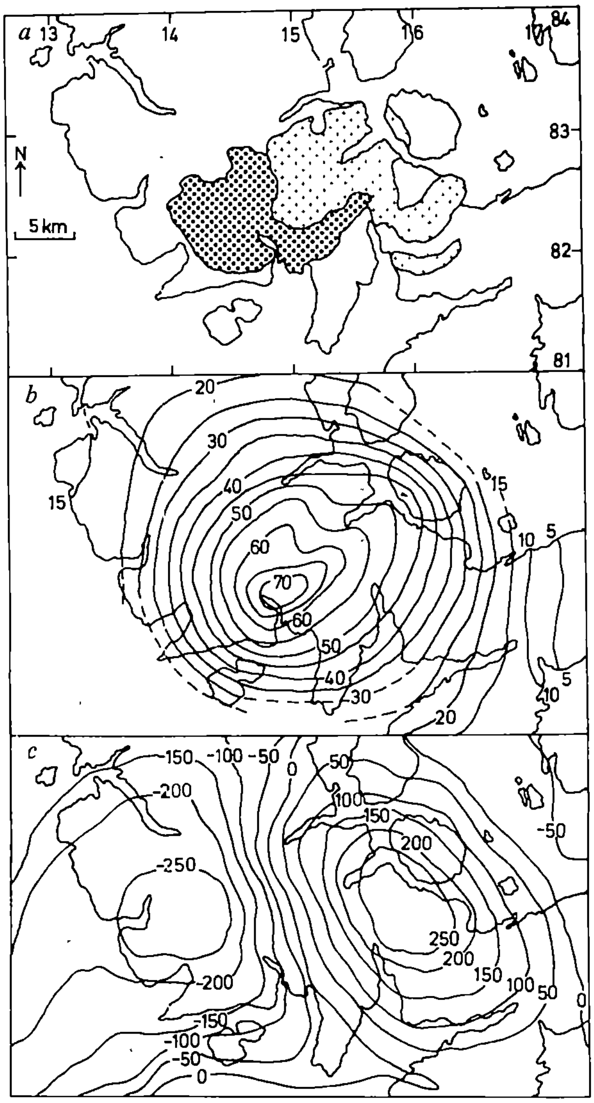

Fig. 1 *a*, Map of southern Skye showing the juxtaposition of intrusive centres at outcrop level[1]. Distances are given in tens of kilometres north and east of the national grid origin. Dotted pattern, Cuillin gabbro; crossed pattern, Red Hills granite; blank areas, Tertiary lava and older rocks. *b*, Gravity anomaly[2] on the same scale with contours at 5-mgal intervals. *c*, Total field aeromagnetic anomalies filtered at 3.33-km intervals[5], representing anomalous material buried beneath ~5 km (ref. 6). Promotion and retardation of heat transfer by electric fields

I REPORT here on the effects of an electric field on heat transfer. The effects depend on the applied voltage, the shapes, number and locations of the electrodes, and the frequency of the electric field[1,2].

The vaporisation of water is enhanced remarkably in an electric field: at 12 °C, the rate increases by up to 40–50 times[2]. This phenomenon suggests that heat transfer may well be influenced by electric fields; the experiments reported here show this to be the case. The rate of heat transfer in a gas can be increased by up to 1.5 times, in liquids by up to 2.0 times, and in solids by up to 1.6 times, according to the positioning of the electrodes and the strengths of the electric fields.

Under the influence of electric fields another interesting phenomenon has also been observed: the rate of cooling can be retarded. If an electrode is located within material that is to be heated, cooling proceeds more slowly after the heat source is removed. Cooling takes place 1.5 to 2.0 times more slowly than in the absence of an electric field.

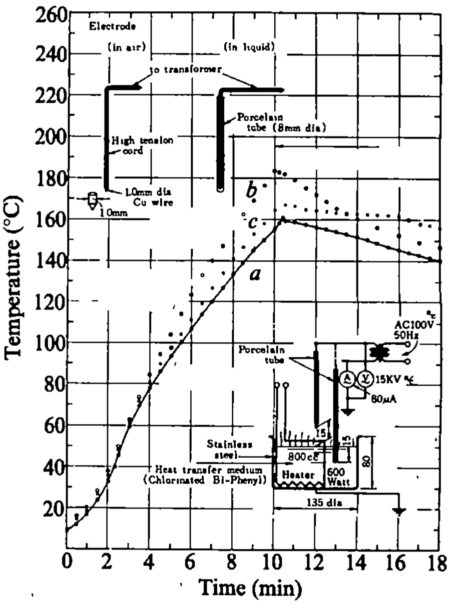

Fig. 2 Heating and cooling curves of chlorinated biphenyl (liquid) contained in a stainless steel beaker (diameter 135 mm), with the heating source placed within the liquid: *a*, in the absence of an electric field; *b*, in the presence of an alternating field (15 kV; 80 µA) with the electrode (Cu wire, diameter 1.0 mm) outside the liquid; *c*, in the presence of an alternating field (15 kV; 80 µA) with the electrode (Cu wire, diameter 1.0 mm) inside a porcelain tube within the liquid. After heating for 10 min, temperatures of 161, 184, and 167 °C were attained in cases *a*, *b*, and *c*, respectively. When the heat source was removed (after 10 min) the temperatures fell in 8 min to 140, 146, and 156 °C, respectively, in cases *a*, *b*, and *c*. In cases *b* and *c* the alternating current remained on, and cooling was 1.7 times slower (*b*) and 1.8 times slower (*c*) than in case *a*.

The restriction of heat transfer can be compared to the behaviour of current flow in an electrostatic transistor.

The methods and apparatus used in the experiments are described in Figs 1–3. It should be noted that no energy is absorbed from the electric field, except for 1.5–2.0 W as a result of ionisation or leakage.

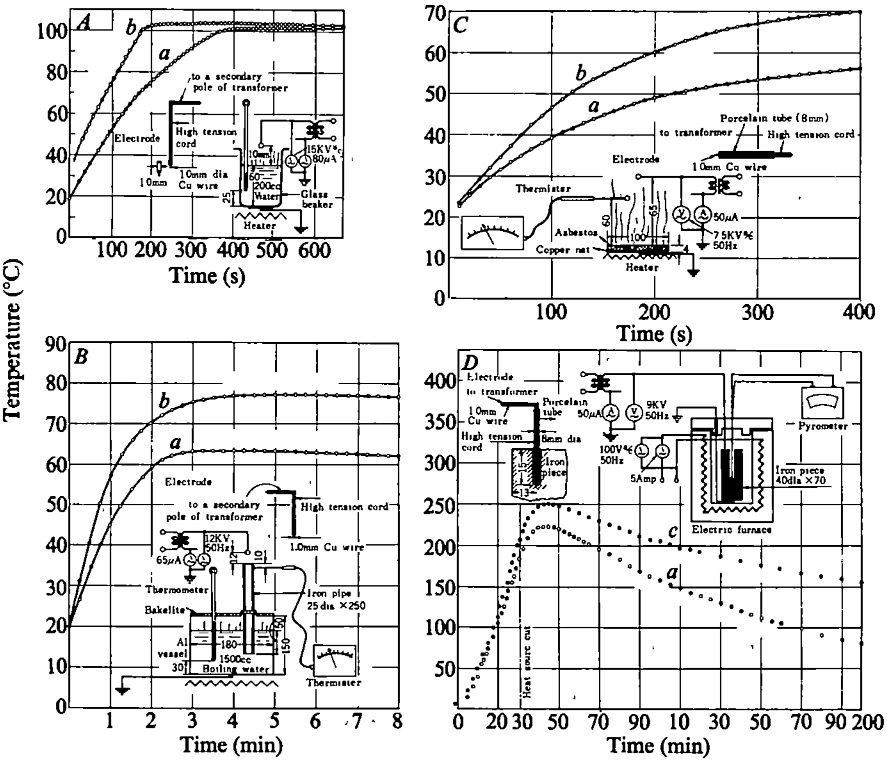

Fig. 1 *A*, Heating curves of 200 cm³ water contained in a glass beaker: *a*, in the absence of an electric field; *b*, in the presence of an alternating electric field (15 kV; 80 µA) with the electrode (Cu wire, diameter 1.0 mm) placed 10 mm above the water. Boiling point is attained twice as quickly in case *b*. *B*, Heating curve of an iron pipe (diameter 25 mm, length 250 mm): *a*, in the absence of an electric field; *b*, in the presence of an alternating field (12 kV; 65 µA) with the electrode (Cu wire, diameter 1.0 mm) placed 12 mm above the end of the pipe. The pipe was heated by placing its lower end in 1,500 cm³ of boiling water contained in an aluminium vessel insulated with a bakelite lid. In the presence of the electric field a temperature of 76 °C was obtained (*b*), compared with a maximum temperature of 63 °C with no electric field (*a*). *C*, Heating curves of free air: *a*, in the absence of an electric field; *b*, in the presence of an alternating field (7.5 kV; 50 µA) with the electrode (Cu wire, diameter 1.00 mm) placed 65 mm above a heated asbestos mat. Temperature of the air between the electrode and the mat reached 70 °C in case *b*, as opposed to 56 °C in case *a*. *D*, Heating and cooling curves of an iron cylinder (diameter 40 mm; height 70 mm): *a*, in the absence of an electric field; *b*, in the presence of an alternating field (9 kV; 50 µA) with the electrode (Cu wire, diameter 1.0 mm) inserted 15 mm into the cylinder. The cylinder was heated within an electric furnace, and in case *b* cooling was 1.6 times as slow as in case *a*.

If the nature of the promotion of heat transfer is considered thermodynamically, it can be regarded as a phenomenon in which materials (fluids) change their qualities so as to absorb more heat energy from their surroundings or transfer more heat energy within themselves.

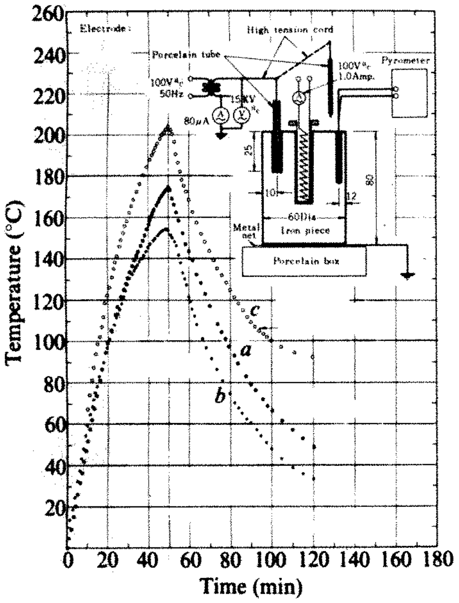

Fig. 3 Heating and cooling curves of an iron cylinder (diameter 60 mm, height 80 mm) with the heat source placed within the cylinder: *a*, in the absence of an electric field; *b*, in the presence of an alternating field (15 kV, 80 μA) with the electrode outside the cylinder; *c*, in the presence of an alternating field (15 kV, 80 μA) with the electrode (Cu wire, diameter 1.0 mm) inserted 25 mm into the cylinder. After heating for 50 min, temperatures of 175, 155, and 205 °C were attained in cases *a*, *b*, and *c*, respectively. In this case, when the heat source is removed cooling is more rapid in case *b* than in case *a;* a similar phenomenon occurs with liquids, however, if only small quantities of heat are supplied initially.

The phenomenon could be investigated further through studies of infrared absorption patterns[4] and increases of vapour pressures[5,6].

Microfossils from a newly discovered Precambrian stromatolitic iron formation in Western Australia

THE Nabberu Basin is a newly discovered sedimentary basin of probable early Proterozoic age in Western Australia[1-3] (Fig. 1). It covers an area of ~60,000 km², and contains ~6,000 m of shallow-water clastic and chemical sediments. It is essentially unmetamorphosed in the south-east but is metamorphosed to granulite facies in the west, where folding and deformation are more pronounced.

In the middle of the Nabberu Basin sequence is the Frere Formation—~2,000 m of alternating banded iron formation and shale, with thin stromatolitic dolomite at its base. The iron formations are granular and are very similar to those of the Animikie Basin and Labrador Trough in North America[4,5]. Within the Frere Formation at a location of about 2.5 km north-east of Camel Well in the south-eastern part of the basin (latitude 26°08′, longitude 121°18′), a thin oncolitic iron formation is interbedded with peloidal and oolitic ferruginous chert. The oncolites and associated stratiform stromatolites contain the abundant microfossils[6,7]. Microfossils, as yet unstudied, are also present in the Windidda Formation, overlying the Frere Formation, in thin, black to grey apatitic and sulphidic cherts near Tooloo Bluff (latitude 26°27.5′, longitude 122°14′).

The iron formation microfossils are of special interest because the assemblage is almost identical to that of the Gunflint Iron Formation of Ontario[8], but is different in many respects from other described Precambrian assemblages[9]. This similarity may result from the facies similarity or from the probable penecontemporaneity of the two deposits, which we shall discuss. This is the first time that two particularly distinctive and comparable assemblages of Precambrian microfossils have been found widely separated on two continents and the biostratigraphic significance of this discovery must be assessed. The nature of the occurrence of microfossils within oncolites indicates a benthonic mode of life, conflicting with an interpretation[10] of a planktonic mode for several of the same taxa from the Gunflint. Here we briefly describe the Nabberu Basin microfossils and consider the questions and comparisons outlined above.

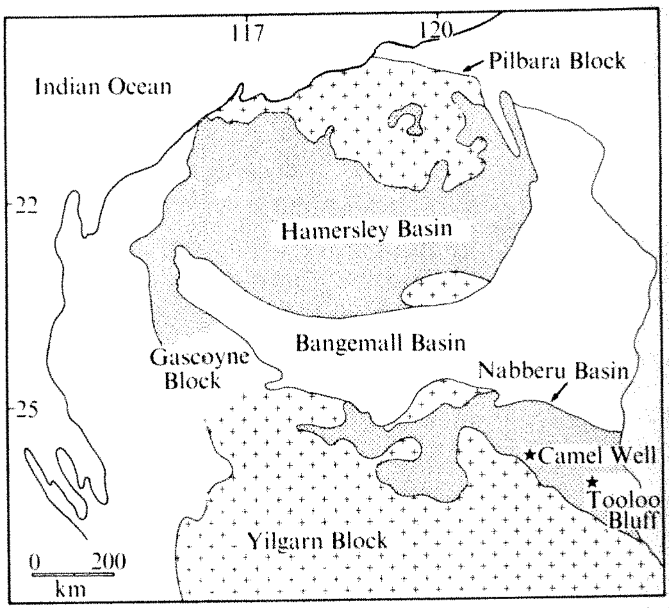

Fig. 1 Locality map. Crosses represent Archaean rocks, stippled areas are early Proterozoic sedimentary basins; the Bangemall Basin is Middle Proterozoic; the remaining unornamented areas are underlain by Phanerozoic rocks.

The Nabberu sediments unconformably overlie the Archaean granite/greenstone basement of the Yilgarn Block, and are unconformably overlain by sediments of the approximately 1,100-Myr-old Bangemall Basin (Fig. 1). Glauconites from the basal Yelma Sandstone of the Nabberu Basin give an average minimum age of 1,700 Myr (ref. 3), which is about the time of tectonism of the nearby Hamersley Basin. There is evidence to suggest that the Nabberu Basin can be traced through the high grade Gascoyne Block at its western extremity into the sediments of the Hamersley Basin, which are well dated as approximately 2,000 Myr old[11]. Thus the Frere Formation of the Nabberu Basin seems to be approximately the same age as the Gunflint Iron Formation.

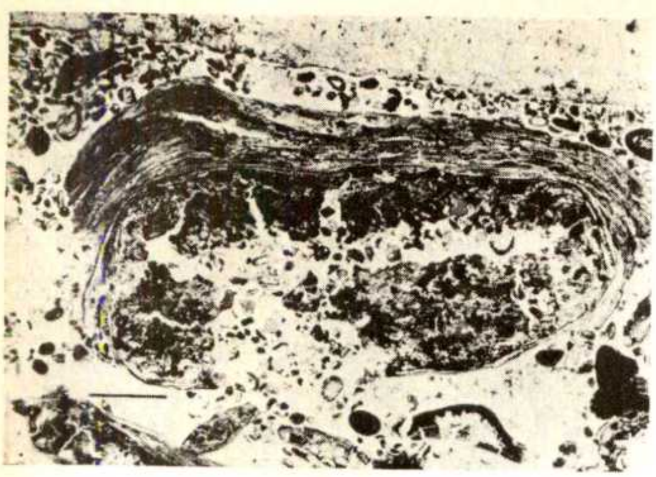

Fig. 2 Microfossiliferous oncolites and granules, Frere Formation. Scale bar represents 2 mm. Thin section BHP 5319D3. All specimens are kept in the Bureau of Mineral Resources, Geology and Geophysics, Canberra.

The microfossils occur within discoidal and subspherical stromatolites (that is, oncolites), stratiform stromatolites, and large granules (peloids) (Fig. 2). Filaments 1–2 μm wide and up to hundreds of microns long (here identified as *Gunflintia minuta* Barghoorn) are abundant and ubiquitous in the stromatolites (Fig. 3, *a* and *b*), and most are contorted and randomly oriented. Not uncommonly, however, groups of filaments are aligned roughly parallel to the stromatolite laminae, and occasionally such groups can be followed into contiguous laminae where they turn to become approximately perpendicular to the laminae. The organisms represented by these filaments seem to have constructed the stromatolites. The filaments, which are preserved as segmented rods of iron oxide, sometimes occur within tubes of iron oxide (Fig. 3*c*). These and other non-septate tubes 4–9 μm wide (Fig. 3*d*) without internal filaments (trichomes) are interpreted as the former mucus sheaths of cyanophytes, as is *Animikiea septata* Barghoorn from the Gunflint[10]; the Frere Formation tubes have a slightly different range of sizes and are less clearly annulate than the Gunflint forms and are therefore referred to a new species of *Animikiea*.

Rosettes of filaments occur singly and in clusters within the stromatolites and granules (Fig. 3*e–g*). Each rosette consists of 5–20 filaments of variable width (0.5–1.5 μm); the width of the rosettes is 5–25 μm. The filaments are unbranched (here referred to *Eoastrion simplex* Barghoorn) or, rarely, dichotomously branched (referred to *E. bifurcatum* Barghoorn). The degree of mineralisation of the filaments is variable; they are often heavily encrusted with iron oxides and so coalesce into a subspherical central body. They closely resemble the extant benthonic iron- and manganese-precipitating bacterium *Metallogenium personatum*[12], as has been noted previously[13].

Hollow spheres and ellipsoids of iron oxide referable to the genus *Huroniospora* Barghoorn occur singly or, more commonly, in groups with separate individuals (Fig. 3*h–k*). They range in width from 2.5 to 12.0 μm, with a mode and a mean of 6 μm. There are several examples of apparently dividing cells (Fig. 3*i* and *j*). The three species originally described from the Gunflint were distinguished by their wall textures and thicknesses, features that are now considered as possibly secondary[10]. The species have not yet been redefined. It is notable, however, that many of the cells in the Frere Formation resemble those in the Gunflint originally called *H. psilata* Barghoorn.

One of the most distinctive microfossils in the Gunflint is *Kakabekia umbellata* Barghoorn. This is also present, but relatively rare, in the Frere Formation (Fig. 3*l–o*), where it occurs separately or in small groups within the stromatolites. An extant homoeomorph has been described from soils[14]. One example has been found of a structure that resembles the branched tubular fossil *Archaeorestis schreiberensis* Barghoorn from the Gunflint, but identification must wait until more samples have been discovered.

In the Gunflint Iron Formation there are two different microfossiliferous chert facies: "One, a thin bedded chert, contains what is interpreted as a planktonic assemblage of microorganisms dominated by *Kakabekia umbellata* Barghoorn, *Eoastrion simplex* Barghoorn, and *E. bifurcatum* Barghoorn"[10]. The other is stromatolitic, and thus benthonic, and is dominated by *Gunflintia minuta* and *Huroniospora* spp., with rarer specimens of *G. grandis* Barghoorn, *Animikiea septata* and other forms. The Frere Formation stromatolitic assemblage described here contains

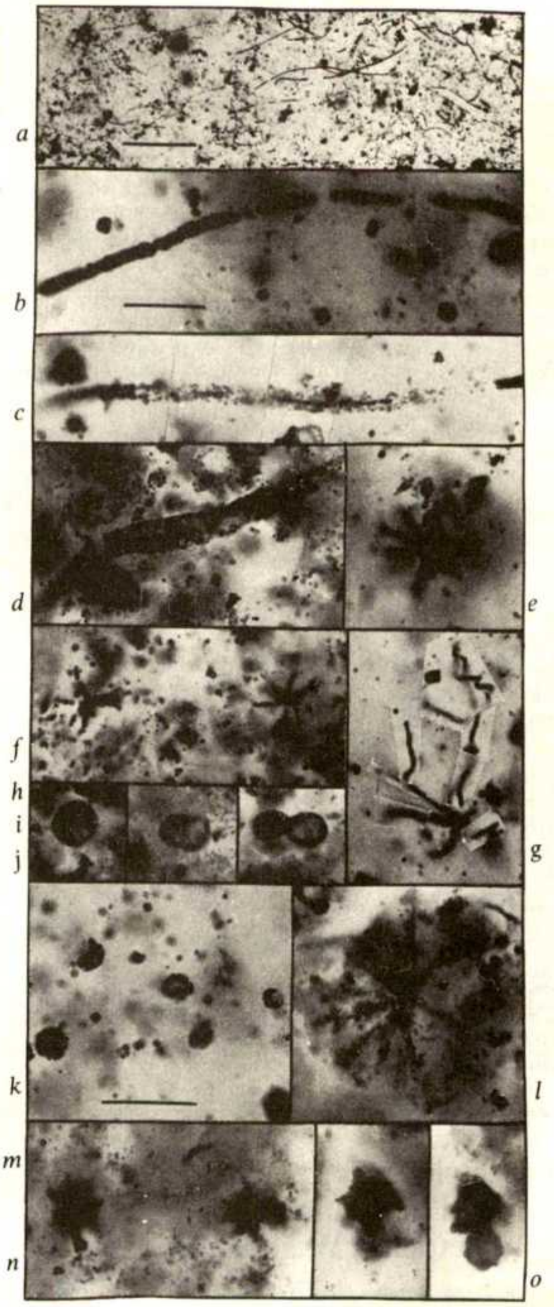

Fig. 3 Microfossils from the Frere Formation. All photographs are of petrographic thin sections of ferruginous chert in transmitted light. Scale bar in *a*, 100 μm; in *b*, 10 μm; in *k*, 20 μm (that in *k* applies to photographs *c–o*). *a* and *b*, *Gunflintia minuta*; *c* and *d*, *Animikiea* sp. nov., in *c* with an internal *G. minuta* trichome; *e*, *f* and *g*, *Eoastrion simplex*; *h–k*, *Huroniospora* spp.; *l–o*, *Kakabekia umbellata*, photographs *n* and *o* are of the same fossil at 2 different focal levels. All are in thin section BHP 5319D1.

representatives of both these Gunflint assemblages: it resembles the Gunflint stromatolite assemblage in that it is also dominated by *G. minuta* and *Huroniospora* spp., but in addition contains abundant *E. simplex* and rare *E. bifurcatum* and *K. umbellata*, considered by Awramik[10] to have been planktonic (although the basis for this interpretation has not yet been published). The occurrence of *E. simplex* in clusters within the Frere Formation oncolites strongly suggests that at least in the Nabberu Basin this organism was benthonic, an interpretation that is consistent with the fact that the most similar extant organism, *Metallogenium personatum*, inhabits lacustrine muds[12]. Furthermore, at least some extant rosette-forming bacteria attach to a substrate before forming rosettes[15]. Similarly, *K. umbellata* may also have been benthonic since it occurs in clusters and the only known extant homoeomorph inhabits soils. The search for microfossils in non-stromatolitic laminated cherts of the Frere Formation has been so far unrewarded, and only dubious microfossils have been reported[16] from the possibly correlative non-stromatolitic, non-granular iron formations of the nearby Hamersley Basin.

The stromatolites of the Gunflint Iron Formation and the Frere Formation seem likely to have formed in very similar environments. Both are composed of almost certainly primary silica and iron compounds and occur with granules and ooids which suggest a turbulent sub-aqueous environment. These palaeoenvironmental similarities may be sufficient to explain the near identity of the two assemblages of microfossils and their differences from older and younger assemblages[7,17], since these older and younger assemblages are almost entirely from fine grained siliciclastic rocks and secondary cherts in stromatolitic carbonates. Such a close similarity of two probably penecontemporaneous microfossil assemblages, however, certainly encourages further investigation of the biostratigraphic usefulness of Precambrian microfossils. It is not possible to consider this aspect in detail here, but it is evident that the discovery of the Frere Formation microbiota will prove important in studies which use chert microbiotas in Precambrian biostratigraphy.

We thank the Director, Bureau of Mineral Resources, Geology and Geophysics, and the General Superintendent, Exploration, of the Broken Hill Proprietary Company Limited, Australia for encouragement, and J. H. Oehler for critically reading the manuscript.

Population genetic, social, linguistic and topographical relationships in north-eastern Arnhem Land, Australia

GENETIC differentiation has been found among Australian Aboriginal tribes[1], but no previous attempt has been made to assess intratribal differentiation. We report here on genetic differentiation within an Aboriginal 'tribe' related to linguistic, social and topographical components of the population, together with confirmation of the importance of drainage systems as natural barriers to gene flow. An estimate of inbreeding in a traditionally structured Aboriginal local group is given.

In an earlier intertribal study[1] we found that genetic differentiation was highly correlated with linguistic and sociocultural divisions. More recently we have concentrated on genetic differentiation at the level of the territorial and marriage unit within the Yolngu (a collective term for the dialects of the region (B. Schebeck, personal communication)) of the north-eastern Arnhem Land region of the Northern Territory of Australia (Fig. 1). This region is of considerable anthropological importance[2–4]. It is one of few remaining areas of Aboriginal Australia where the simultaneous effect of ecological, demographic, sociocultural, linguistic and biological influences on phenotypic variation can be investigated. The Yolngu population is consistent with a biological definition of tribe[5] being at least 90% endogamous. They are organised into localised totemic clans and dialect units which are territorially based and exogamous[4]. They now number about 2,400 and occupy a territory of about 26,000 km^2, bounded by coastline to the north and east and river systems to the west and south (Fig. 2).

This report concerns two dermatoglyphic traits, fingerprint pattern index and total ridge-count, both strongly heritable[6]. In addition, phenylthiocarbamide (PTC) taster ability, red–green colour blindness, handedness, earlobe form, hairy pinnae and skin colour were studied and generally supported our findings from the dermatoglyphic

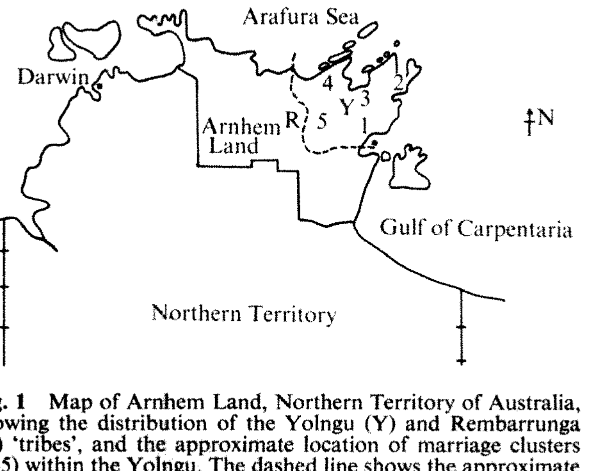

Fig. 1 Map of Arnhem Land, Northern Territory of Australia, showing the distribution of the Yolngu (Y) and Rembarrunga (R) 'tribes', and the approximate location of marriage clusters (1–5) within the Yolngu. The dashed line shows the approximate boundary of the Yolngu.

Table 1 The relationship of the various population units to the genetic structure of the Yolngu, as assessed by dermatoglyphics

Marriage clusters	5	10	3	2	1	—	60
Drainage divisions	6	15	—	4	1	7	80

*Pairwise *t* comparisons.

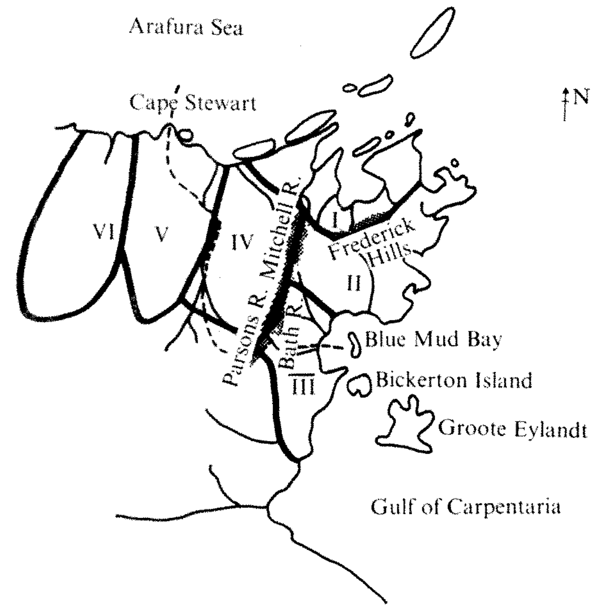
data. A total of 744 Yolngu were sampled, that is, 31% of the population. In addition to biological information, data were obtained on the social affiliation of the parents and spouse(s) of each subject, their ages and places of birth, together with information on marriage networks, genealogies and the distribution of the territorial units.

Table 1 indicates some genetic differentiation among the dialect groups of the Yolngu. Nine such groups, of which we have adequate data for seven, each consisting of a number of dialect units, are recognised by both linguist and Aboriginal, all but two being potentially endogamous[7]. Each statistically significant comparison involved the same dialect group, which suggests that the dialect groups form an intermarrying complex with no genetically significant endogamy within them, although there is some support for the suggestion of two linguistic "divisions" among the dialect units of the Yolngu[8].

Total ridge-count was analysed according to dialect unit affiliation within recognised ceremonial/fighting groups. These groups were said by Aboriginal informants to be "tied together for maridjama (fighting) and manikaj (ceremonial singing)". The analysis revealed statistically significant differences, all of which were accounted for by the 'fighting' group known as the Balamumu, a collection of dialect units in the Blue Mud Bay area (Fig. 2). This suggests that the Balamumu, at least, functions largely as an endogamous unit, being genetically distinguishable.

Marriage 'clusters' were recognisable from the marriage data and correspond to those dialect units among which there was at least 70% endogamy. The dialect units that intermarried most generally had adjoining territories.

Fig. 2 Map of north-eastern Arnhem Land, Northern Territory, showing drainage divisions (I–VI) and some topographical features. Solid lines indicate major river systems, and the dashed line is the approximate boundary of the Yolngu.



There were similarities between the structure of the ceremonial/fighting groups and marriage 'clusters', suggesting that the former groups are based on marriage relationships. The marriage cluster centred on the Blue Mud Bay region (Fig. 1, cluster 1) was distinctive, an observation consistent with our findings for the Balamumu fighting group.

The marriage clusters are also associated with drainage divisions. Peterson[9] highlighted the role of drainage basins in the cultural and social differentiation in Aboriginal Australia. He noted that watersheds might have acted as natural barriers to communication. Independently we considered the drainage basins as units for analysis: our results (Table 1) indicate that these natural divisions are important in terms of genetic differentiation. In this analysis, data are included from some other neighbouring tribes, as drainage basins overlap the Yolngu territory (Fig. 2).

For the dermatoglyphic traits the greatest and most statistically significant difference was between the Aborigines living in the Blue Mud Bay area, and those living at the western boundary of the Yolngu. These two groups are separated topographically by a complex of low ranges (Fig. 2) which almost certainly restrict intermarriage although important ceremonial links exist. There is also evidence for gene flow from some neighbouring tribes into the western Yolngu group. This no doubt increased the extent of the differences between the groups. We found for the fingerprint, and other biological traits, that the three Yolngu dialect units along the western boundary are not significantly different from their immediate western tribal neighbours, the Rembarrunga (Fig. 1). There is also no sharp linguistic boundary to the west (B. Schebeck, unpublished).

We concentrated on a traditionally structured local group in the western Yolngu region made up of about 60 people belonging mainly to two intermarrying dialect units. The average level of inbreeding for this local group was estimated to be 0.02 from genealogical data—a value similar to that for Central and South American Indian populations[10]. The highest individual coefficient of inbreeding was 0.07 from data over five generations.

In conclusion, the Yolngu function as a marriage network of endogamous units within a broad cultural and linguistic complex. At both the 'tribal' and regional level these endogamous units seem to be closely related to the drainage basin. This finding supports Warner's[2] description of "Murngin" (Yolngu) society as a "confederacy" of several "tribes", at least when the term 'tribe' is used in the biological sense.

This project was supported by the Australian Institute of Aboriginal Studies. We thank N. H. Scarlett, Dr D. Biernoff and several Aboriginal informants for field assistance and discussion, and the Aborigines who cooperated in the study.

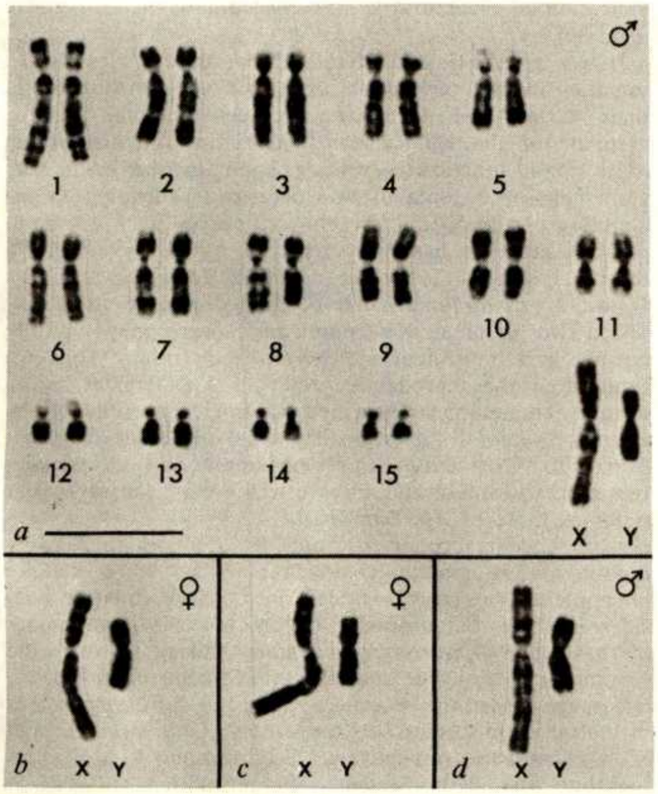
Fertile XX- and XY-type females in the wood lemming *Myopus schisticolor*

THE wood lemming (*Myopus schisticolor* Lilljeborg), a small rodent inhabiting mossy forests of northern coniferous areas of Eurasia, is unique with respect to sex ratio, showing a definite prevalence of females, and with respect to the occurrence of two types of female, one producing daughters only, the other producing progeny of both sexes[1,2]. We thought that these phenomena might be associated with chromosome constitution, and as the chromosomes of this species were poorly known, we have made a detailed study of its karyotype. Some additional observations, pertinent both to the occurrence of chromosome variation and to reproduction, will be reported elsewhere. We report here two remarkable findings: (1) the existence of two types of fertile female with different somatic sex chromosome constitutions—the orthodox female complement, XX, and the male complement, XY, and (2) evidence for selective non-disjunction in XY females, leading to the formation of X-type egg cells only.

The material for the chromosome study consisted of 29 specimens collected in four areas of Sweden, and some 180 descendants of animals trapped in a fifth locality in Sweden (Table 1). Mitotic chromosomes were studied in direct preparations from bone marrow, and in fibroblast cultures from lung, heart or embryonic tissues. Cells were usually processed by the conventional air drying procedure and the preparations were stained with orcein, Giemsa or the fluorochromes 33258 Hoechst and acridine orange. G and C staining[3,4] were applied to preparations from most of the animals. The late replication pattern of the chromosomes was examined by autoradiography. Meiosis was studied in testes from eight males and in ovaries from 19 females. In males, meiotic chromosomes were studied by the method of Evans *et al.*[5]. For females the method described by Tsuchida and Uchida[6] was used. Primarily diakinesis and metaphase I were evaluated. Histological sections of the female reproductive tract were prepared in the usual manner from most animals studied.

Fig. 1 G banded chromosomes of *M. schisticolor*. *a*, Karyotype of a male. *b* and *c*, XY sex chromosomes of a female. *d*, XY sex chromosomes of a male. Scale = 10 μm.



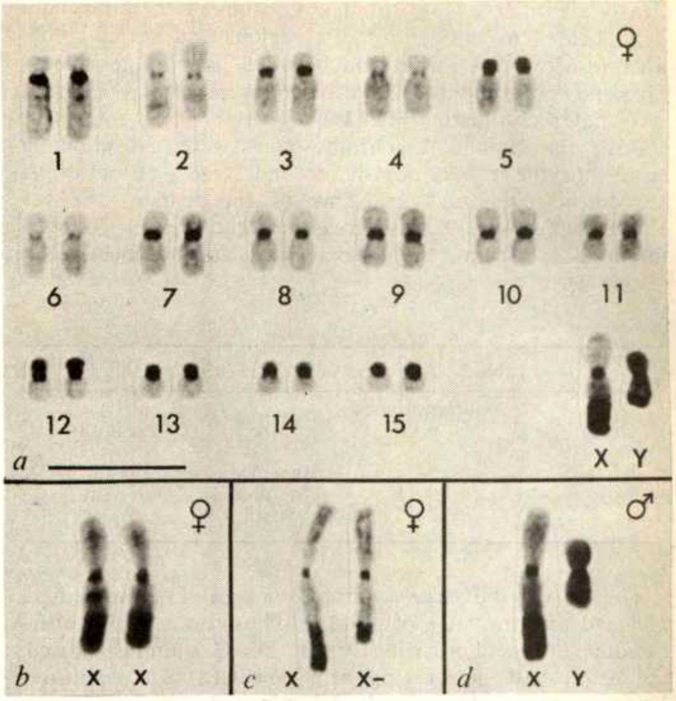


Fig. 2 C-stained chromosomes of *M. schisticolor*. *a*, Karyotype of an XY female. Note the absence of centromeric heterochromatin in nos. 2, 4 and 6. Pair no. 2 is dimorphic in this individual. *b*, XX sex chromosomes of a female. *c*, Sex chromosomes from a female with one normal and one deleted X. *d*, XY sex chromosomes from a male. Note the same staining pattern as in the XY female. Scale = 10 μm.

The chromosome number of the animals was $2n=32$ (Fig. 1), confirming Matthey's study[7]. The autosomes were divided into three groups on the basis of size and arm ratio (nomenclature according to Levan *et al.*[8], Table 2). Chromosomes 5 and 12 had satellites attached to their short arms. After G staining, every autosome pair was

clearly identifiable (Fig. 1*a*). The C bands of the autosomes were located in the centromeric regions and varied somewhat in size both within and between populations. Three pairs, however, numbers 2, 4 and 6, were regularly devoid of C heterochromatin (Fig. 2*a*).

Both the X and Y chromosomes were exceptionally large, but the Y was not the second largest chromosome as Matthey[7] reported. In some of the females the sex chromosomes were XX, whereas in others they were indistinguishable from the male sex chromosomes, XY (Table 1).

Table 2 Autosomes of *M. schisticolor*

Group	Chromosomes no.	Size	Centromeric position
1	1– 5	Large–medium	sm—st
2	6–11	Medium	m—sm
3	12–15	Small	sm—st

The X was the largest chromosome of the complement and had an arm ratio of 1.5–1.7. Thus it was an m chromosome on the borderline of sm. As C staining showed, the distal half of its long arm consisted of constitutive heterochromatin (Fig. 2*a–d*). It stained darkly by C staining, fluoresced comparatively weakly after staining with Hoechst 33258 and showed late DNA synthesis. Occasionally, a finer substructure of heavily stained bands was seen within the C segment. Sometimes on an X there were faint indications of gaps between the euchromatic and heterochromatic parts and within this latter segment. This observation was possibly related to occasional variations in the size of the heterochromatin: in one XY female it was about two-thirds, and in one X chromosome of one XX female it was only one-third of the normal size (Fig. 2*c*). The centromeric region of the X was C-band positive.

The Y was an m chromosome of medium size, similar to numbers 9–10 but with a somewhat higher arm ratio. These and the following features apply equally to the Y in males and to the Y-like sex chromosome in XY females. The entire Y was dark after C staining, clearly darker than the euchromatic parts of the X, although often less dark than the heterochromatic parts of the X. There were different intensities of staining within the Y, the distal part of the long arm being darkest. The centromeric region of the Y was not particularly heavily stained. The Y synthesised DNA late. Both Y and X showed characteristic G-band patterns, even though the bands in the entire Y, as well as in the distal half of the long arm of X, were less distinct than in the autosomes (Fig. 1).

C and G staining showed that the Y of the females was not a deleted or rearranged X chromosome. This is supported by the following evidence: (1) the 'female Y' always had exactly the same morphology as the 'male Y', including every detail of the banding pattern, and (2) the 'female Y' did not have any of the staining properties of the regular X chromosome.

Further clarification was obtained from an examination of meiosis. In male diakinesis the X and Y chromosomes were associated end-to-end (Fig. 3*a*). The sex bivalent, however, usually had a coiled configuration, not allowing distinct recognition of the two constituents. The structure of the 15 autosomal bivalents, on the other hand, was mostly clear and distinct. At diakinesis of XX females there were 16 symmetrical bivalents, 15 of them autosomal and one—the largest—formed by the two Xs (Fig. 3*b*). The XX bivalent had one or two chiasmata. In all 29 diakinesis figures from 10 XY females, the composition and type of bivalents was the same. Again the large sex-bivalent was clearly identifiable as a symmetrical figure with lateral pairing and one or two chiasmata and with no indication of structural or heterochromatic heterozygosity (Fig. 3*c*).

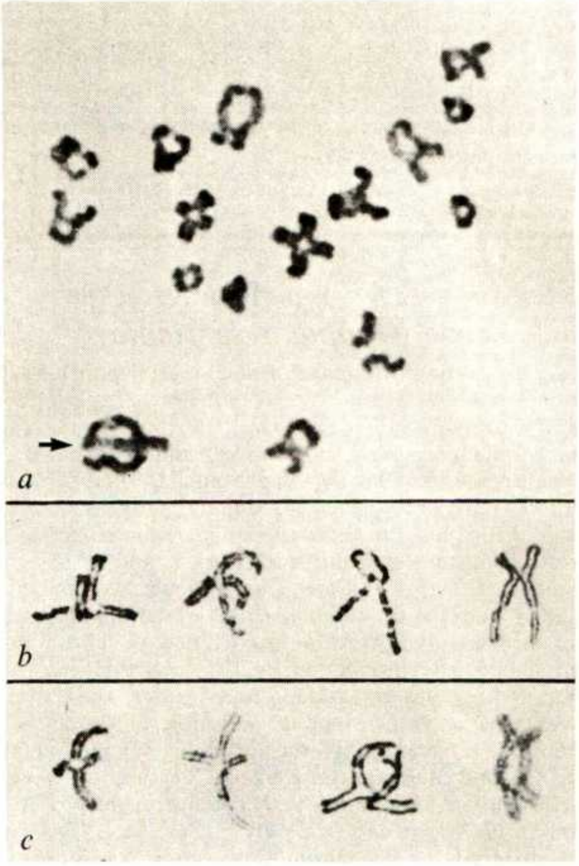

Fig. 3 Male (*a*) and female (*b* and *c*) meiosis in *M. schisticolor*. *a*, Complete cell in diakinesis showing 15 autosomal bivalents and the XY bivalent (arrow indicates the site of end-to-end association between X and Y). *b* and *c*, Sex bivalents from eight cells in diakinesis from XX (*b*) and XY (*c*) females (four and three different individuals, respectively). Note that in both XX and XY females the bivalent is symmetrical and composed of two Xs with one or two chiasmata.

It has to be assumed therefore that the females with a somatic XY set possess an orthodox XX constitution in their oocytes. This discrepancy between the soma and the germline of the XY females necessitates the assumption of a non-disjunctional event, possibly in the primordial germ cells or oogonia of the foetal ovary, leading to the doubling of the X and the elimination of the Y. A comparable situation has been reported by Ohno *et al.*[9] in *Microtus oregoni*, a species with XO females.

Both kinds of female, irrespective of whether they possessed two Xs or an XY complement, were phenotypically normal and indistinguishable from each other. Thus we found that the reproductive tract of XY females had a normal female appearance, and histological sections of the ovaries revealed follicles in different stages of development similar to XX females. Correspondingly, the XY females reproduce normally and their litters are of the same size order as those of XX females.

Is the occurrence of XX and XY females in *Myopus* unique among mammals? As far as we know such a phenomenon has not been described before, but we consider it likely that a similar condition exists in lemmings of the species *Dicrostonyx torquatus* (Pallas), in which the chromosomes of three subspecies have been described[10–13]. We suggest that the so-called x, X_2 and X_3 chromosomes in the three subspecies *D. t. stevensoni*, *D. t. torquatus* and *D. t. chionopaes*, respectively, all correspond to a Y chromosome, just as in *Myopus*. We postulate that both in

Myopus and in *Dicrostonyx* some of the XY animals function as fertile females due to an X-linked gene repressing the male-determining effect of the Y (our work in preparation).

This work was supported by grants from the Swedish Natural Science Research Council (K.F.) and the Deutsche Forschungsgemeinschaft (A.G.). We thank Miss G. Noack (Lübeck) for her help.

Epithelial origin of starfish coelomocytes

THE various theories proposed to explain the origin of echinoderm coelomocytes can be classified into two groups, depending on whether they refer to a cytopoietic organ or tissue (Tiedemann bodies[1–3], Polian vesicles[1], axial organ[1,4], connective tissue[5,6] and coelomic epithelium[7–9]) or whether they imply self-replication of free cells[9–11]. So far no theory has been confirmed. We now report that in the starfish (*Asterias rubens*) coelomocytes are produced in the coelomic epithelium.

A. rubens has only one type of coelomocyte[12], which, like the coelomic epithelial cells[13], is easy to label by intracoelomic injection of ferritin (cadmium-free, Calbiochem, final concentration 3–5 mg ml^{-1} of coelomic fluid). The iron is then made visible by applying Perls' reaction[14] on smears and histological sections.

Cuénot's observations[13] are correct: only the coelomocytes and the coelomic epithelial cells absorb ferritin. Injections have shown that there is no transfer of cells from one coelom to another (Table 1). Therefore, the coelomic epithelium which lines the axial organ is not labelled unless ferritin is injected into the axial sinus. Also labelled coelomocytes are never found in the general body cavity after injection into the hydrocoel or the axocoel, and *vice versa*. Contrary to what happens in other echinoderms, the starfish's coelomocytes leave the coelom only to be eliminated into the external medium.

To determine the site of origin of the coelomocytes, two starfish which had been injected with ferritin (into the general body cavity) were bled several times. After the first bleeding, quite a large number of new coelomocytes

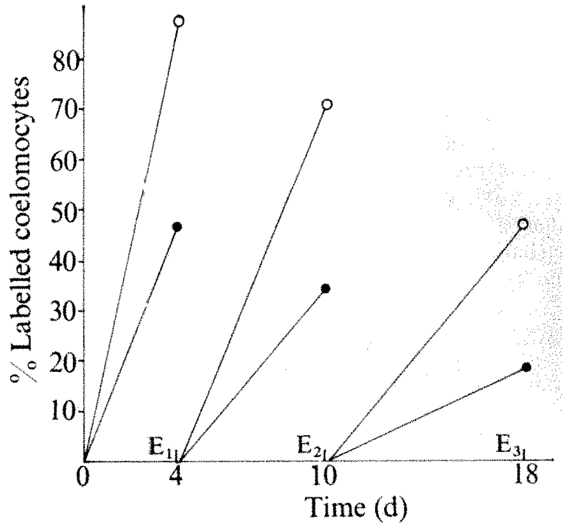

Fig. 1 Production of labelled coelomocytes at each bleeding (E_1, E_2 and E_3) in two starfish (○, ●).

contained ferritin (Fig. 1), showing that they must originate from the somatocoelic epithelium. A piece of pyloric caecum was cut off after each bleeding and its peritoneal labelling was measured (number of iron particles per 300 μm epithelium): there was a progressive decrease of label (Fig. 2). A similar decrease of labelled free cells was found after each successive bleeding (Fig. 1). Thus, the labelled epithelial cells fall progressively into the body cavity.

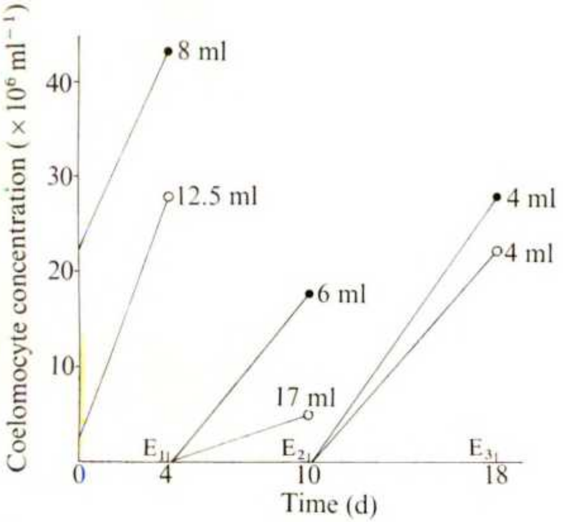

Fig. 3 Change of coelomocyte concentration. Total volume of coelomic fluid is marked for each line.

The introduction of foreign particles into the general coelom induced a considerable increase in the coelomocyte concentration (Fig. 3, T → E$_1$). Similarly, the concentration several days after bleedings E$_1$ and E$_2$ shows that the starfish can renew its coelomocytes remarkably quickly.

Table 2 shows the evolution of the total number of coelomocytes in the two starfish we used. Many of the new coelomocytes contained no iron. These cells obviously cannot have come from the division of circulating coelomocytes because the starfish had been bled. Furthermore, the results of injections demonstrate that no cells can have come from outside the coelomic cavity. All this suggests that the new coelomocytes in the general body cavity can have come only from the somatocoelic epithelium. This epithelium thus seems to offer great potential, as it could be the origin of both coelomocytes and digestive epithelial cells (in the case of regeneration)[15].

Observations of *A. rubens* larvae *in vivo* showed that the first free cells appear at the late bipinnaria stage (larvae ± 25 d old). At this stage the subdivision of the coelom is not yet complete and none of the presumed cytopoietic organs is present. Here again, the only possible source of coelomocytes is the coelomic epithelium.

Coelomic epithelial cells have a precisely known structure[16]. They are choanocyte-like cells, each apex of which is fitted with a long flagellum surrounded by a crown of microvilli. To form the coelomocytes, the cells detach themselves from the epithelium by stretching from their base (Fig. 4). Shortly after release, each cell loses its flagellum. This happens very fast, and it was by stimulating the formation of coelomocytes by injecting ferritin or Indian ink that we were able to observe it. This explains why flagellated cells had not previously been reported in the coelomic cavities of *A. rubens*[12].

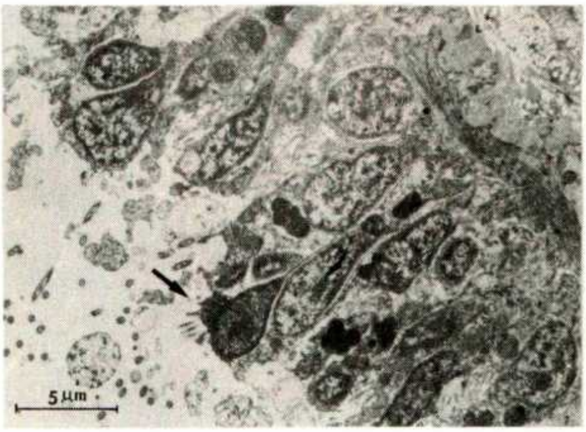

Fig. 4 Transformation of a coelomic epithelial cell into a coelomocyte (epithelium of the rectal caeca).

We conclude that the sole origin of coelomocytes in *A. rubens* is the coelomic epithelium and thus all organs lined with such epithelium can be considered to be cytopoietic.

Electrophoretic evidence that selection reduces ecological overlap in marine limpets

CHARACTER divergence between sympatric, ecologically similar species has been attributed to selection which tends to increase the ecological difference between such species and to reduce the zone of their ecological overlap[1].

Evidence for this phenomenon is based solely on morphological characters which are presumably controlled by a number of genetic factors. There is, however, no documentation of divergence between sympatric species at the allelic level. During the course of a study of the population genetics of the intertidal limpet *Acmaea pelta,* I discovered what seemed to be an effect of coexistence with congeners on the frequencies of allozymes at a leucine aminopeptidase (*Lap*) locus. Populations of this highly eurytopic species from habitats offering widely different algal food and physical conditions, had similar frequencies of Lap allozymes, except from habitats where the populations were mixed with large populations of another acmaeid species (unpublished results).

A. pelta is one of fifteen intertidal species of its genus that are sympatric along the rocky shores of central California. A few of these species are rigidly stenotopic obligates of a single plant species, but most are eurytopic species that overlap considerably in their vertical distribution as well as in their utilisation of algal food[2,3]. A further study of the *Lap* loci of nine species of *Acmaea* using starch gel electrophoresis showed that each species has one *Lap* locus that gives a gel pattern of either two or four bands per individual. The pattern may be explained by proposing two polymeric enzymes which share a common polymorphic subunit as well as having different monomeric subunits[4]. Thus homozygotes show one band pair and heterozygotes two. This genetic interpretation of the patterns is supported by the fact that in none of the samples did the zygotic frequencies differ significantly from Hardy–Weinberg equilibrium, assuming two Mendelian alleles per animal. A total of eight band pairs were found each of which corresponded in mobility to one of the pairs found in *A. pelta.* The inferred alleles responsible for the mobility of these band pairs are designated $Lap^{0.19}$, $Lap^{0.46}$, $Lap^{0.73}$, $Lap^{1.00}$, $Lap^{1.24}$, $Lap^{1.54}$, $Lap^{1.81}$ and $Lap^{2.08}$, in order of increasing anodal mobility, with the most frequent allele of *A. pelta* as standard. Each species possesses two or more of these alleles. Figure 1 shows the frequencies of these alleles in six of the eurytopic species that commonly occur in mixed acmaeid assemblages. All of these species have different distributions of *Lap* alleles.

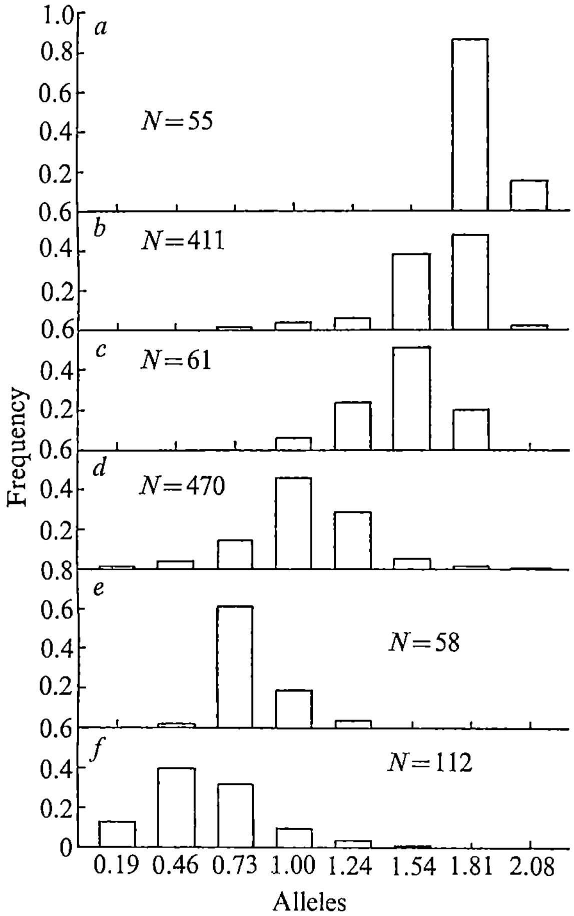

Fig. 1 *Lap* allele frequency distributions of six eurytopic species of the genus *Acmaea. a, A. persona, b, A. digitalis; c, A. scutum; d, A. pelta; e, A. strigatella; f, A. scabra.* Animals were held in running seawater for <24 h after capture. Extracts were made from live tissue, or from animals frozen intact and stored for less than two weeks at −20 °C. Repeated electrophoresis of individual extracts shows that storage for over a month at −20 °C results in a slight loss of Lap activity, but no change in electrophoretic pattern. The hepatopancreas of each limpet was removed and homogenised in an equal volume of gel buffer. After centrifugation, the extract was absorbed with 5-mm squares of Whatman 3MM filter paper. The squares were inserted into Electrostarch gels cast in moulds described by Smithies[5]. Gels were prepared and stained according to Brewer[6], except: 4% (w/v) sucrose was added to the gel; 0.32 M sodium citrate at *p*H 7.1 was used for electrode buffer, and a constant current of 10 mA was applied for 6 h. This method produced clear zymograms with good resolution of all allelic variants. Internal standardisations of mobility variants were carried out by including *A. pelta* individuals of known genotype on each gel. *N*, number of animals.

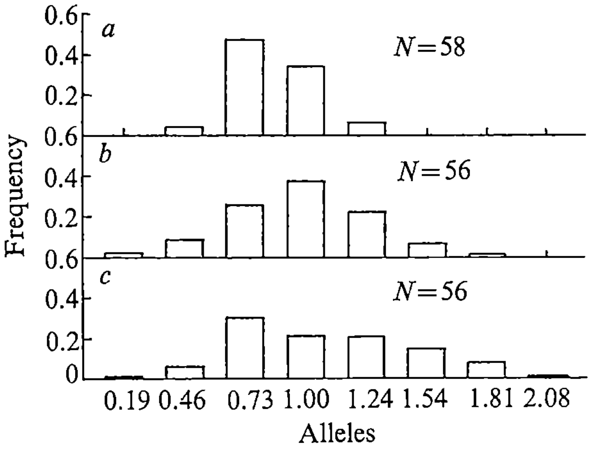

Fig. 2 *Lap* allele frequency distributions for three specialised species of the genus *Acmaea. a, A. instabilis; b, A. insessa; c, A. asmi.*

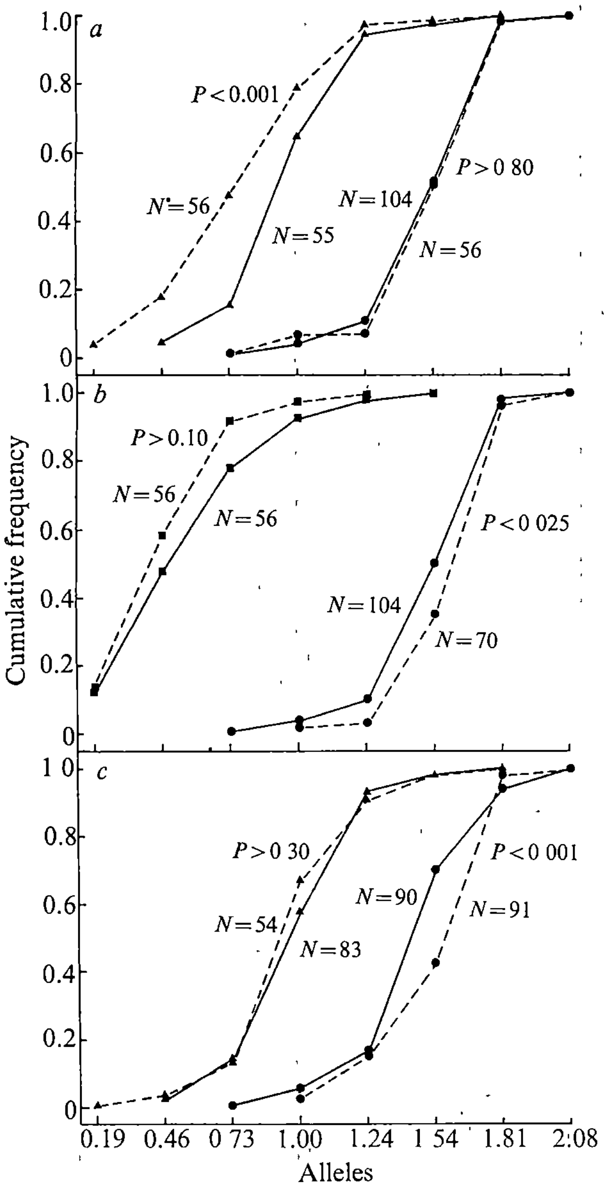
A. pelta is the most eurytopic of these species and coexists, at times, with all species in Fig. 1 except *A. persona. A. scutum* often coexists with *A. pelta* in the mid-interdial zone. Both here and at high interdial zones *A. scabra* and *A. digitalis* often occur in close association; either of these species can coexist with *A. persona* in the upper reaches of their vertical ranges. Lower down, either can coexist with *A. strigatella,* although *A digitalis–A. strigatella* associations are more common than *A. scabra–A. strigatella* associations. The *A. scabra–A. digitalis* association has been studied experimentally by Haven[7] and constitutes the only documented instance of interspecific acmaeid competition.

Since coexistence of ecologically similar species is likely to result in selection that will cause changes at many gene loci, the operation of this selection on closely related species that share identical alleles may have resulted in the species differences shown in Fig. 1. A precedent for the selective importance of the charge on molluscan Lap allozymes has been reported by Koehn and Mitton[8]. If the allelic differences among species that commonly coexist are instances of divergence resulting from selection to reduce ecological overlap, then a primitive or optimal distribution of alleles should be preserved in species which, in spite of their sympatry with others, do not compete. Several of the Californian acmaeids should escape competition since, as theorised by MacArthur and Levins[9], narrowly specialised species do not compete for those resources for which they are specialised. Three of these species are *A. instabilis*, an epizoite on Laminarian kelps, *A. insessa*, an epizoite on the kelp *Egregia menziesii*, and *A. asmi*, an epizoite on living shells of the snail *Tegula funebralis*. The distributions of *Lap* alleles in these three species tend to be broad, and all three have similar central tendencies (Fig. 2).

All eurytopic acmaeids that occur in mixed assemblages are also found in unispecific populations in some habitats. According to my interpretation of the above evidence, selection should operate only in habitats where species coexist, and there the interspecific similarity at the *Lap* loci should be a minimum. In order to test this prediction, habitats along 2 km of coast at Pigeon Point, San Mateo County, California, and along 200 m of coast at Pacific Grove, Monterey County, California, were chosen on the basis of their acmaeid assemblages. At each location samples were taken from habitats that supported unispecific populations of *A. pelta* or *A. digitalis*; samples of both species were also collected from a habitat that supported mixed populations of *A. pelta* and *A. digitalis*. In addition, at Pigeon Point, a sample of *A. scabra* from a unispecific population, and samples of *A. scabra* and *A. digitalis* from mixed populations, were collected. The results of the Lap allozyme analyses of these samples are shown in Fig. 3. In all instances, allelic distributions of coexisting populations differed more than the distributions of unispecific populations of the same species from the same location. The allelic distribution of only one species of each coexisting pair shifted in the predicted direction by a statistically significant ($P<0.05$) amount using a one-tailed Kolmogorov–Smirov two-sample test[10]. At Pigeon Point, where *A. digitalis* was twice as numerous as *A. pelta* in their shared habitat, the allelic distribution of *A. pelta* was affected (Fig. 3*a*), but that of *A. digitalis* was displaced at Pacific Grove, where it was mixed with about an equal number of *A pelta* (Fig. 3*c*). This agrees with a model of character displacement at one locus proposed by Crozier[11], which predicts that competition will cause displacement in both of a pair of sympatric species only in a narrow range of relative reproductive rates, and otherwise displacement will occur only in the more slowly reproducing species.

Fig. 3 Cumulative frequency diagrams of *Lap* alleles of unispecific (——) and coexisting (– – – –) populations of limpets. ▲, *A. pelta;* ●, *A. digitalis;* ■, *A. scabra* *a* and *b*, Pigeon Point, San Mateo County, California; *c*, Pacific Grove, California. *P* derives from the Kolmogorov–Smirov test of the H_1 that the allelic distribution of the coexisting population is not shifted in the predicted direction. *N*, number of animals.



The selection mechanism responsible for the observed genetic displacement is not known for certain. The possibility of selective settling of planktonic larvae of these limpets cannot be ruled out. Post-larval migration over short distances can be shown to be important in the distribution of *A. digitalis* of different shell patterns to appropriately coloured substrates[12]. Migration of settled acmaeids is, however, limited by their inability to cross sandy areas[13], which would have made post-larval migration between habitats unlikely in most of the cases I studied. Differential survival may be the agent, but my data show no significant correlation between size and genotype. This may mean that selection operates primarily on limpets too small for electrophoretic analysis.

Allelic accommodation in apparent response to competition has not been reported before, and, with acmaeids, should make possible the experimental study of the genetics involved in phenomena such as character displacement and niche diversification.

I thank A. R. Moldenke and J. L. Cox for their suggestions and criticism of an earlier draft of the manuscript. This work was partially supported by the NSF.

Preferential pollination of yellow-flowered morphs of *Raphanus raphanistrum* by *Pieris* and *Eristalis* spp.

COROLLA-COLOUR polymorphisms occur in wild populations of many angiosperms, but little is known of the selective factors that maintain them. Valentine has suggested that yellow/white corolla-colour polymorphisms may be adaptively neutral[1]. I have observed extremely strong discrimination by some insect pollinators between the yellow and white corolla-colour forms of polymorphic wild radish. These observations, which are described below, indicate that corolla-colour differences are of adaptive importance in this and similar cases.

I have investigated the behaviour of pollinating insects visiting the flowers of wild radish (*Raphanus raphanistrum* L.), a self-incompatible annual[2] in which mixed populations of white-flowered and yellow-flowered morphs with sharply different corolla reflectance spectra (Fig. 1) are common in southern Britain. These forms differ only in a single allele, and no other characters have been observed to be associated with the difference in flower colour. Pollinator behaviour was observed in five polymorphic populations in central England and southern Wales during the summer of 1975. Bumble bees (*Bombus* spp.) and sometimes honey bees (*Apis mellifera*) were the chief pollinators, but in all populations *Pieris* spp., especially *P. rapae* (Lepidoptera, Pieridae) were important, often making 10–15% of the total number of visits to *R. raphanistrum*. *Eristalis* spp. (Diptera, Syrphidae) were minor pollinators, comprising up to ~5% of the visitors to *R. raphanistrum*.

Pieris spp. and *Eristalis* spp. showed a strong or very strong preference for the yellow-flowered morph of *R. raphanistrum* in four populations in which the frequencies of the yellow morphs ranged from 7.3 to 60.8% (Table 1). At the Sketty site, for example, where the frequency of the yellow-flowered morph was 60.8%, 307 visits by female *P. rapae* to *R. raphanistrum* were observed; 306 of these visits were to yellow flowers and only one to a white flower. *P. napi* and *P. brassicae* showed an equally strong preference for yellow-flowered *R. raphanistrum* at the same site. At this site, and at Brownhills and Beenham, *R. raphanistrum* was abundant, with yellow-flowered and white-flowered morphs closely intermingled in a mixed stand of field weeds. The Singleton population, which was the only artificial population, consisted of well-spaced rows of F_2 plants segregating at random for yellow or white flower colour. Although the frequency of yellow-flowered plants was only 27.3% in this population, the proportion of visits made to yellow flowers by *P. rapae* was higher than at the Brownhills site (42.3% yellows), and the proportion of visits made to yellow flowers by *E. arbustorum* was higher than at any other site, perhaps as a result of the spatial separation of individual plants at Singleton.

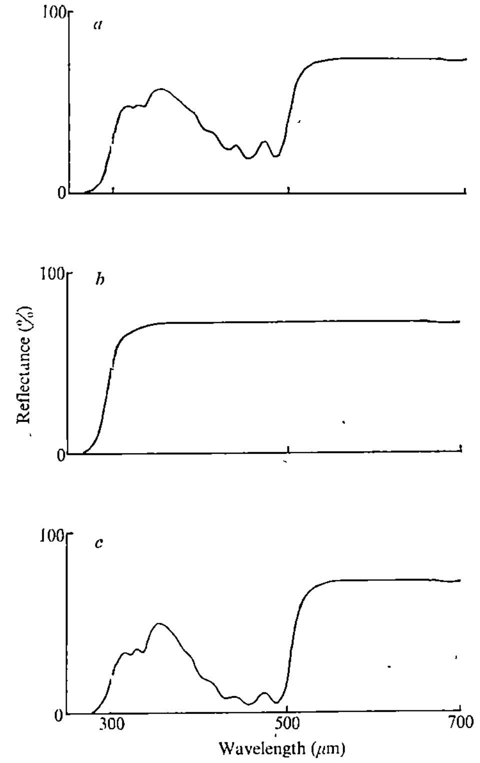

Fig. 1 Reflectance spectra of petals. Measurements were made using a Unicam SP 8000 recording spectrophotometer fitted with an SP 890 diffuse reflectance unit. *a*, *R. raphanistrum*, yellow morph; *b*, *R raphanistrum*, white morph; *c*, *Sinapis arvensis*.

The Landimore population differed from the others both in the low frequency of the yellow morph (0.8%) and in the occurrence of abundant *Sinapis arvensis* L., a crucifer with yellow flowers which resemble those of *R. raphanistrum* and have a closely similar reflectance spectrum to that of yellow *R. raphanistrum* (Fig. 1). *E. arbustorum*, *E. tenax* and other *Eristalis* spp. were abundant on *S. arvensis* flowers at this site, but did not visit *R. raphanistrum*. *P. rapae* and *P. napi* visited white-flowered *R. raphanistrum* and *S. arvensis* with approximately equal frequency. Only two cases of apparently preferential visits to yellow-flowered *R. raphanistrum* were observed at Landimore; a male *P. rapae* was involved in each case. Most male *P. rapae*, and all *P. napi* and female *P. rapae*, did not seek yellow-flowered *R. raphanistrum*.

In all populations the distances that were flown by individuals of the *Pieris* spp. between visited plants were commonly one to several metres, and flights of 15–40 m between successively visited plants were not unusual, with total distances of at least 150 m being covered during a series of visits. Recognition and location of yellow-flowered plants seemed to be entirely visual. Differences in behaviour between different individuals of *P. rapae* were observed at

Table 1 Frequency of visits by pollinators to the yellow-flowered morph of *R. raphanistrum* in five polymorphic populations

Site	Frequency of yellow morphs in population (%)	% of total visits made to yellow flowers *P. rapae* Males	*P. rapae* Females	*P. napi*	*P. brassicae*	*E. arbustorum*	*E. tenax*
Sketty	60.8 (418)	94.5† (292)	99.7† (307)	99.1† (111)	100† (107)	89.0† (556)	87.7† (235)
Brownhills	42.3 (130)	89.8† (303)	81.1† (169)	ND	ND	66.0* (47)	70.7† (75)
Singleton	27.4 (73)	92.3† (1,769)	89.3† (131)	93.7† (142)	ND	96.0† (569)	ND
Beenham	7.3 (303)	27.4† (446)	25.8† (190)	ND	ND	ND	40.8† (49)
Landimore	0.8 (240)	4.8† (268)	0.0 (233)	0.0 (470)	ND	ND	ND

The size of each sample is shown in parentheses. Significant differences from the population morph frequencies are indicated: $^*P<0.01$; $^\dagger P<0.001$. The grid references of the sites are as follows: Sketty, SS 623921; Singleton, SS 629917; Brownhills, SK 068052; Beenham, SU 592690; Landimore, SS 473926. ND, not done.

all sites but were most obvious at the Beenham site, where less than half of the individuals of both sexes sought yellow-flowered *R. raphanistrum*. In the natural populations, the strength of the preference that *P. rapae* showed for the yellow morph clearly decreased with decreasing frequency of the yellow morph. Pollinator discrimination of this type may have a role in determining the balance of the flower-colour morphs in *R. raphanistrum*, which shows both geographic clinal variation and local mosaic differentiation in flower-colour morph frequency. In Britain, the white morph predominates in polymorphic populations in southern and eastern England, but the yellow morph predominates or forms monomorphic populations in western and northern Britain.

There have been few investigations of pollinator behaviour in plant populations with flower-colour polymorphism, and no other case has been described in which pollinators discriminated so strongly between flower-colour forms of a wild species. Levin[3] found differences in attractiveness of about 1 : 1.49 between the least attractive (coral) and the most attractive (lavender) colour-forms of *Phlox drummondii* Hook. in artificial populations of mixed cultivars; he used pollen-load on the stigma as a measure of attractiveness, but did not observe the behaviour of pollinator species (mainly Lepidoptera) directly. Mogford[4] observed that some species of *Bombus* discriminated between purple and white flower-colour morphs of *Cirsium palustre* (L.) Scop. in some mixed populations; the greatest discrimination was shown by *B. lapponicus*, which made 88.4% of its visits to the white morph in a population with only 64.0% of white morphs, but discrimination was not consistent. The preference shown by *Pieris* spp. for the yellow morphs seems to conflict with the observations of Ilse[5] and Bennett[6], who reported preference for blue, violet, purple and white colours and relative avoidance of yellow flowers of various types by *Pieris* spp. The reflectance spectrum of yellow *R. raphanistrum*, however, shows a complex pattern of reflectance in the near ultraviolet between 275 and 400 nm (Fig. 1) and is thus bee purple[7] to bees and other insects with trichromatic colour vision extending into the near ultraviolet. Work on the spectral sensitivity of the eye of the butterfly *Heliconius*[8] has suggested that *P. rapae*, which is certainly sensitive to near ultraviolet reflectance[9], has this type of colour vision, and similar work on the spectral sensitivity of *E. tenax*[10] suggests that *Eristalis* spp. may have a similar type of colour vision. Ilse and Bennett did not consider ultraviolet colour components. Ilse[11] investigated the behaviour of *E. tenax* in relation to flowers of different colours, and successfully trained *E. tenax* to prefer yellow flower models (of Ostwald yellow paper, probably lacking an ultraviolet component) to those of other colours. Obara[9] observed that male *P. rapae* strongly preferred yellow to white paper models of females in summer, but did not discriminate in autumn; the near ultraviolet component of the colour may have been important. I did not, however, observe any consistent difference between male and female *P. rapae* in preference for the yellow morphs of *R. raphanistrum*, and it seems likely that feeding behaviour rather than mating behaviour determines the flower-colour preferences of *Pieris* spp.

Vegetative reproduction and close packing in a successional plant species

HERBACEOUS perennials with determinate shoots commonly produce new aerial stems by rhizomes, stolons or adventitious root buds[1–5]. The usual result is a more or less dense clone. Preliminary field studies were made of tightly packed clones of goldenrods (*Solidago* spp., Compositae), common in late herbaceous stages of succession in the eastern USA. These studies suggested orderly geometric patterns of rhizome production.

A geometric model for development of dense clones was devised (Fig. 1). It was assumed that an optimal pattern of stem production maximises rate of centrifugal spread, maintains sufficient stem density in already colonised sites to produce a closed canopy, and minimises total rhizome length (and thus, biomass and respiratory load). The model requires that most parental rhizomes produce two or more daughter rhizomes, and that most daughter rhizomes diverge from the direction of parental growth by 60°, with one growing to the left (−60°) and one to the right (+60°) of the parental line of growth. Such a pattern, by itself, produces frequent gaps in the clone. The model also requires that occasional daughter rhizomes continue in the direction of parental growth. The stems subsequently produced by these 'non-divergent' rhizomes reduce the number of gaps left by divergent (60°) rhizomes. They also increase the rate of clone expansion.

The model incorporates some redundancy—that is, in ideal conditions, more than one stem may be produced at

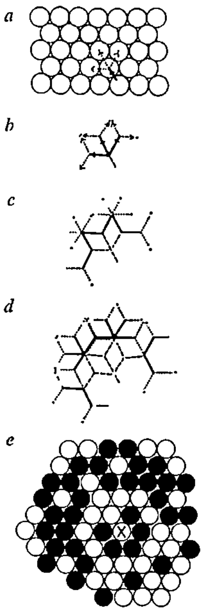

Fig. 1 Model of rhizome development during a 5-yr sequence. Dotted lines represent new rhizomes terminating in live aerial stems; solid lines represent 1-yr-old rhizomes; dashed lines represent rhizomes 2 yr old or more; *a*, parent rhizome and three daughter rhizomes; ○, represents a space to be filled by foliage from an aerial stem; *b*, same system 1 yr later; non-divergent (0°) daughter rhizomes are not produced in this and subsequent years; *c*, same system 2 yr later; *d*, same system 3 yr later; *e*, 4 yr later; ●, represents a space filled by foliage from one or more aerial stems; gaps could be filled by more frequent production of non-divergent rhizomes and by production of aerial stems directly from old stem bases; X, point of origin of the three daughter rhizomes shown in 1*a*.

a given point within the clone. In field conditions, rhizome mortality or damage, combined with environmental heterogeneity, would degrade optimal developmental patterns. Redundancy increases the probability that a given clone will maintain a closed canopy and maintain a rapid rate of centrifugal spread, in spite of environmental variables and developmental errors.

Clones of *Solidago canadensis* L. were used to test the model. *S. canadensis* is a common successional species which can form dense circular clones at least 2 m in diameter. Vegetative reproduction is by rhizomes, which produce aerial stems at their tips. Occasionally, new stems are produced directly from old stem bases. New rhizomes are produced only from stem bases. The study site was a field in eastern Pennsylvania (Lima, Delaware County) which was last ploughed 7 yr before the study. Slope was approximately 6–8% and the soil was a well-drained Glenelg channery silt loam[6]. Fifteen sod blocks were excavated from dense *S. canadensis* clones; each block was 0.7 m long, 0.4 m wide and 15–20 cm deep. Soil was washed off and rhizome geometry measured. Data included: the number of daughter rhizomes produced by each stem base; the rhizome length; and the angle formed by the base of each daughter rhizome and the straight line projected from the end of the parent rhizome. Rhizomes grew horizontally with little variation in depth below the surface. Thus, systems were described in a two-dimensional plane. All rhizomes had scale leaves oriented in the direction of growth, permitting separation of parent and daughter rhizomes.

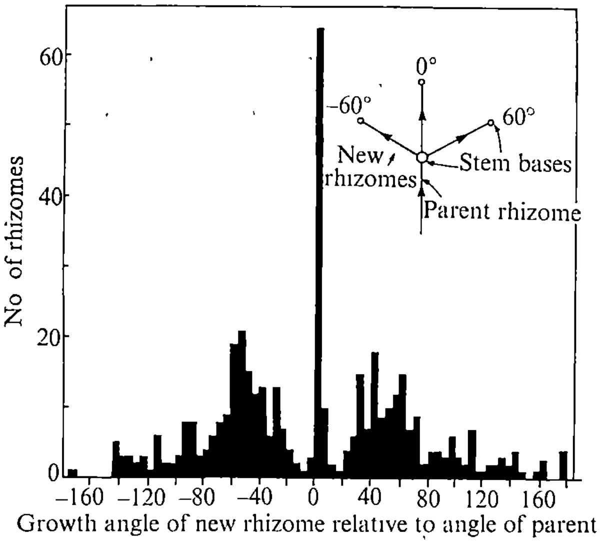

Fig. 2 Frequency distribution of rhizome growth angles. See text for explanation

Eighteen per cent of all rhizomes excavated continued in the direction of parental growth ('non-divergent'; Fig. 2). Any angle falling within 10° of parental growth direction was considered non-divergent. Of the remaining, divergent rhizomes, those that diverged to the left had a mean angle of −66.0±2.41° (mean±s.e.); those that diverged to the right had a mean angle of 67.6±2.95°. Mean number of daughter rhizomes per stem base was 2.43±0.104.

The data of Fig. 2 do not, in themselves, provide an adequate test of the model. Similar data could result from production of rhizomes diverging only to the right by one-half of all stem bases, and only to the left by the remaining stem bases. This pattern would not result in the predicted clone geometry of Fig. 1. Of the 106 stem bases that produced at least two diverging daughter rhizomes, 85.8% produced at least one rhizome diverging to the left and one diverging to the right. Of the 53 stem bases which produced at least two diverging rhizomes falling within 1 s.d. of one or both of the mean divergence angles (−66.0±32.98° and +67.6±37.97°), all had rhizomes falling within 1 s.d. of both left and right means. Thus, it was rare for all rhizomes produced at a given stem base to diverge in one direction.

Rhizome length could not be accurately determined for most systems because of breakage, because older rhizomes decay rapidly, and because the youngest rhizomes had not yet terminated in aerial stems. Mean linear distance between each stem base and the nearest adjacent stem base was 7.5±0.61 cm ($n=170$). It seems that rhizome length is frequently greater than this. New aerial stems are occasionally produced directly from old stem bases, increasing centripetal density. Some rhizomes grow at angles much greater than 60°, further increasing stem density in older portions of the clone.

Mean rhizome angles correspond closely to the model, suggesting some selection pressure for geometrical order. There is considerable variability in growth angle and rhizome frequency, resulting in breakdown of clone symmetry. The high degree of redundancy in the system, however, seems to compensate for this variability, resulting in the commonly observed pattern of closely packed aerial stems.

We thank Mr Franklin Haas, Superintendent of Ridley Creek State Park, for permission to carry out the study; and Drs Jack McCormick and Marilyn Jordan Buchauer for guidance and collaboration during preliminary studies.

Complementation of *ts* mutants by a herpes simplex virus *ts*-transformed cell line

THE first evidence that human herpesvirus could transform cultured cells was provided by Munyon *et al.*[1] who showed that the thymidine kinase activity of herpes simplex could be expressed in mouse-derived L cells lacking this enzyme (LTK^- cells). The oncogenic potential of human herpes virus was demonstrated by Duff and Rapp[2,3] who showed that hamster embryo cells transformed by ultraviolet-inactivated herpes simplex virus (HSV) were oncogenic in newborn hamsters. Further evidence of HSV transformation has been described in cultured human, rat and mouse cells[4–7]. The exact role played by HSV in transformation of primary embryo cells and the amount of information (if any) required to maintain the transformed state is not known. Temperature-sensitive (*ts*) mutants of HSV-2, HG 52 have been shown to complement each other[8]. These *ts* mutants may be used in complementation tests together with rat embryo cells transformed by another *ts* mutant to demonstrate the expression of herpes information in the transformed line. We report here evidence of such complementation between an HSV-2 *ts* mutant-transformed rat embryo line and three superinfecting HSV-2 *ts* mutants. This complementation suggests that this oncogenically

*Plaques obtained on titration at 31 °C: no plaques were found on titration at 38.5 °C

†Plaques obtained by infection of RE 1 cells by *ts* 4 were consistently larger than those on control plates.

‡Infection of transformed and control cells by *ts* 1, the mutant used for the original transformation of RE 1, was included as a control of the specificity of the complementation.

transformed line can express herpes information sufficient to complement at least three genes.

The transformation of rat embryo cells by *ts* mutants of HSV has been described[9,10]. Lines of HSV-transformed cells produced by picking foci and passaging these cells in tissue culture, have been shown to express HSV information in immunofluorescence tests with herpes-specific antiserum. Some of the transformed lines have been shown to be tumorigenic in rats (ref. 10 and our unpublished data) and the tumour cells, cultured *in vitro* express HSV information as seen by immunofluorescence. Extracts of tumours and of transformed cells express herpes-specific thymidine kinase (our unpublished data). Serum from tumour-bearing animals contains neutralising antibody and also antibody to herpes-coded thymidine kinase activity. Kimura *et al.*[11] have reported that at 38 °C the growth of two *ts* mutants was significantly enhanced in cells transformed by ultraviolet-inactivated HSV-2.

The line of transformed cells used was the RE 1 line described before[9,10]. Control cells were hooded Lister rat embryo primary cells and "hood" cell lines derived from them. Unpublished experiments have shown that it is not possible to distinguish the RE 1 line from primary rat embryo cells or hood cells by growth curves or saturation density attained. BHK 21 cells were used to prepare stocks of mutant virus and also for titration of virus in the complementation tests.

Tests for complementation were carried out by comparing the yields of virus from transformed RE 1 and from rat embryo control cells. Monolayers of transformed cells and of rat embryo control cells were infected with a *ts* mutant at a multiplicity of infection of 5 PFU per cell. Duplicate plates were used throughout. After adsorption for 1 h at 37 °C the virus inoculum was removed, and the plates were washed twice with Eagle's medium, incubated for 30 min at 38.5 °C with 5% antiserum, washed twice again with Eagle's medium and then incubated in Eagle's medium with 5% calf serum at 38.5 °C for 24 h. The cells were then scraped into the medium, disrupted by sonication and 0.2-ml samples were shaken with a suspension of 6×10^6 BHK 21 cells for 45 min at 37 °C. These cells were then divided between two 50-mm Petri dishes containing Eagle's medium with 5% calf serum; one plate was incubated at 38.5 °C for 2 d and the other at 31 °C for 3 d. Plates were then stained with Giemsa stain and the number of plaques obtained from infection of the RE 1 cells by a *ts* mutant was compared with the number obtained from control cells infected with the same mutant. A yield from the RE 1 cells of more than twice the number of plaques obtained from the control cells was regarded as evidence of complementation of the mutant virus by the transformed cells.

Results obtained with the HSV-2 mutants, *ts* 3 *ts* 4 and *ts* 10 are shown in Table 1. In each case there was evidence of complementation of the mutants by the transformed cell line. We have shown by fluorescence that HSV-specific proteins are produced in rat embryo cells infected with *ts* mutants (unpublished data) at 38 °C. This indicates that neither uptake nor uncoating are blocked.

Yields from the transformed cells infected with *ts* 4 regularly produced larger plaques than the parallel yields of control cells infected with this mutant, a finding which is under investigation.

No significant increase in yield was seen when the transformed cells were infected with *ts* 1, the mutant originally used to transform the cells. The information expressed in RE 1 cells cannot complement the homologous *ts* 1 mutant. It is also implied that complementation was specific for the expression of HSV information in the transformed cell line. In addition, the mutants *ts* 2 *ts* 5, *ts* 6, *ts* 7, *ts* 8 and *ts* 9 were tested, in duplicate on at least three separate occasions, but none showed significant complementation (Table 2), indicating that the relevant genetic information to complement these mutants is either absent or not expressed in the RE 1 cells.

Virus from plates showing complementation was tested for the presence of recombinants by replating the yield at 38 5 °C, but no recombinants were detected. Control hood cells after 21 and 34 passages behaved like primary rat embryo cells when infected with *ts* mutants. Thus the complementation of HSV *ts* mutants by RE 1 cells is unlikely to be just a consequence of their multiple passages in culture.

The four mutants *ts* 1, 3, 4 and 10 complement each other in standard genetic complementation tests[8] and the mutations are therefore in different genes. The fact that cells transformed by *ts* 1 complement the three mutants, *ts* 3, 4 and 10, suggests that at least three HSV functions are expressed in the transformed cells. HSV-specified thymidine kinase activity is expressed in RE 1 cells (our

unpublished data), but this TK activity is not likely to be relevant to the *ts* mutant complementation demonstrated here, both because it is not normally an essential function for HSV replication[12], and because it is produced in normal amounts by all four mutants at 38 °C (ref. 13). Both *ts* 3 and *ts* 4 are DNA-synthesis-positive mutants but *ts* 1 and *ts* 10 are DNA synthesis negative[14]. *ts* 10 is slightly defective in production of viral DNA polymerase at 38 °C whereas *ts* 1 produces somewhat larger amounts than wild-type virus at 38 °C (ref. 13). Polymerase production, however, is probably not the primary defect of *ts* 10 and it is not yet possible to identify the functions involved in the complementation reaction in transformed cells. Our work suggests that the transformed RE 1 cells express not only HSV-specific antigens detectable by fluorescence and HSV-specific thymidine kinase activity, but also the HSV genetic information defective in three different HSV *ts* mutants. Our results with seven other mutants show that a large proportion of HSV-specified information is not expressed in these cells.

We thank Professor J. H. Subak-Sharpe for his interest, and Mrs Alice Birrell and Mrs Linda Calder for technical assistance.

Lectin-mediated attachment of glycoprotein-bearing liposomes to cells

LIPOSOMES have been used as vehicles for transporting drugs or enzymes into cultured cells and into tissues[1–8]. Before the full potential of liposome delivery systems can be realised, however, means must be found to direct the drug or enzyme bearing particles to specific sites within the body. Some modulation of the *in vivo* distribution of liposomes can be achieved by altering the size or charge of the vesicles[9,10]. More precise control of the interaction of liposomes with cells, and their distribution *in vivo*, may, however, be possible through the introduction of specific macromolecular entities into the liposome membrane. As a preliminary step in this direction we have incorporated a macromolecular lectin receptor into liposome membranes and have examined the lectin-mediated attachment of such liposomes to cells *in vitro*.

Our choice as a lectin receptor was the major sialoglycoprotein of the human erythrocyte membrane[11]. This component was extracted and purified to homogeneity[12] as evidenced by polyacrylamide gel electrophoresis (Coomassie blue staining). The erythrocyte sialoglycoprotein bears receptor activity for the lectins from wheat germ (WGA) and from *Phaseolus vulgaris* (PHA), but does not have appreciable receptor activity for concanavalin A (con A)[12,13]. The sialoglycoprotein was incorporated into liposomes which were mainly of the unilamellar type as formed by the technique of Batzri and Korn[14]. Briefly, an ethanolic solution of egg phosphatidyl choline and cholesterol (2 : 1 molar ratio) was injected rapidly into a solution of sialoglycoprotein in phosphate buffer. The sialoglycoprotein-containing liposomes formed were separated from free sialoglycoprotein by ultrafiltration through an Amicon XM 100A membrane, or by filtration on Sepharose 4B. The

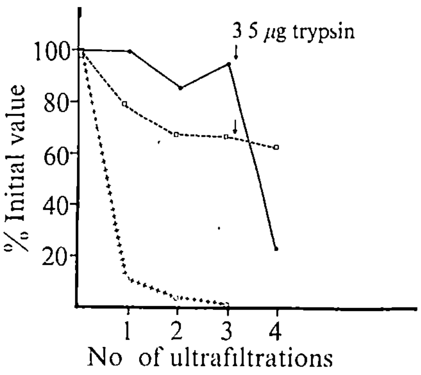

Fig. 1 Sialoglycoprotein liposomes were prepared by injecting 200 µl of an ethanolic solution of lipids (6 µmol egg phosphatidyl choline, 3 µmol cholesterol and a tracer amount of ^{3}H-dipalmitoyl phosphatidyl choline) into 4 ml of Dulbecco's phosphate buffer (*p*H 7.2). The buffer contained 100–500 µg of erythrocyte sialoglycoprotein and tracer amounts of ^{14}C-sialoglycoprotein; occasionally, low molecular weight solutes were included for trapping in the aqueous compartment of the liposomes. Free sialoglycoprotein and low molecular weight solutes were separated from liposome-bound material by repetitive ultrafiltration in Diaflow apparatus using an XM-100A membrane. Samples were repeatedly concentrated approximately tenfold by ultrafiltration and then diluted to the original volume. Aliquots were taken and sampled for radioactivity. At the indicated point the sialoglycoprotein liposomes were incubated with 3 5 µg ml^{-1} twice-crystallised trypsin for 30 min at 37 °C. ○, Free ^{14}C-sialoglycoprotein (SP); ●, liposome-bound sialoglycoprotein (SP), □, lipid-^{3}H-phosphatidylcholine (PC). The loss of ^{3}H-lipid during the first two ultrafiltrations is probably due to absorption of isotope on to hydrophobic sites in the membrane filter. It can be reduced by prewashing the filter with an albumin solution.

Table 1 Haptene inhibition of sialoglycoprotein liposome attachment to red cells

	Expt	WGA(%)	PHA (%)	RCA (%)
Lectin	I	100	100	100
	II	100	100	100
Lectin + haptene	I	47	91	0
Sugar	II	0	0	—
Lectin + non-haptene	I	106	107	125
Sugar	II	—	53	—
Lectin + post-treatment	I	105	—	0
W. haptene	II	99	25	—

Erythrocytes were treated with the indicated concentration of lectins washed and exposed to sialoglycoprotein liposomes for 2 h at 25 °C. In some cases appropriate haptene sugars (*N*-acetylglucosamine for WGA, *N*-acetylgalactosamine for PHA and galactose for RCA) or mannose as a non-haptene sugar were included in the reaction mixture. The samples were then processed as described in Fig. 2. Nonspecific attachment (in the absence of lectin pretreatment) was subtracted from the data. The results are expressed as the percentage of the effect produced by the lectin alone. The results represent the means of triplicate determinations. Experiment I, lectin concentrations were 50, 20 and 80 µg ml^{-1} for WGA, PHA and RCA, respectively. The haptene and non-haptene sugars were present at a final concentration of 50 mM. Experiment II, lectin concentrations were 100 and 20 µg ml^{-1} for WGA and PHA, respectively. The haptene and non-haptene sugars were present at a final concentration of 250 mM.

sialoglycoprotein from erythrocytes has previously been incorporated into artificial lipid membranes by several other workers[15–18].

The degree of incorporation and the ratio of protein to lipid in the liposome preparations were measured using ^{3}H-dipalmitoyl phosphatidyl choline and ^{14}C-sialoglycoprotein (labelled by reductive alkylation with ^{14}C-formaldehyde[19]), both of known specific activity. The sialoglycoprotein was readily incorporated into the liposomes at low protein–lipid ratios and somewhat less efficiently incorporated at higher ratios. Thus the percentage incorporation varied from 90 to 30% using 10–200 μg protein per mg phosphatidyl choline. Most of our preparations had a sialoglycoprotein–phosphatidyl choline weight ratio of 0.10–0.30, but higher ratios could also be achieved. Assuming a mean molecular weight 2×10^6 for unilamellar vesicles[20], and a molecular weight of 53,000 (ref. 12) for the sialoglycoprotein, then most of our preparations contained an average of 2–6 sialoglycoprotein molecules per vesicle. Much of the incorporated sialoglycoprotein seemed to be arrayed at the outer surface of the liposome since it could be cleaved from the vesicles by low doses of trypsin (Fig. 1*a*). In experiments using 3.5–75.0 μg ml^{-1} trypsin, from 72 to 87% of the sialoglycoprotein was cleaved from the vesicles as judged by release of radioisotope. It is unlikely that the protease penetrated into the vesicles in the conditions used since incubation with substantially higher doses (100 μg ml^{-1}) of trypsin failed to release any of the ^{3}H-sucrose sequestered within the aqueous compartment of the liposomes. These results contrast with those of MacDonald and MacDonald[17] who used another technique for preparing sialoglycoprotein liposomes and found only 50% of the incorporated protein exposed at the outer surface of the vesicles. We have not yet characterised the physical properties of the sialoglycoprotein liposomes in great detail; however, columns of Sepharose 4B largely retarded these liposomes yielding an elution profile typical of a preparation containing mainly small unilamellar vesicles[21].

Liposomes bearing sialoglycoproteins can participate in agglutination reactions mediated by appropriate lectins such as WGA. This can be in the form of self agglutination as first described by Redwood and Jansons (ref. 16 and Fig. 2*a*) or it can be mixed agglutination with lectin-coated cells such as erythrocytes (Fig. 2*b*). Both types of agglutination reaction exhibit apparent saturation and display a sigmoidal dependence on the amount of lectin used. The rate of lectin-mediated attachment of liposomes to cells is rapid at first and then slows substantially, with maximal attachment after 3–4 h at 25 °C (Fig. 2*c*). The mixed liposome–cell agglutination reaction seems slow compared with the reported kinetics of lectin-mediated agglutination of cells, where the reactions went to completion in about 20 min (ref. 22). The participation of the liposomes in lectin-mediated agglutination to cells is governed by the receptor specificities borne by the sialoglycoprotein. Thus WGA and especially PHA, which have high affinities for isolated sialoglycoprotein[12],

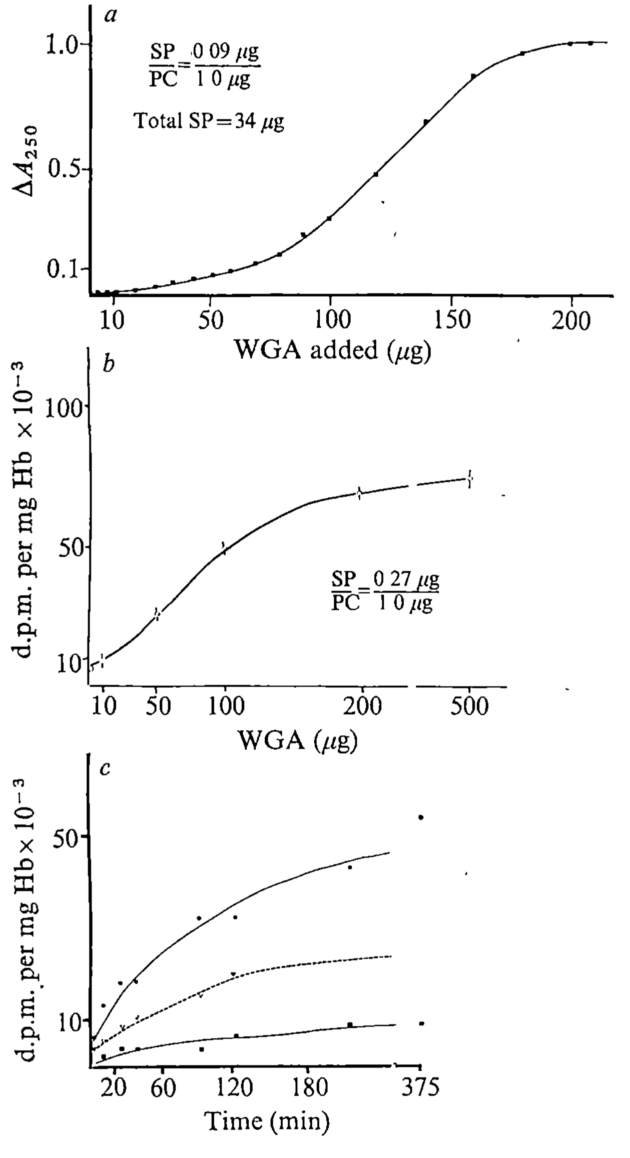

Fig. 2 *a*, Self agglutination of sialoglycoprotein liposomes. The agglutination of sialoglycoprotein liposomes was followed by light scattering measurements in a Beckman CII double-beam spectrophotometer. The absorbance of a sample cuvette containing sialoglycoprotein liposomes and WGA was compared with that of a reference cuvette containing an equal amount of sialoglycoprotein liposomes and WGA as well as 100 mM *N*-acetyl glucosamine. The difference in absorbance A_{250} was determined just after stirring both cuvettes and 5 min after each addition of WGA. The sialoglycoprotein (SP) – phosphatidyl choline (PC) ratio is indicated. Attachment of sialoglycoprotein liposomes to cells—experiments involving the binding of sialoglycoprotein liposomes to erythrocytes were conducted as follows. Aliquots (5 ml) of a 2% suspension of human red cells in Dulbecco's buffer were incubated with the indicated doses of lectins for 30 min at 4 °C. The lectin-coated cells were recovered by centrifugation and washed three times in buffer. Clumps of cells were dispersed by gentle pipetting Aliquots (2 ml) of lectin-coated red cells in buffer were incubated with 100 µl of sialoglycoprotein liposomes containing ^{3}H-dipalmitoyl phosphatidyl choline at 25 °C and usually for 120 min with constant mixing. The liposome–cell mixture was layered on 2 ml of a 10% albumin solution in buffer and the red cells were separated from unbound liposomes by sedimentation at 2,500 r.p.m. for 15 min. The cell pellet was dispersed and aliquots were taken for haemoglobin determination and for radiation counting. Efficiency corrections were made using a curve generated from samples quenched with whole blood. *b*, Dose dependence of WGA-mediated attachment of sialoglycoprotein liposomes to red cells at 25 °C. Abscissa, WGA (µg) used in pretreating red cells; ordinate, d.p.m. of ^{3}H-phosphatidyl choline per mg of haemoglobin. Mean ± s.e. shown ($n=3$). *c*, Kinetics of WGA-mediated attachment of sialoglycoprotein liposomes to red cells. Erythrocytes were treated with 100 µg of WGA in buffer, or with buffer only. The time course of attachment of sialoglycoprotein liposomes to cells at 25 °C was measured as above. ●, + WGA; ▽, + WGA + 50 mM *N*-acetylglucosamine; ■, − WGA. For these experiments wheat germ agglutinin (WGA) and con A were obtained from Sigma, crude PHA was from Difco RCA was prepared as described previously[30].

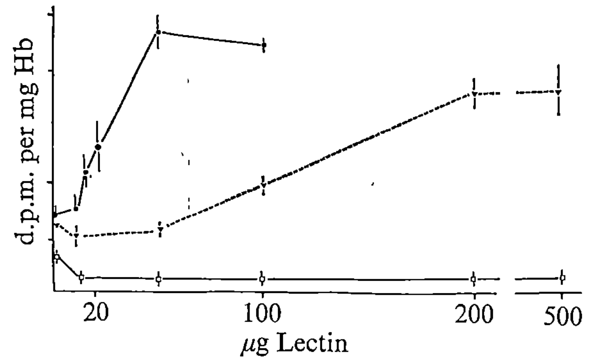

Fig. 3 Dose dependence of lectin-mediated attachment of sialoglycoprotein to erythrocytes at 25 °C. Protocol as in Fig 2*b*. Abscissa, lectin (μg) used in pretreatment of erythrocytes; ordinate, d.p.m of ^{3}H-phosphatidyl choline per μg of haemoglobin ●, PHA; ▼, RCA; □, con A. Mean ± s.e. shown (n=4).

are effective in promoting liposome attachment to cells, whereas con A, which does not interact with the sialoglycoprotein, fails to cause liposome–cell attachment (Fig. 3). A possible anomaly in our results seems to be the case of *Ricinus communis* agglutinin (RCA) which has been reported to interact only weakly with the isolated sialoglycoprotein[12], but which promotes strongly sialoglycoprotein liposome attachment to cells (Fig. 3). This discrepancy may be due to the presence of RCA receptor components in our sialoglycoprotein preparation which react poorly with Coomassie blue or with periodic acid–Schiff stains. RCA receptors from erythrocytes are known to have such characteristics and to overlap partially with the major sialoglycoprotein in gel electrophoresis[13]. As Table 1 shows, the presence of appropriate haptene sugars reduces the lectin-mediated attachment of sialoglycoprotein liposomes to cells. Only in the case of RCA, however, can the liposomes be fully released from the cell–liposome aggregate by post-treatment with the haptene sugar. It seems likely, in this case at least, that the liposomes are bound at the surface of the erythrocyte and are not internalised.

The maximal levels of lectin-mediated sialoglycoprotein liposome attachment to erythrocytes seen in Figs 2 and 3 represent the binding of 10–25 μg of phospholipid per mg of haemoglobin. By comparison, the normal human erythrocyte contains approximately 8.9 μg of phospholipid per mg of haemoglobin[23]; thus the liposomes bound to the erythrocytes by lectins comprise 2–3 times the total lipid of the red cell membrane. Since these liposomes probably possess a single bilayer membrane, our observations would suggest that, at maximal levels of attachment, the erythrocyte surface is largely covered by the bound vesicles.

Table 2 Efflux rates of $^{35}SO_4^{2-}$ from liposomes

	First hour	Second hour	Third hour
Sialoglycoprotein liposomes	11.8	11.4	9.8
Sialoglycoprotein liposomes + 100 μg ml^{-1} RCA	16.2	14.0	13.9
Sialoglycoprotein liposomes + 100 μg ml^{-1} RCA + 50 mM galactose	12.5	10.8	8.4
Sialoglycoprotein liposomes + 1 mg ml^{-1} RCA	26.6	18.0	12.9
Sialoglycoprotein liposomes + 1 mg ml^{-1} RCA + 50 mM galactose	16.5	13.8	11.8
Triton X–100 (0.5%)	77.3		

Sialoglycoprotein liposomes were prepared containing trapped $Na_2{}^{35}SO_4$ and the efflux rate at 25 °C of $^{35}SO_4^{2-}$ was measured as previously described[29]. Results are expressed as percentage efflux per h.

To assess the possibility that lectins disrupt the structure of sialoglycoprotein liposomes during aggregation reactions, we have studied the efflux of $^{35}SO_4^{2-}$ from such liposomes. Table 2 shows that the efflux rate of $^{35}SO_4^{2-}$ from sialoglycoprotein liposomes was approximately 10% per h, which is within the range commonly observed for anion fluxes in negatively charged liposomes[21]. The introduction of a lectin (RCA) at a concentration up to 1 mg ml^{-1} had less than a twofold effect on the efflux rate, and some of this effect may have been due to nonspecific protein–lipid interaction. These results suggest that lectin-mediated aggregation of sialoglycoprotein liposomes does not result in gross perturbation of the structure of the liposome membrane.

The SP liposome–lectin system described here may be applicable to investigation of the biochemical basis of lectin-mediated agglutination of cells. This phenomenon is a complex one, involving the number and affinity of lectin receptors, the mobility of receptors in the membrane and the interactions of receptors with active cytoplasmic elements[22,24,25]. In our system, several of these factors are subject to precise experimental manipulation. For example, the average receptor density per particle may be varied by altering the lipid–protein ratio during liposome formation. The receptor mobility may be controlled by preparing liposomes from synthetic phospholipids with known transition temperatures, followed by investigation of the agglutination reaction above or below the thermal transition. This approach may be complementary to studies using glutaraldehyde fixation to modify receptor mobility[26] since fixation may indirectly affect receptor mobility by altering intracellular elements such as microtubules or microfilaments, whereas alteration of the lipid composition of the SP liposome would directly modify membrane fluidity.

The system we have studied, namely the mixed aggregation of receptor-bearing liposomes and cells, may have some advantages over systems which use the self aggregation of liposomes[16,27]. Thus, we can examine the interaction of a well characterised receptor-bearing particle with undefined receptors on cells. The effects of manipulating cellular physiology on the aggregation reaction can also be studied.

We feel that our studies represent a step towards the development of liposomes which can be 'targeted' to specific cell types *in vitro* or *in vivo*. During the course of these studies Gregoriadis and Neerunjun[28] reported on the use of specific antibodies to 'target' drug bearing liposomes *in vitro*. Our endeavours and those from Gregoriadis' laboratory seem similar in intent although different in approach.

This work was supported by the National Cancer Institute of Canada. We thank Dr D. Papahadjopoulos for ^{3}H-dipalmitoyl phosphatidyl choline.

Mycoplasma pneumoniae is a polyclonal B-cell activator

MYCOPLASMA PNEUMONIAE (MP) is an important causative agent of lower respiratory tract illness in man[1]. Lymphocytes from subjects who have experienced MP infection show a high degree of stimulation when cultured in the presence of MP antigen[2,3]. But high concentrations of MP antigen also stimulate, to some extent, lymphocytes from individuals without serological evidence of previous MP infection, suggesting that these subjects have either been infected with MP in the past or that MP also has a non-antigen-specific, mitogenic effect[2]. Several mitogens are known: the plant lectins phytohaemagglutinin (PHA) and concanavalin A, for example, have a mitogenic effect on T lymphocytes[4], and certain bacterial products, such as lipopolysaccharide (LPS) of *E. coli*[4] and a purified protein derivative of tuberculin (PPD) are mitogenic for mouse B cells[5] and induce polyclonal antibody synthesis in mouse spleen cells[4]. These substances are called polyclonal B-cell activators (PBA) (ref. 6). We now report that MP is mitogenic for mouse and guinea pig lymphocytes and induces polyclonal antibody formation in mouse spleen cells.

Cells were obtained from inbred C57BL mice, specific pathogen-free congenitally athymic Nu/Nu mice on a BALB/c background (Bomholtgaard, Ry, Denmark) and normal outbred guinea pigs. Spleen or thymus cells were cultured as described previously[7] in Eagle's medium in Eagle's solution, or in RPMI 1640 medium with added L-glutamine, penicillin and streptomycin. Unless otherwise stated, serum was omitted from the cultures. DNA synthesis was measured and antibody-secreting cells were counted as before[7]. Briefly, 5×10^5 cells in 0.2 ml were cultured per well in microplates, usually for 48 h with a 24-h pulse of 1 μCi ^{3}H-thymidine or an 18-h pulse of 0.05 μCi ^{14}C-thymidine, and collected in a multiple cell culture collector (Skatron A/S, Lierbyen, Norway). Radioactivity was measured in a liquid scintillation counter. To determine antibody secretion, 10^7 cells per ml per dish were cultured in plastic Petri dishes. Antibody-secreting cells were counted after 2 d of incubation in a modification of Jerne's haemolytic plaque assay, using as targets sheep red blood cells (SRBC), horse red blood cells (HRBC), or SRBC coupled with the following haptens or antigens: (4-hydroxy-3,5-dinitrophenyl) acetyl (NNP), trinitrophenyl (TNP), fluoresceinisothiocyanate (FITC)[7] or dextran[8].

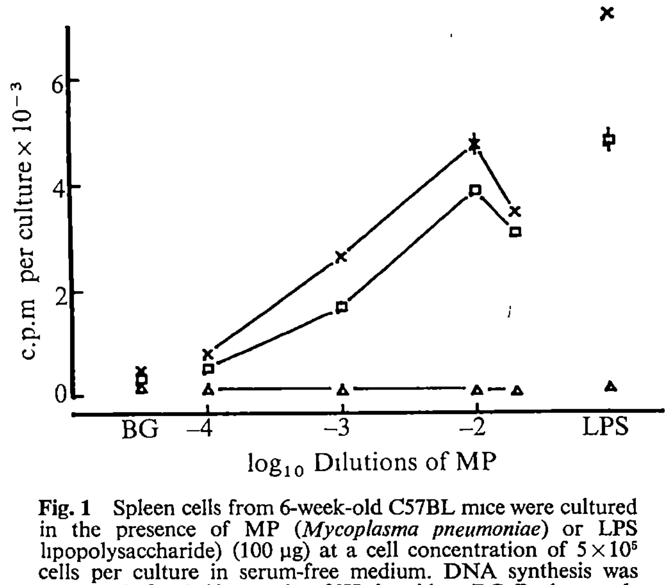

Fig. 1 Spleen cells from 6-week-old C57BL mice were cultured in the presence of MP (*Mycoplasma pneumoniae*) or LPS lipopolysaccharide) (100 μg) at a cell concentration of 5×10^5 cells per culture in serum-free medium. DNA synthesis was measured after 2 d by uptake of ^{3}H-thymidine. BG, Background; □, spleen cells; ×, spleen cells treated with carbonyl iron; △, thymus cells

Table 1 Response of spleen cells to various antigens

	PFC per culture ± s.e. BG	MP	LPS
NNP–SRBC	153±12	2,376±125	2,297±294
TNP–SRBC	177±7	1,773±104	2,290±215
FITC–SRBC	90±6	1,233±151	1,480±114
Dextran–SRBC	10±1	133±17	120±20
SRBC	20±6	113±9	137±9
HRBC	100±30	516±68	380±55
DNA synthesis (c.p.m. per culture)	5,236±276	25,697±881	33,940±1,060

Spleen cells from Nu/Nu mice were cultured in the presence of MP antigen (diluted 1/100) or LPS (100 μg) at a cell concentration of 5×10^6 cells per culture in medium with 5% foetal calf serum. Polyclonal antibody synthesis was measured after 2 d by detecting numbers of PFC to SRBC, HRBC and SRBC coupled with NNP, TNP, FITC or dextran. Determination of DNA synthesis was done in microcultures (5×10^5 cells per culture) pulsed for 24 h with 1 μCi ^{3}H-thymidine. BG, Background.

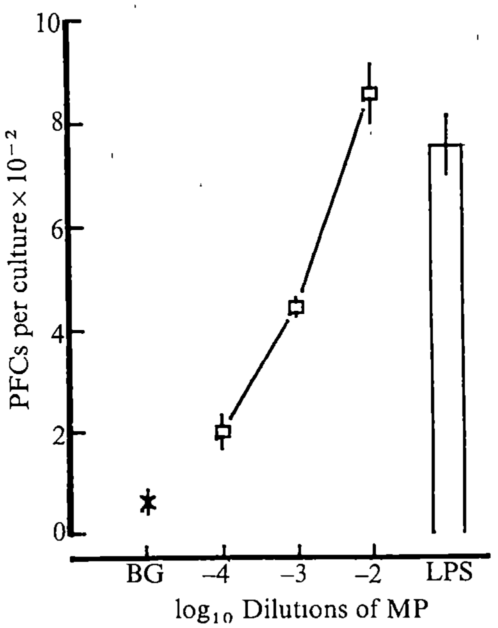

Fig. 2 Spleen cells from 6-week-old C57BL mice were cultured in the presence of MP or LPS (100 μg) at a cell concentration of 10^7 cells per culture, in serum-free medium. Polyclonal antibody synthesis was measured after 2 d by detecting numbers of PFC against SRBC coupled with NNP.

MP antigen was prepared as before[2] from organisms grown in broth on a glass surface. A concentrate of MP organisms was ultrasonicated and heated at 56 °C for 30 min to kill all viable organisms. The protein concentration of undiluted antigen was $2.5\ \mathrm{mg\ ml^{-1}}$. LPS (obtained from Dr T. Holme, Stockholm) was extracted from *E. coli* 055 : B5 by the phenol water method. PPD (tuberculin RT 32) was obtained from Statens Seruminstitut, Copenhagen.

After addition of MP, spleen cells from normal mice responded with increased thymidine uptake (Fig. 1) as well as antibody secretion (Fig. 2). The peak of activation occurred on days 2 and 3 (data not shown). Removal of adherent cells only enhanced DNA synthesis (Fig. 1), and normal thymocytes did not respond. As the medium used for growing the MP organisms had no effect on either DNA synthesis or antibody secretion, we concluded that MP acts as a polyclonal activator for mouse spleen cells.

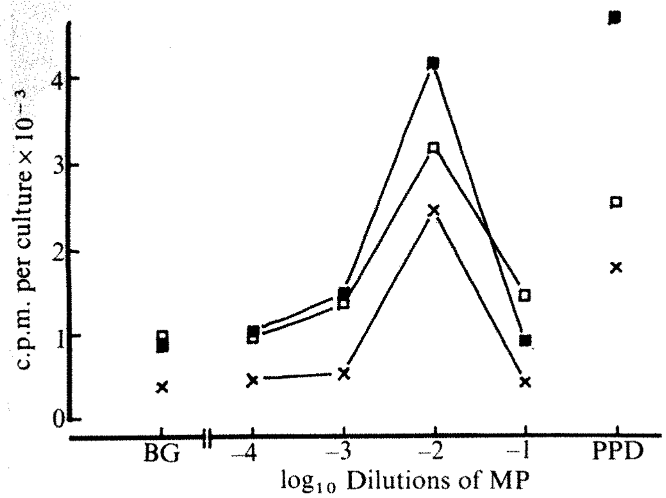

Fig. 3 Spleen cells from each of three guinea pigs were cultured in the presence of MP or PPD (100 μg) at a cell concentration of 5×10^5 cells per culture in serum-free medium. DNA synthesis was measured after 2 d by the uptake of ^{14}C-thymidine. Each symbol represents the mean of triplicates of cells from one animal.

Adherent cells were not necessary for activation, and thymocytes did not respond, indicating that MP was a polyclonal B-cell activator. Indeed, spleen cells from Nu/Nu mice responded both by increased thymidine uptake and by producing increased numbers of antibody-secreting cells to various antigens (Table 1).

The multispecificity of the MP-induced antibody response and the fact that cells from pathogen-free mice responded makes it unlikely that stimulation was due to a previous *in vivo* infection by a microorganism cross reacting with MP antigens.

MP also stimulated DNA synthesis in spleen cells from normal guinea pigs (Fig. 3). Some animals showed a stronger response to MP than to PPD, whereas others responded better to PPD. Experimental MP infection in guinea pigs serves as a model for mycoplasma infection in man[9], and so the guinea pig is a suitable animal for studies of the mitogenicity of MP *in vivo*.

An animal mycoplasma, *M. pulmonis*, has been shown to stimulate rat lymphocytes nonspecifically[10]. It is not known whether the responding cells were B or T lymphocytes. The stimulating factor of this mycoplasma was heat labile, in contrast to the mitogenic component of MP.

The results reported here do not provide information about the chemical nature of the MP component responsible for the mitogenic effect. The antigens eliciting specific antibodies to MP are located mainly in the mycoplasma cell membrane, which consists essentially of a lipid bilayer with proteins[11]. The main serologically active MP components are glycolipids with haptenic properties[12,13]. Previous studies have shown that a lipid extract of MP, reacting with MP antisera in the complement-fixation test, did not stimulate sensitised or non-sensitised human peripheral blood lymphocytes[2]. Further studies are necessary to elucidate the relationship between antigenicity and mitogenicity of various MP components.

Antibodies synthesised by mitogenically activated cells *in vitro* are most often of the IgM class[6]. Since MP infection in man is often followed by an increase in serum IgM, which is only partly due to specific anti-MP antibodies[14], we suggest that this increase could in part be the result of MP-induced mitogenic activation of B cells. The fact that IgM antibodies directed to autoantigens are found after MP infection[1,15] supports our suggestion. Mitogenicity of MP towards human lymphocytes has still to be firmly established, however.

In summary, our data show that MP, an important pathogen in man, is a polyclonal activator for mouse B lymphocytes and has a mitogenic effect on guinea pig spleen cells *in vitro*. The ability of MP to activate B cells polyclonally might influence the antibody response of patients and experimental animals infected with this microorganism. Finally, the fact that almost all substances which act as polyclonal B-cell activators are derived from microorganisms might indicate the importance of mitogenic activation for an effective immune defence[16].

Purported difference between human T- and B-cell surface morphology is an artefact

BECAUSE of the previous inability to detect differences in lymphocyte morphology by light or transmission electron microscopy[1], reports that B and T lymphocytes examined with scanning electron microscopy (SEM) could be identified by their distinctive surface morphology have been met with interest[2–6]. In these studies, most 'villous' cells were identified as B lymphocytes and T lymphocytes were described as 'relatively smooth'. Some investigators have reported that T lymphocytes are more villous than B lymphocytes[7–9]; others, however, have not detected a difference in surface form among human[10,11], or murine lymphocytes[12–14]. The present study demonstrates that the

collection and fixation technique used in those studies that initially described the dichotomy in lymphocyte SEM morphology[2-5], artefactually produces smooth cells.

The surface morphology of normal mononuclear leukocytes prepared for SEM by the aspiration filtration technique[2-5] was contrasted with that of cells from parallel samples fixed in suspension (Table 1). When cells were fixed in suspension and processed on poly-L-lysine-coated glass coverslips, more than 97% of the cells were retained for SEM observation[15]. Approximately 93% were covered uniformly with variable numbers of short microvilli, 6% were ruffled, and less than 1% was smooth (Table 1, Fig. 1*a*). When parallel cell suspensions were aspirated live on to the filters with subsequent fixation, however, approximately 95% of the leukocytes appeared relatively smooth (Table 1).

Leukaemic cells of B- or T-lymphocytic origin were analysed in the same manner. Ninety-nine per cent of the blood lymphocytes from a patient with Sezary's syndrome were considered to be T lymphocytes on the basis of the formation of spontaneous E rosettes with sheep erythrocytes and the failure to stain with fluoresceinated anti-human immunoglobulin. Approximately 80% of the purified lymphocytes from a chronic lymphocytic leukaemic (CLL) patient were B lymphocytes, by the criteria of the presence of surface immunoglobulin and the binding of heat-aggregated immunoglobulin and antigen–antibody complexes, and 99.5% failed to form E rosettes. Although 98% of the lymphocytes from these patients with leukaemias of B- or T-cell origin were villous or ruffled when fixed in suspension, 81% of the T-leukaemic cells and 86% of the CLL cells appeared smooth when aspirated live on to filters (Table 1 and Fig. 1*b*, *c*, *e* and *f*).

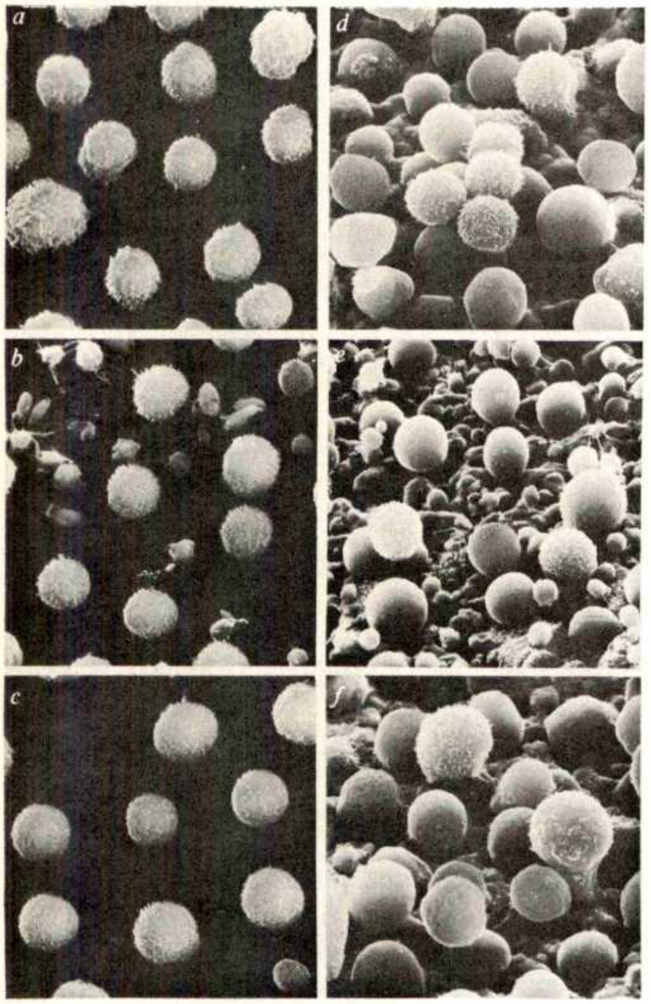

Fig. 1 Human peripheral mononuclear leukocytes were obtained from the defibrinated fresh blood of four normal donors by Ficoll–Hypaque density gradient centrifugation[16]. Differential counts indicated that on the basis of morphology 3% of the white cells were polymorphonuclear lymphocytes, 12% monocytes, and the remaining 85% lymphocytes. Leukaemic lymphocytes were obtained from the heparinised blood of a patient with CLL and by leukophoresis from a patient with Sezary's syndrome, and processed as outlined for normal human peripheral blood. 95–98% of the cells in these populations were lymphocytes. Surface marker studies were carried out on these purified leukaemic lymphocyte populations. E rosettes were carried out by a method published previously[17]. Surface immunoglobulin and aggregate binding and antigen–antibody complex binding were detected as described previously[18,19]. Cell viability as determined by Trypan blue dye exclusion was greater than 95% for all preparations. Cells from each donor were processed for SEM by each of two methods. First, cells were fixed in suspension for 24–48 h at 22 °C by centrifuging 2×10^6–8×10^6 cells at 200*g* for 10 min, resuspending the cell pellet in 1.0 ml RPMI1640, and adding 0.8 ml 2.5% glutaraldehyde (Tousimis, Rockville, Maryland) in Sorensen's buffer (*p*H 7.2, 380 mosmol). This final 1% fixative concentration was selected to correspond to that previously utilised in studies reporting a difference in lymphocyte topography[2-5]. The fixed cells were then washed twice in Sorensen's buffer and processed on poly-L-lysine-coated glass coverslips as described previously[15]. The second method consisted of processing parallel samples by the aspiration filtration method according to Polliack *et al.*[2-5]. From 2×10^6 to 8×10^6 cells suspended in 5.0 ml of media were aspirated live on to silver membrane filters (13 mm diameter; Flotronics, Selas, Spring House, Pennsylvania) in Swinex holders (Millipore) with a peristaltic pump at a flow rate of 1.0 ml min^{-1}. When 0.5 ml of the suspension remained above the filter, 2.0 ml 1% glutaraldehyde in Sorensen's buffer were added dropwise. After 10 min, the filters were transferred to small plastic Petri dishes for continuing fixation in fresh fixative for 24–72 h. Fixation was carried out at 22 °C. All specimens were prepared in triplicate. Subsequently, the fixed cells on coverslips and silver filters were dehydrated through a graded series of ethanol and prepared by the critical-point drying method[20]. Samples were processed entirely in the liquid phase to avoid air drying. The specimens were vacuum coated with gold–palladium on a tilting, rotating stage, examined with an Etec Autoscan microscope at 20 kV and 45° tilt, and photographed using Polaroid 55 film. The surface morphology of cells prepared by each of the two methods was classified into 'relatively smooth', 'villous', and 'ruffled' categories to correspond with previous descriptions of leukocyte surface morphology[2-5]. Percentages of smooth cells are reported in Table 1. *a–c*, Human leukocytes fixed in suspension, attached to poly-L-lysine-coated glass coverslips, and processed for SEM[15]. Cells are spherical and uniformly covered with short microvilli. Several ruffled cells and platelets are present. *d–f*, Parallel samples of populations illustrated in *a–c* prepared for SEM by the aspiration–filtration technique used in the descriptive studies[2-5]. The majority of cells shown have lost their villous surface topography. The field in *d* was selected from a filter with a high cell density to illustrate both villous and smooth forms. Ninety-five per cent of the cells were smooth on filters to which fewer cells (2×10^6) had been applied (Table 1). When cell density exceeds a monocellular distribution, cells not in direct contact with the filter tend to retain their villous structure (*d–f*). Smooth lymphocytes tend to be smaller and located within the crevices of the filter (*d–f*). Note the partially villous cell which seems to have been partly aspirated into a filter crevice (*f*). *a* and *d*, Normal peripheral blood leukocytes; *b* and *e*, cells from patient with CLL, B-cell leukaemia; *c* and *f*, cells from patient with Sezary's syndrome, T-cell leukaemia. ×1,750.

By varying the number of cells applied to the filters, we have been able to vary further the ratio of smooth to villous cells in any given population. On filters where the cell density exceeded a monolayer, the surfaces of cells in direct contact with the substrate tended to be smoother than those of cells retained on the filters by way of attachment to other cells (Fig. 1*d*) Many of the smooth cells seemed to have been aspirated into crevices of the filter and such cells tended to be smaller than the more villous cells which were situated on top of the substrate or of other cells (Fig. 1*d*–*f*).

The present investigation demonstrates that smooth lymphocytes can be artefactually and variably generated from villous cells by the SEM preparative technique used in those studies that initially described B cells as villous and T cells as relatively smooth[2–5] The alteration induced by this technique also seems to be nonspecific since it affects normal mononuclear leukocytes as well as leukaemic lymphocytes of both B and T origin. Thus, using the aspiration filtration method[2–5], we have been unable to reproduce the observation that populations of T cells are predominantly smooth, whereas B cells are villous. A likely explanation for these differences lies in the way the experiments of Polliack *et al.*[2–5] were carried out and the manner in which the results were interpreted.

For example, we have demonstrated that the technique of aspiration filtration[2–5] smooths the surfaces of living cells in direct contact with the filters and aspirates portions of some of the cells into the filter crevices. Thus, it seems that the surface characteristics of the final population are likely to depend on the specific conditions used, such as duration of contact with substrate, the negative pressure applied to the filter, and/or cell density. It is not clear that these important variables were controlled adequately in the previous experiments[2–5]. In addition, control of other important factors, such as the conditions in which cells were handled before aspiration filtration has not been reported by proponents of the T–B surface structure dichotomy[2–5]. Cold temperature, for example, has been shown to smooth the surface architecture of lymphocytes[21,22]. Normal T lymphocytes induced to form E rosettes at 4 °C are relatively smooth[3,23], but are villous when E rosettes are formed at 20 °C (refs 8 and 24). R.B. (unpublished) has demonstrated that lymphocytes from the same E-rosetting T-cell population are villous at room temperature and relatively smooth at 4 °C. When all these variables are controlled we observed no difference between the surface morphology of B and T lymphocytes. Thus it is possible that the initial results, that ratios of T to B cells in normal human peripheral blood seemed to correlate with surface morphology, were secondary to one or any combination of these variables and erroneously attributed to a structure–function relationship. Differences in the handling of various samples without regard to these variables could have led to a perpetration of the error with rosetted cells, cell lines and leukaemic populations.

The investigators correlating ratios of villous to smooth cells with proportions of B and T lymphocytes[2–5,25] determined by surface marker studies also failed to appreciate that there is no *a priori* reason to assume that the sets of surface morphological characteristics (that is, smooth and villous) are coextensive with the sets of functional classes of lymphocytes identified by surface markers (that is, T and B cells). This is particularly true when the populations used for markers may not have been comparable with those used for SEM (see ref. 26 for discussion). The analysis of individual cells fixed in suspension and positively identified by SEM surface markers demonstrated no difference in the surface morphology of surface immunoglobulin-positive and -negative cells[12,13].

A study using Hoffmann modulation contrast light microscopy (40× Nikon achromat objective; NA 0.65) with a maximal theoretical resolution just at or below the limits needed to delineate lymphocyte microvilli, failed to detect surface microvilli on most murine lymphoid cells[25]. When living human lymphocytes from monocyte-depleted Ficoll–Hypaque preparations, however, were processed at room temperature and examined with light microscopy (100 × Zeiss Planachromat objective; NA 1.25), 98% were villous (unpublished). These results are consistent with the report[27] that murine θ-positive and surface immunoglobulin-bearing lymphocytes stained with fluoresceinated ligands are equally villous.

In conclusion, it is not possible to identify reliably classes of lymphocytes *in vitro* exclusively on the basis of their SEM surface topography. Our observations challenge the concept of 'villous B' and 'smooth T' lymphocytes and indicate the necessity for a more critical approach to the preparation of cells of all types for SEM. These results do not exclude the possibility that subpopulations of lymphocytes may demonstrate distinctive differences in surface morphology with higher resolution electron microscopy. Nor do they preclude the possibility that lymphocyte subpopulations might respond differentially to certain microenvironmental manipulations with distinctive changes in surface morphology[28]. Because it has been amply demonstrated that lymphocyte surface morphology is dynamic and exquisitely susceptible to changes in *in vitro* conditions[7,10,24,26–28] it is likely that lymphocytes undergo continual alterations in their shape and form as they mature, divide, circulate, migrate and interact with surfaces and other cells as they function *in vivo*.

Microbial cells living immobilised on metal hydroxides

THE immobilisation of enzymes by attachment to water-insoluble materials has received considerable attention recently[1], both for academic reasons and for possible industrial applications. A logical extension of this approach, especially where multi-stage enzymic reactions are being considered, is the immobilisation of microorganisms, which are often the source of many enzyme preparations. The advantages of such an approach are immediately obvious. The tedious and time consuming procedures for enzyme extraction and purification are instantly eliminated, cofactors and coenzymes are readily at hand, the cellular enzymes are often organised into the requisite metabolic pathways and problems associated with enzyme instability may also be avoided. Furthermore, the use of immobilised cells would avoid the problem in industrial processes of separating the product from the enzyme. The immobilisation of cells by the standard glutaraldehyde procedure, however, causes their decease, and entrapment in polyacrylamide gel is commonly used instead to achieve immobilisation[2,3]. This method produces a minimum of interaction between the microbial cell and the insoluble matrix, thus maximising the probability of the cell's survival. On the other hand, the availability of the cell to any intended substrate is seriously reduced, since it can reach the cell only by diffusion. An alternative approach of immobilising cells on collagen, by the formation of a stable network of multiple ionic (salt) linkages, hydrogen bonds and Van der Waals' interactions has been successful[4]. We have now pursued an independent approach and report here the successful immobilisation of cells on the hydroxides (hydroxyoxides) of titanium (IV) and zirconium (IV) by a chelation process.

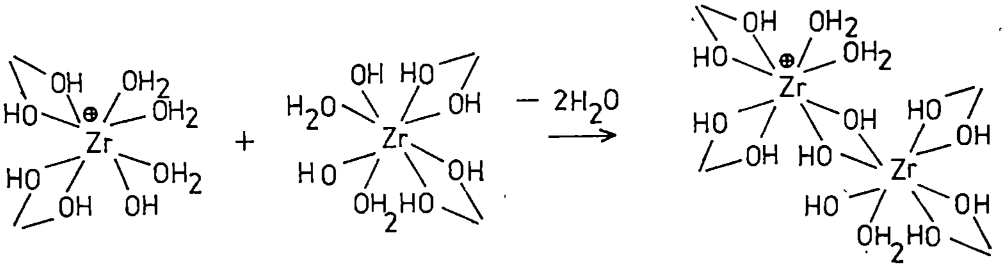

Fig. 1 The polymerisation of hydrolysed zirconium complexes.

Titanium hydroxides are insoluble over the normal physiological pH range, and acting as enzyme immobilisation matrices give good retention of enzymic activity[5,6], they thus seem to have little or no effect on the function of biologically active molecules. If enzymic activity, which is extremely sensitive to conformational changes in the enzyme molecule, is not seriously affected by immobilisation, then there seems to be little reason why cell walls should be disrupted or destroyed by this process and the cells themselves, therefore, have a good chance of remaining viable. Zirconium has an outer electron configuration of $4d^2 5s^2$ and occurs almost exclusively in its compounds in the 4+ oxidation state. Bonding to the maximum possible extent results in a maximum coordination number of 8. The zirconium ion can use various hybrid orbitals to give strongly directional bonds. For eightfold coordination, the orbitals used are d^4sp^3, leading to a dodecahedral arrangement, or d^5p^3, giving a square antiprismatic configuration[7]. In the latter, the lone pairs of electrons in the ligands form coordinate bonds with the vacant 4d and 5p orbitals of the zirconium ion, which are essentially covalent, involving the sharing of the lone pair of the oxygen atom.

The behaviour of zirconium complexes in aqueous solution is characterised by hydrolysis and polymerisation. When zirconium (IV) chloride is dissolved in water the reactions which occur can be formulated as below

$$\mathrm{ZrCl_4 + 8H_2O \rightarrow [Zr(H_2O)_8]^{4+} + 4Cl^-}$$

$$\mathrm{[Zr(H_2O)_8]^{4+} + H_2O \rightarrow [Zr(OH)(H_2O)_7]^{3+} + H_3O^+}$$

$$\mathrm{[Zr(OH)(H_2O)_7]^{3+} + H_2O \rightarrow [Zr(OH)_2(H_2O)_6]^{2+} + H_3O^+}$$

The final complex cation is then able to polymerise to give a tetrameric complex

$$\mathrm{4[Zr(OH)_2(H_2O)_6]^{2+} \rightarrow [Zr_4(OH)_8(H_2O)_{16}]^{8+} + 8H_2O}$$

This tetrameric complex has been shown[8] to be present in the aqueous solution, which has acidic properties, the H^+ activity of a mM solution being almost equal to that of mM HCl (ref. 9). This arises from the hydrolysis of the tetrameric complex

$$\mathrm{[Zr_4(OH)_8(H_2O)_{16}]^{8+} + 4H_2O \rightarrow [Zr_4(OH)_8(OH)_4(H_2O)_{12}]^{4+} + 4H_3O^+}$$

The charge on the complex is thus reduced to 4+ and, depending on the acid concentration, can be reduced further. Each of the four zirconium ions can hydrolyse separately

$$\mathrm{[Zr_4(OH)_8(OH)_4(H_2O)_{12}]^{4+} + H_2O \rightarrow [Zr_4(OH)_8(OH)_5(H_2O)_{11}]^{3+} + H_3O^+}$$

This results in one neutral group in the tetrameric complex. Assuming that the neutral group is localised on one of the zirconium atoms, the other three retaining their single positive charges, then this can be the starting point for a polymerisation reaction. The neutral site reacts with a singly charged site of another tetrameric complex so that the zirconium ions are connected by two hydroxide bridges (Fig. 1). The degree of polymerisation increases as the acid strength decreases[9] and

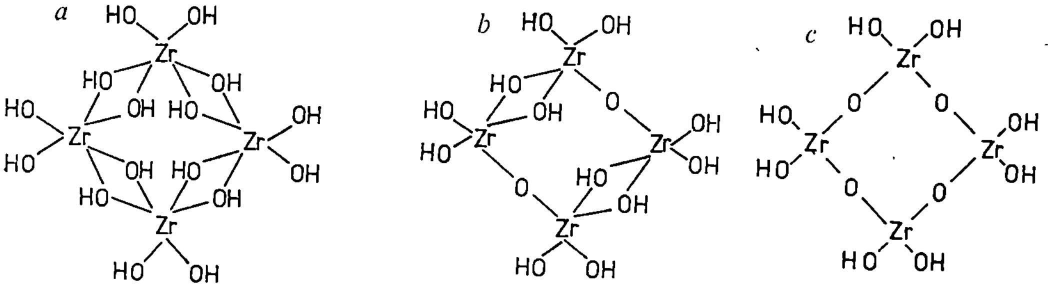

Fig. 2 *a*, *b*, *c*, Structures of zirconium hydroxide.

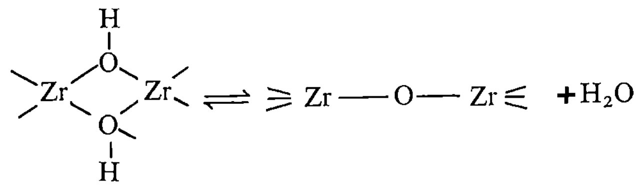
so addition of alkali to neutralise the acidic solution formed on dissolution of zirconyl chloride also increases the degree of polymerisation. When neutralisation is continued to *p*H 3, a precipitate begins to form. At the equivalence point (*p*H 9) precipitation is complete, the gelatinous precipitate being zirconium hydroxide (also known as hydrated zirconium dioxide or hydrous zirconia).

We propose that the precipitate contains a variety of compounds. The formation of the hydrated oxide is preceded by a stage involving the production of a true hydroxide containing hydroxyl groups[10]. The conversion of the hydroxide into 'hydrous zirconia' takes place very rapidly and irreversibly so that in practice the gelatinous precipitate is not the hydroxide.

Zaitsev[11], however, has shown that freshly precipitated zirconium hydroxide contains four hydroxo-groups for every zirconium atom and therefore that the compound with the formula $Zr(OH)_4.nH_2O$ can exist. Its stability is low, and on ageing it is converted into the so-called zirconyl hydroxide, containing two hydroxo-groups for every zirconium atom: $ZrO(OH)_2.nH_2O$ (ref. 11). When this is dried in the cold to a powder, it is converted into hydrated zirconium dioxide, having the formula $ZrO_2.xH_2O$ and containing no hydroxyl groups. Only two hydroxyl groups per zirconium atom of freshly precipitated zirconium hydroxide react with acid, the other two remaining inactive because double hydroxo- (or olate) bridges are formed between the zirconium atoms. The structure of the freshly precipitated hydroxide is thus extremely likely to be that depicted in Fig. 2*a*, together with an indefinite number of water molecules. This structural formula represents the main unit of the hydroxide, but in certain circumstances some of these tetrameric molecules may be joined together by oxo- or olate bridges. Conversion of a double olate bridge into an oxo-bridge is possible[12] by the following mechanism



$$>\mathrm{Zr}\begin{smallmatrix}\mathrm{O(H)}\\ \mathrm{O(H)}\end{smallmatrix}\mathrm{Zr}< \;\rightleftharpoons\; \geqslant \mathrm{Zr}—\mathrm{O}—\mathrm{Zr}\leqslant \;+\mathrm{H_2O}$$

suggesting that two other zirconium hydroxides may exist having zirconium atoms joined alternatively by double olate and oxo-bridges or zirconium atoms joined only by oxo-bridges. The possible structures of these hydroxides are shown in Fig. 2*b* and *c*; Fig. 2*b* represents a hydroxide having the formula $(OH)_3Zr–O–Zr(OH)_3.n\ H_2O$ and Fig. 2*c* corresponds to the hydroxide with the formula $ZrO(OH)_2.nH_2O$. The infrared absorption spectra of these two compounds indicate that they do not contain the $Zr{=}O$ group, and so must be cyclic polymers of the type indicated. We therefore conclude that in precipitated hydrous zirconium hydroxide there is an abundance of hydroxy groups replaceable by ligands.

Since the immobilisation process for a number of metal hydroxides is envisaged as involving the replacement of hydroxyl groups[13] on the surface of the metal hydroxide by suitable ligands from enzyme or cell, resulting in the formation of partial covalent bonds, we conclude that zirconium hydroxide should be suitable for immobilisation phenomena. In the case of enzymes, such ligands could be the side-chain hydroxyls of L-serine or L-threonine, the carboxyls of L-glutamic acid or L-aspartic acid and the ε-amino group of L-lysine residues, (Fig. 3), oxygen-containing ligands being preferred to those containing nitrogen[14]. In the case of cells, the structural complexity of the cell wall ensures the availability of a great diversity of suitable ligands from both protein and carbohydrate moieties.

Samples (each of 1.3 mmol) of the metal hydroxides for use in cell immobilisation were prepared from solutions of their tetrachlorides (titanium tetrachloride 15% w/v in 15% w/v hydrochloric acid (BDH) and zirconium tetrachloride (BDH) 0.65 M in 1.0 M hydrochloric acid) by the slow addition of 2.0 M ammonium hydroxide to neutrality (*p*H 7.0). The samples were washed with saline solution (0.9% w/v, 3 × 5.0 ml) to remove ammonium ions and then used for cell immobilisation studies as below.

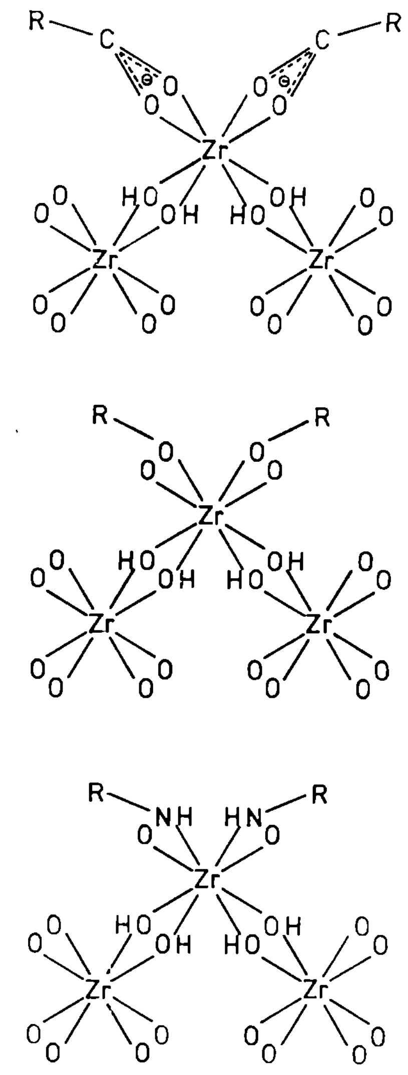


Fig. 3 Projected structures of the complexes of zirconium hydroxide with carboxyl, hydroxyl and amino groups respectively.

The procedure for cell immobilisation is very simple and is illustrated by the following example. A suspension (in 10 ml 0.9% w/v saline) of *Escherichia coli* cells (A_{600} 0.216) was mixed with a sample of the metal hydroxide prepared as above and agitated gently for 5 min at room temperature. The mixture was then allowed to stand at room temperature and the suspension settled out, leaving a clear supernatant (A_{600} 0.022) which was practically devoid of microorganisms (shown by microscopy) The immobilised cell preparation was consolidated by centrifugation at low speed and removed from the supernatant for further examination.

Saccharomyces cerevisiae and *E. coli* cells were immobilised in this manner and the preparations were examined for continued viability by measurement of their oxygen uptake (at 25 °C in aerated 0.2 M sodium acetate buffer *p*H 5.0, or 0.9% w/v saline by use of an oxygen electrode (Pye Unicam Ltd). The rate of oxygen uptake of the immobilised cells was ~30% of that of the same number of free cells. This result showed that respiration of the cells could continue when the cells were immobilised. The reduced rate of oxygen uptake is probably caused by the restriction by the metal hydroxide of access of aerated buffer to the cells and a decrease of the area of cell surface available for oxygen transfer.

To show that the cells were firmly attached to the surface of the metal hydroxide and not just loosely trapped in the gelatinous matrix, a number of arguments are invoked. Free cells of *E. coli* are comparatively small and cannot be centrifuged down to any significant extent in the centrifugation conditions used for collecting the immobilised cells; they are not particularly robust and so any disruption process which had occurred would, therefore, have rendered them inactive and unable to respire. Solutions of bicarbonate, phosphate, fluoride (and so on) ions which have been shown[6] to remove loosely bound proteinaceous and other materials from zirconium (IV) hydroxide were singularly ineffective in the attempted release of the immobilised cells from the matrix.

To show further that the cells were firmly attached to the metal hydroxide, a different microorganism, *Serratia marcescens*, was employed. When incubated in nutrient medium at 25 °C, this organism produces a distinctive red colouration, which enables the immobilised cells to be distinguished readily from those of any other contaminating microorganisms and also obviates the need for sterile experimental conditions.

On adding cultures of *S. marcescens* to zirconium (IV) and titanium (IV) hydroxides, the red colouration (that is, the cells) became associated with the insoluble matrix, the supernatant and subsequent washings (with saline solution) being almost cell free, thus demonstrating the strength of the cell–metal hydroxide interaction. When samples of these immobilised cells were added as a small inoculum to fresh culture medium, growth was observed (as detected by the large increase in numbers of red cells). Since at no time throughout extended studies of the growth of *S. marcescens*, in various conditions of humidity, oxygen tension, temperature and medium composition and ultraviolet irradiation-induced mutation, was release of colour from the cells observed, this was taken as evidence that the cells had suffered no deleterious effects on immobilisation.

It was also found that cells could be immobilised at lower *p*H, titanium (IV) hydroxide being more effective for this purpose, in the range studied (*p*H 2–5). This phenomenon is useful since not all microorganisms exist in a neutral *p*H environment (for example, *Lactobacillus* and *Acetobacter*) and enabled us to produce a small scale immobilised cell reactor. *Acetobacter* cells, immobilised on titanium (IV) hydroxide, were able to produce acetic acid from an alcoholic medium in a continuous reactor, often at rates higher than those obtained when free cells were used (a basic rate 87 g acetic acid per day (86% conversion) increased to 263 g per day (99% conversion) after immobilisation), thus demonstrating the practicability of this immobilisation method. If this simple means of cell immobilisation was applied to other microorganisms it could well result in further immobilised cell reactors of this sort, for the selective production of commercially important biochemical and pharmaceutical compounds. Furthermore, we conclude from the results that immobilised cells can retain their activity for a matter of weeks at least.

As with immobilised enzymes, immobilised cell systems have been applied to very few industrial processes, partially because of the inertia of established methods and partially because of the increased difficulty of operating such systems. It seems certain, however, that the inherent advantages of these systems will eventually prevail and there will be an increasing use of immobilised systems by the pharmaceutical, chemical and food industries.

Phenotypic difference between *uvrA* and *uvrB* mutants of *E. coli*

THE synthesis of colicin E1, an antibiotic protein, by cells of *Escherichia coli* is coded for by a bacterial plasmid, colicinogenic factor E1 (ColE1). The synthesis is induced by agents such as ultraviolet light[1] or mitomycin C (mit C)[2]. Ultraviolet and mit C are known to modify the base portions of DNA to form pyrimidine dimers[3] and cross linkages between complementary strands[4], respectively. Damage to DNA caused by ultraviolet or mit C is repairable by a similar molecular mechanism[5,6], but the relationship between these repair systems and the induction process of ColE1 synthesis has not been established unequivocally We have analysed the induction of the colicin by ultraviolet and mit C in various ultraviolet-sensitive mutants to which the colicinogenic factor was transferred. Among the mutants tested, the *recA* mutant did not synthesise the colicin in response to ultraviolet or mit C as reported previously[7]. In addition, however, we have now found that the induction of the colicin synthesis is greatly delayed in the *uvrB* mutant, but is normal in the *uvrA* mutant.

Both *uvrA* and *uvrB* mutants are deficient in removing pyrimidine dimers, or cross linkages caused by mit C,

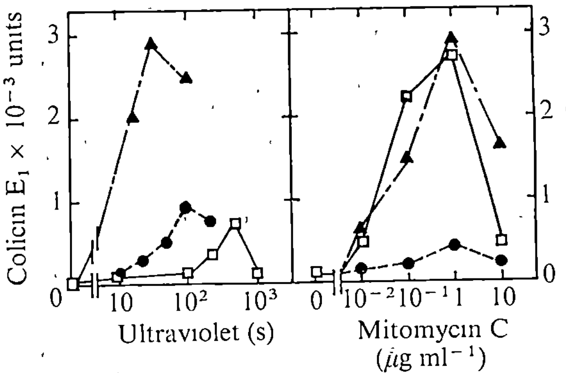

Fig. 1 Effect of varying doses of ultraviolet light and mitomycin C on the induction of colicin E1 synthesis The following strains of *E. coli* K12 were used: AB1157 (uvr^+, thr^-, pro^-, leu^-, his^-, arg^-, thi^-, lac^-, gal^-, ara^-, xyl^-, mtl^-, tsx^r, str^r, F^-), AB2437 ($uvrA^-$, his^-, thi^-, str^r, Hfr), and AB1885 (AB1157 $uvrB^-$) ColE1 DNA was transferred to these strains according to the method previously described[14]. For the growth of bacteria, minimal salt media (M-9) supplemented with vitamin-free casamino acids (0.15 %), thiamine (10 μg ml^{-1}) and glucose (0.4%) were used[14] Cells of each strain which were aerobically grown to log phase (1×10^9 cells ml^{-1}) were washed and incubated without aeration in the above synthetic media at 37 °C in the dark after addition of mit C or irradiation with ultraviolet light After 2 h the incubation mixtures were treated by sonic oscillation and the colicin activities were determined as previously described[14]. The colicin activity of untreated cells (less than 20 units per A_{660}) was subtracted from activities obtained. For ultraviolet induction, the bacterial suspension (2.5 ml) was irradiated in 9-cm diameter Petri dishes with a 6 W low pressure mercury National germicidal lamp from the height of 1 m. In these conditions, irradiation for 60 s is equivalent to 30 erg mm^{-2}. □, uvr^+; ▲, $uvrA^-$; ●, $uvrB^-$.

Table 1 Time course of the induction of colicin E1 synthesis by mitomycin C and decarbamoyl mitomycin C

Strain	mit C-induced colicin E1 activity at (h)					DCmit C-induced colicin E1 activity at (h)	
	0	1	2	4	8	0	2
AB1157 (ColE1) *uvr*$^+$	0	25	100	69	54	0	90
AB2437 (ColE1) *uvrA*$^-$	0	50	100	42	26	0	100
AB1885 (ColE1) *uvrB*$^-$	0	5	10	33	80	0	81
KMBL49 (ColE1) *uvr*$^+$	0	56	100	100	100	0	88
KMBL90 (ColE1) *uvrB*$^-$	0	1	20	38	53	0	70
KMBL101 (ColE1) *uvrB*$^-$	0	14	32	32	70	0	68

AB1157 (ColE1), AB2437(ColE1), and AB1885(ColE1) were described. KMBL90 *dar*$_1$$^-$ (*uvrB*$^-$) and KMBL101 *dar*$_6$$^-$ (*uvrB*$^-$) were derived from KMBL49 (KA22 *dar*$^+$, *thr*$^-$, *leu*$^-$, *thi*$^-$, *pyr*$^-$, *thy*$^-$)[11]. For the growth of these KMBL strains, M-9-glucose-casamino acids media (see Fig. 1) were further supplemented with thymine (20 μg ml^{-1}), uridine (200 μg ml^{-1}), and biotin (4 μg ml^{-1}). Transfer of ColE1 DNA to these strains was made from *nadC*13(ColE1) with the aid of W3110 prototroph F$^+$. The concentration of mitomycin C or decarbamoyl mitomycin C was 1 μg ml^{-1}. Conditions for induction and determination of colicin E1 activity have been described previously.

compared with the *uvr*$^+$ strain[5,6,8] and are considered to be defective in the endonucleolytic steps of excision repair[9]. Apart from the difference at the genetic locus[10,11], no phenotypic differences between these two mutants have been found with respect to the following points at least: sensitivity to ultraviolet, mit C (ref. 5) and X rays[10]; the capacity of ultraviolet or mit C to induce mutations[6,12]; the ability to reactivate ultraviolet-irradiated T1, or λ phage[5,13]; the inducibility of prophage by ultraviolet or mit C (ref. 13); and the absence of endonuclease activity[9]. As far as colicin E1 induction was concerned, however, the *uvrB* mutant behaved differently from the *uvrA* mutant and this provides evidence for the first time that the functions of *uvrA* and *uvrB* genes are not completely identical.

Cells of the *uvrA* and *uvrB* mutants and a *uvr*$^+$ strain[10] which were made colicinogenic were treated with various doses of ultraviolet and mit C and incubated for 2 h in the standard induction conditions[14]. In the case of ultraviolet induction, both mutants synthesised greater amounts of colicin E1 in response to lower doses of ultraviolet than did the wild type (Fig. 1). In contrast, on mit C induction, little colicin E1 was produced in *uvrB* mutants at any concentration of mit C, whereas colicin E1 synthesis in *uvrA* mutants was almost the same as in the *uvr*$^+$ strain (Fig. 1). The optimal concentrations of mit C for induction were the same for these mutant strains, whereas the optimal doses of ultraviolet for induction were different in the two strains. Ranking the mutants according to the ultraviolet dose required for maximum colicin induction correlated with the order of sensitivity to ultraviolet-induced killing; the *uvrA* mutant was the most sensitive to ultraviolet and the optimal dose for colicin induction was also the lowest.

In the *uvrB* mutant, however, when the cells were incubated for a longer period, the colicin was gradually synthesised (Table 1). After 8 h, the mutant produced almost the same amount of colicin E1 as the *uvr*$^+$ strain. The same findings were obtained from other *uvrB* mutants such as KMBL90(ColE1) and KMBL101(ColE1)[11]. Thus, it can be concluded that colicin E1 synthesis was greatly delayed in *uvrB* mutant.

Viable cell number of the *uvrB* mutant decreased to 1% after a 30-min incubation with mit C (1 μg ml^{-1}). In addition, when the *uvrB* cells were incubated for 30 min with mit C, followed by washing and additional incubation in the fresh medium without mit C, the same time course of colicin E1 synthesis was obtained as without treatment. These observations suggest that the first step of the action of mit C is already complete within 30 min of incubation in the *uvrB* mutant and that a certain process after this step to colicin E1 protein synthesis is impaired.

Decarbamoyl mitomycin C (DCmit C), a monofunctional alkylating agent, could induce colicin E1 synthesis at a normal rate in all of the above *uvrB* mutants (Table 1). DCmit C attaches to a single strand of DNA and does not cross link between the strands[6]. In addition, the DNA damage caused by the monofunctional mit C was repairable by an excision repair system similar to that for ultraviolet-irradiated DNA. Thus, the delayed response of the colicin synthesis in *uvrB* mutant was associated with the formation of the cross linkages between the DNA strands.

Although the *uvrA* mutant lacks the ability to repair DNA damage caused by mit C, DCmit C and ultraviolet[5,6] by excision, the mutant was induced to synthesise colicin E1 by these agents. It is, therefore, unlikely that the excision repair process itself is directly involved in colicin induction. In these mutant strains, another repair mechanism, the post-replicational repair system, will operate in some cases[15]. The operation of post-replicational repair seems to be essential for colicin induction, since neither mit C nor ultraviolet could induce colicin E1 synthesis in a *recA* mutant. The *recA* gene is believed to control the whole process of the post-replicational repair system[15].

We thank Drs K. Mizobuchi and K. Suzuki for bacterial strains and Dr M. Tanaka for DCmit C. This research was supported in part by the Scientific Research Fund of the Ministry of Education of Japan.

An intracistronic region of gene *A* of bacteriophage φX174 not involved in progeny RF DNA synthesis

GENE *A* of the single-stranded DNA bacteriophage φX174 has a key position in the replication of the first double-stranded replicative form (parental RF) to progeny RF DNA molecules. The action of gene *A* manifests itself in the introduction of a nick in the viral strand of the parental RF (ref. 1), which seems to be a condition for the RF DNA replication. The nick is located within gene *A* (ref. 2)

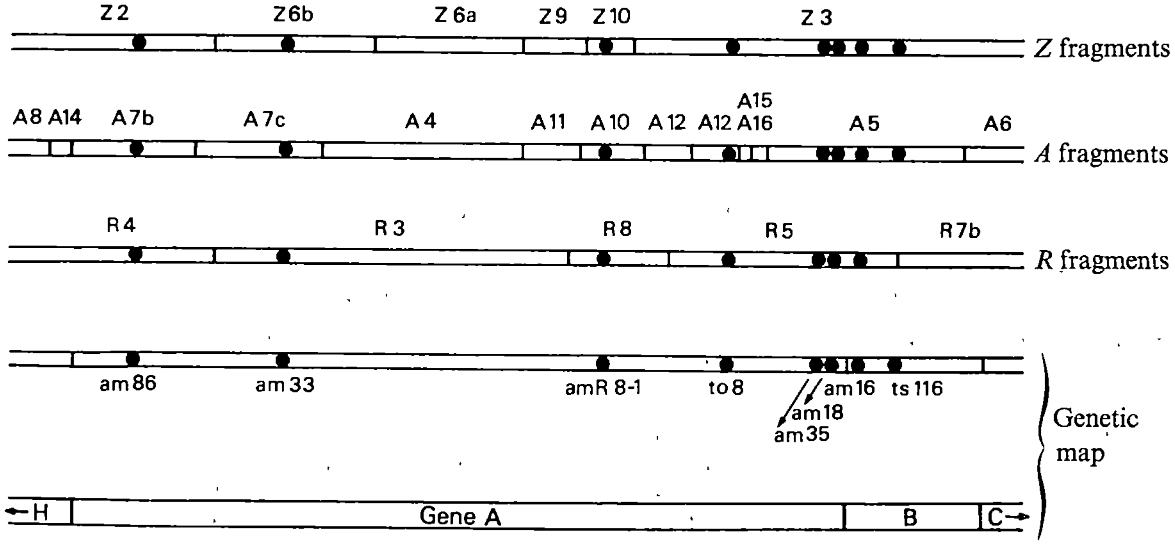

Fig. 1 Genetic map of the gene *A* and gene *B* region.

and is achieved by a *cis*-acting gene product[3,4]. It has been shown that gene *A* codes for two overlapping proteins, *A* and *A′* (molecular weights 35,000 and 60–65,000, respectively)[5,6]. The molecular weight of the large protein corresponds to the size of gene *A* as determined using restriction enzyme fragments[7]. The large A protein may be involved in achieving the nick[8], the small A protein in the shut-off of the host DNA replication[9]. We present here genetic evidence that gene *A* consists of three different regions. Two of them are involved in double-stranded DNA replication. They are physically separated by a third region, characterised by mutations that leave double-stranded DNA synthesis unaffected.

We have isolated a group of conditional lethal nonsense mutants of φX174 which could not be assigned unambiguously to one of the known genes. In complementation tests these mutants complemented well with mutants of genes *A*, *C* up to and including *H*, but the complementation behaviour with mutants of gene *B* was aberrant. This is shown in Table 1 for *to8*, one of the mutants[10] of that group. No complementation could be found between *to8* and the amber mutants of gene *B*, whereas complementation with the gene *B ts* mutants did occur, although marginally (the temperature seemed to be very critical to the selfing of these *ts* mutants).

In the first instance we supposed that *to8* belonged to a new cistron, located (in terms of translation) distally of and adjacent to gene *B* (ref. 12). If so, the complementation behaviour could be explained by a polarity effect of the amber mutants of gene *B* over the mutants of the new cistron. After the development of the new technique of localisation of mutants with the help of restriction enzyme fragments[7], however, we found (Table 2) that the *to8* mutation is covered by the R5 fragment made by the restriction enzyme *Hin*dII from *Haemophilus influenzae* Rd, the Z3 fragment made by *Hae*III from *H. aegyptius*, one of the four A12 fragments made by *Alu*I from *Arthrobacter luteus*, and the R5A12 fragment (= the A12

Escherichia coli C (su^-) cells were grown with aeration to log phase, centrifuged and resuspended in fresh medium to a concentration of 10^8–5×10^8 cells ml^{-1}. Ten minutes after addition of KCN (final concentration 0.003 M) the phage mutants were added at a multiplicity of three of each in the mixed infection and of six in the selfings. After a 10-min adsorption period the unadsorbed phage were inactivated by incubation with φX174 antiserum for 10 min. The adsorption mixture was diluted 10^4 times in prewarmed medium and after a 1-h growth period the yield of mutant particles was determined by plating on *E. coli* HF4712 (su^+) at 30 °C. In the combination with *och6* the growth period was shortened to about 30 min, and the yield of the mixed infection and of the selfings was scored on *E. coli* WWU (*su*VIII) at 30 °C. Growth medium for *E. coli* WWU was TPG medium[11] supplemented with 0.05 g methionine, 0.05 g tryptophan, 0.05 g proline, 0.04 g thymidine and 0.03 g cytidine l^{-1}. Other growth media were as described previously[10]. Each combination of mutants was tested in at least two different experiments. Test mutants were provided by Dr R. L. Sinsheimer *et al.*, except for *amH210* which was provided by Dr M. Hayashi.

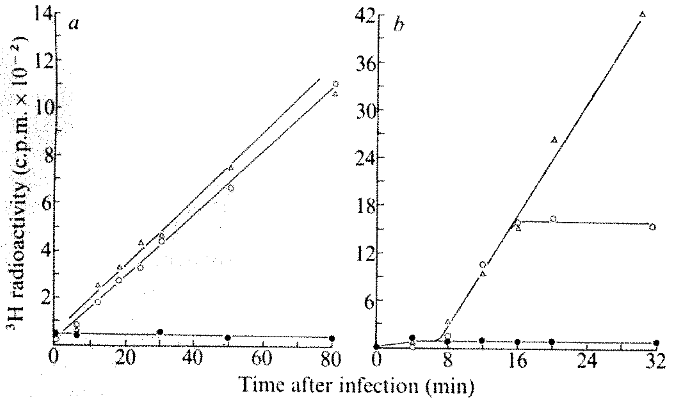

Fig. 2 Measurement of DNA synthesis. *E. coli* HF4704 (thy$^-$, *uvrA*, *su*$^-$) was grown in TPG medium[11] containing 200 μg casamino acids and 2 μg thymine ml^{-1} to a concentration of 3×10^8 cells ml^{-1} and treated with mitomycin C (50 μg ml^{-1}) for 25 min at 37 °C in the dark to block host DNA synthesis. The cells were centrifuged down and resuspended in fresh TPG medium containing 200 μg casamino acids and 1 μg thymine ml^{-1}, plus 35 μg chloramphenicol (CAM) ml^{-1} (*a*) or without CAM (*b*). After a 10-min incubation period at 37 °C ^{3}H-thymidine (specific activity 40 μCi μg^{-1}) was added to a final concentration of 2.5 μCi ml^{-1}, simultaneously with the phage (multiplicity of infection = 3). DNA synthesis was measured by the incorporation of ^{3}H-thymidine into TCA-precipitable material. The precipitation was accomplished by adding 100 μg bovine serum albumin as a carrier to a 0.5-ml sample. After 20 min in the cold the precipitate was spun down and washed twice with cold TCA, solubilised in 1 ml 0.55 N KOH and counted for radioactivity in a liquid scintillation counter. A correction was made for non-infected cells. ○, *to8*; ●, *am33*; △, *am3*.

The observation that *to8* is not affected in the progeny RF DNA synthesis, although it maps within gene *A*, leads to a division of gene *A* into three functionally distinct regions. Two regions are involved in the progeny RF DNA replication. They are separated by a third region in which mutations permit normal progeny RF DNA synthesis. Also, these mutants do not show the asymmetry in complementation as mutants in both the other regions do[10].

How can we interpret these results in terms of the functioning of gene *A*, considering our present knowledge? Both *am86* (*A*) and *am18* (*A*) interfere with the synthesis of the 60,000 molecular weight protein[9], although they are separated by the *to8* region that seems to have a different function. The complementation results indicate three separate genes, two of which are involved in the progeny RF DNA synthesis in such a way that mutants in both functions do not complement each other. The 60,000 molecular weight protein could then be a read-through product, without any function. This, however, is in conflict with the endonuclease activity ascribed to this protein[8].

On the basis of our experiments we prefer the hypothesis of three separate cistrons. Probably the real situation is even more complex, considering the finding that *to8* can be complemented by the *ts* mutants of gene *B*, but not by its amber mutants. This suggests a functional relationship between the products of the genes *A* (*to8* cistron) and *B*. Work is in progress to elucidate these phenomena.

We tried to estimate the size of the *to8* region by inducing amber mutations in that part of gene *A* by the technique of fragment mutagenisation[18]. We found three mutants which behaved like *to8* in the complementation test, and all mapped on the R5A12 fragment. Several 'real' gene *A* mutants were isolated, of which *amR8-1*, located at the R8 fragment, is nearest to *to8* (Fig. 1). So the maximum size of the *to8* region is the maximum distance between *amR8-1* and *am35* (ref. 7), which is about 600 base pairs.

Table 2 Localisation of *to8* mutation with restriction enzyme fragments

R fragment	Ratio wild type–total	*Z* fragment	Ratio wild type–total	*A* fragment	Ratio wild type–total	*R5* digested with *Alu*I	Ratio wild type–total
R3	7.8×10^{-5}						
R8	1.7×10^{-5}	*Z10*	4.5×10^{-5}				
R5	1.2×10^{-2}	*Z3*	1.5×10^{-2}	*A12**	1.2×10^{-3}	*R5A12*	6.7×10^{-3}
*R7**	2.8×10^{-5}	*Z7*	2.9×10^{-5}	*A5*	1.0×10^{-5}	*R5A5*	1.6×10^{-5}
*R6**	1.0×10^{-4}			*A6*	2.6×10^{-5}		
R1	1.3×10^{-4}						
R9	4.6×10^{-5}						
R10	2.1×10^{-5}						
R2	6.9×10^{-5}						
R4	4.0×10^{-4}						

Wild-type double-stranded DNA molecules were completely digested with *Hin*dII (giving rise to *R* fragments, *Alu*I (*A* fragments) and *Hae*III (*Z* fragments). Subsequently the fragments were fractionated with gel electrophoresis[13,14]. *R5* fragment was completely digested further with the *Alu*I enzyme. Subfragments *R5A5* and *R5A12* were used in the experiments. The fractionated double-stranded DNA fragments were annealed to *to8* single-stranded DNA[7]. These partial hybrid molecules were given to spheroplasts of *E. coli* K58 (*su*$^+$) and after a 2–3-h growth period the yield was determined on *E. coli* HF4712 (total yield) and on *E. coli* C (wild type). The rationale behind the experiment is that if the *to8* mutation is covered by a fragment carrying the wild-type allele, the share of wild-type particles in the yield after spheroplast infection (that is, the ratio wild type–total) will be increased markedly[7,15]. The fragments are ordered according to their sequence on the genetic map. The localisation with the *R* fragments showed *R5* as the fragment with the wild-type allele. So, of the *Z* and *A* fragments only the ones in the region of *R5* had to be tested.

*The *R6*, *R7* and *A12* preparations contain respectively 3, 2 and 4 different fragments of the same size.

fragment made from R5 by *Alu*I digestion). In this way we were able to insert *to8* in the genetic map (Fig. 1). The other mutants of this 'new cistron' also map on the R5A12 fragment. It is clear that *to8* maps within gene *A*, and is separated from gene *B* by the *A* mutants *am35* and *am18*.

We next looked at the DNA synthesis in restrictive conditions in the presence and absence of chloramphenicol (CAM). With CAM only progeny RF DNA synthesis is permitted[16]; without CAM both RF and single-stranded DNA synthesis can proceed. As a control *am3* (gene *E*) and *am33* (gene *A*) were included in the experiment. Figure 2*a* shows that *to8* synthesises progeny RF DNA at the same rate as *am3*, a lysis-defective mutant not blocked in DNA replication[16]. Without CAM (Fig. 2*b*) the DNA synthesis of *to8* stops at a time when single-stranded DNA synthesis starts[17]. The gene *A* mutant *am33* shows no significant DNA synthesis in both experiments.

Expression of flagellar genes carried by bacteriophage lambda

THE specific interaction of many components is necessary for the assembly and function of flagella in *Escherichia coli*. Twenty genes have been shown to participate[1–3] and at least eleven polypeptides are associated with the structure of the flagellar organelle[4]. The synthesis and assembly of these components and of flagellin, the major flagellar subunit protein, is tightly coupled and regulated[5–7]. It has not been possible to analyse these regulatory mechanisms in great detail because: (1) the tight coupling between events usually leads either to the synthesis of a complete organelle, or to no detectable flagellar structure, and (2) most of the flagellar components are present at low levels and their synthesis is difficult to measure. To analyse the hierarchy of control and regulation in this system we have prepared a series of hybrid transducing phages that carry different combinations of flagellar genes. We describe here one of these phages and show that it can be used to study the expression of flagellar gene activities.

Hybrid lambda (λ) *E. coli* DNA molecules were constructed using λgt–λc DNA as the vehicle and isolated F factors as a source of DNA carrying flagellar genes. Figure 1 shows the results of *Eco*RI endonuclease digestion of two of these episomes. F 1338 carries about 2% of the *E. coli* chromosome (Fig. 1) and includes most of the genes that are involved with flagellar assembly and function. F 1906 is a deleted episome[8] derived from F 1338; it lacks more than half the flagellar genes. Approximately 20 distinct bands can be distinguished in the digest of F 1906, and 33 bands in the digest of F 1338. The F 1338 digest was used to prepare hybrids according to the procedures described by Thomas *et al.*[9]. After transfection with hybrid molecules, a large number of λ plaques were picked and purified and lysates were prepared. The lysates were tested for their ability to transduce specific flagellar genes by using them to cross streak various λ lysogens on motility plates. Each lysogen carried a different flagellar gene mutation. Phages that carried specific flagellar genes were able to complement the appropriate lysogen which could then form trails in motility agar. Both abortive transduction and recombination could be scored on the motility plates. In this way various transducing phages have been isolated. We will describe one of these λ*fla*1.

Tests for abortive transduction showed that λ*fla*1 carried the genes *hag*, *fla*N and *fla*B. The *hag* gene controls the structure of flagellin, the major subunit component of the flagellar filament. *Fla*N and *fla*B refer to genes that include mutations resulting in bacterial strains that have no recognisable flagellar filaments. *Eco*RI endonuclease digestion and Agarose gel electrophoresis of λ*fla*1 DNA gave three bands. The relative mobility of the upper band suggested that it represented the left-hand fragment of λgt–λc. The second band had a mobility which corresponded to the right-hand fragment of λ (1.1×10^7 daltons). The third band is barely resolved from the others; it corresponds to the incorporated piece of *E. coli* DNA. Its relative mobility suggests that it is one of the high molecular weight bands seen in the digest of F 1338, but not in F 1906.

To characterise further the incorporated DNA, a series of deletions of λ*fla*1 was prepared. Analysis by abortive transduction revealed the genetic functions that were deleted from each phage, and the Agarose gel electrophoresis patterns of *Eco*RI endonuclease digests showed the corresponding portion of DNA that was removed (Fig. 2). Deletions extending into the incorporated piece of DNA from the right-hand side can remove the *Eco*RI site and fuse the incorporated piece to the right-hand fragment, thus decreasing its mobility on electrophoresis. The same kind of argument applies to deletions entering from the left-hand side and from the middle of the incorporated DNA. The subsequent changes in the apparent molecular weight of the fragments facilitate determination of the relative orientation of the genes with respect to the two ends of λ (Fig. 2).

The deleted phages were used to study the expression of *E. coli* gene activity by measuring incorporation of amino acids into proteins synthesised in ultraviolet-irradiated λ lysogens. Essentially the same procedure was used as that

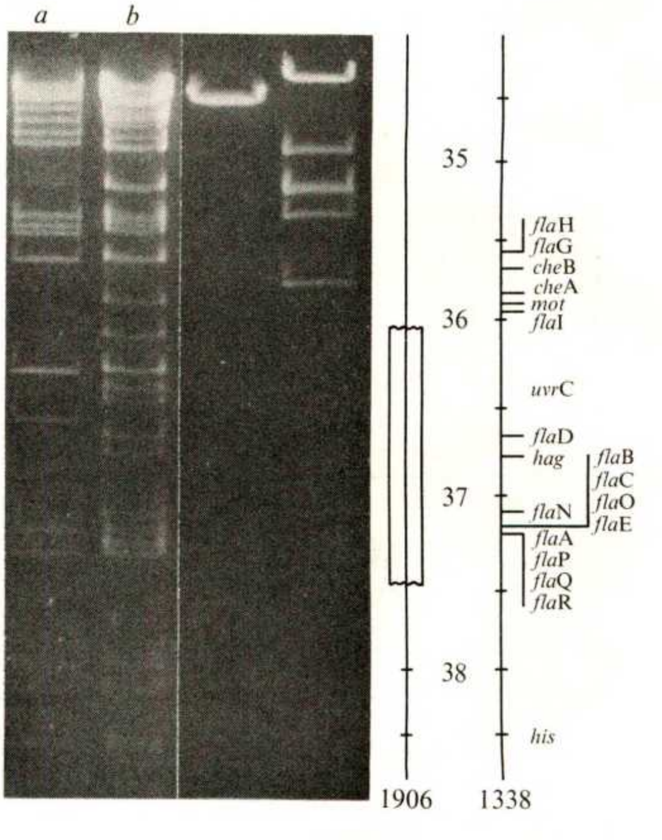

Fig. 1 Electrophoresis of *Eco*RI endonuclease digests of episomal DNA. The episomes were isolated by Sarkosyl lysis[14]. After an initial caesium chloride–ethidium bromide equilibrium centrifugation, the major portion of the chromosomal DNA was withdrawn without perturbing the band of episomal DNA. The solutions containing the episomal DNA were pooled and recentrifuged. Finally, the band corresponding to the density of covalently closed circular DNA was removed carefully. The DNA was precipitated[15] and 2–4 μg was treated with an excess of *Eco*RI endonuclease. After incubation with the enzyme, the samples were heated at 60 °C for 5 min and placed on 0.8% Agarose gel for electrophoresis. On the left is the pattern obtained from F 1906 DNA (*a*) and next to it the electrophoretogram of the digest of F 1338 DNA (*b*). For comparison, the *Eco*RI-treated plasmid (*c*) PML1 (9×10^6 daltons)[16] and λ (*d*) DNA are shown. The map on the right shows the genetic loci carried by the episomes.

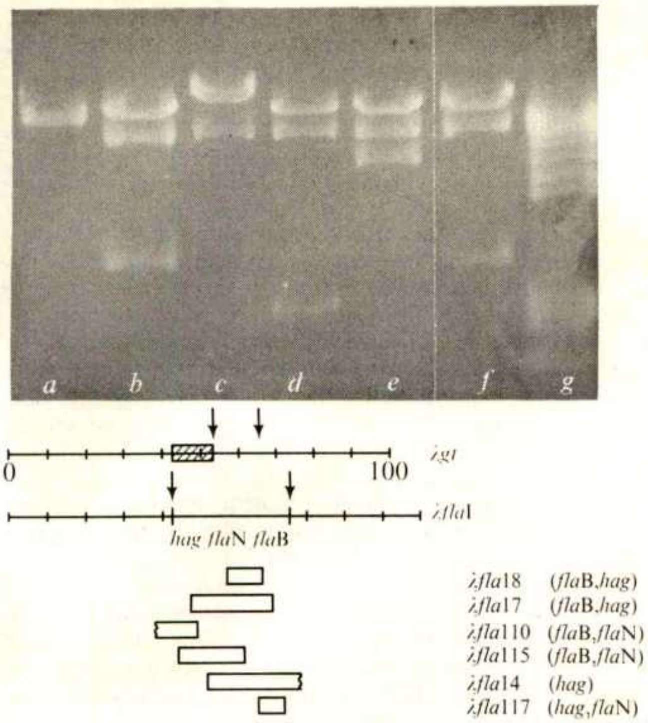

Fig. 2 Mapping of deletions in λ*fla*1. The Agarose gel electrophoretogram shows the results of *Eco*R1 digestion of DNA obtained from deletion mutants of λ*fla*1. The deletions were selected by the pyrophosphate shock technique[17]. Surviving plaques were picked and lysates prepared. After genetic tests to determine the remaining markers, DNA was prepared from the phages by phenol extraction. The DNA was treated with *Eco*RI endonuclease and electrophoresis was on 0.8% Agarose gels. *a*, λ*fla*14; *b*, λ*fla*115; *c*, λ*fla*110; *d*, λ*fla*17; *e*, λ*fla*18; *f*, λgt–λc; *g*, F 1906. The map below is derived from the data in this and other electrophoretograms. The order of the *E. coli* genes is shown. The relative distribution corresponds to that seen on the map in Fig. 1: *fla*N is close to *fla*B and further away from *hag*.

described by Jaskunas *et al.*[10-12]. Figure 3 shows that a major band consistently appears in the acrylamide gel electrophoresis patterns of extracts of cells infected with λs carrying the *hag* gene. Phages that do not carry *hag* but carry either the *fla*B or the *fla*N gene, or both, do not show this band. The band has a mobility which corresponds to an apparent molecular weight of 54,000, and it seems to have two minor bands associated with it, one at about 56,000 and another at 60,000. Furthermore, as the extract is heated at 100 °C for 20 min almost all the material shows a mobility corresponding to a molecular weight of 60,000. This pattern is characteristic of *E. coli* flagellin[13]. The evidence that this band corresponds to flagellin can be summarised as follows. (1) It comigrates precisely with authentic flagellin on one-dimensional acrylamide gels and shows the same characteristic band pattern. (2) It comigrates precisely on two-dimensional acrylamide gels prepared by the techniques described by O'Farrell[14], with authentic *E. coli* flagellin. (3) It only appears in extracts of cells infected with phages that have been shown by genetic techniques to carry the *hag* gene, which is the structural gene for flagellin. (4) Material forming the band which corresponds to flagellin is precipitated by anti-flagellar antibody and removed from the cells by shearing.

To test the regulation of flagellin synthesis, several mutant strains carrying flagellar gene mutations were prepared. Figure 3 shows the results obtained from infections of *hag*, *mot* and *fla*I mutants by λ*fla*1. Clearly flagellin is synthesised in the host strains which carry *hag* (Fig. 3*f* and *i*) or *mot* (Fig. 3*h*) mutations but it is not synthesised in the host which carries the *fla*I (Fig. 3*g*) mutation. Earlier experiments with flagellar mutants[7] suggested that the *fla*I gene product is necessary for *hag* gene expression. This system may be useful for studying the interactions between the *fla*I gene product and the *hag* gene.

We have not so far defined bands on acrylamide gels which correspond to products of the *fla*B or *fla*N genes. If these genes specify structural components of the flagellar basal structure, they may be read at rates that are 100 to 1,000 times slower than flagellin; this could account for our not having observed them. It should be possible, however, to prepare phages where these genes are oriented so that their expression can be affected by the leftward λ promoter. Jaskunas *et al.*[12] have shown that such an arrangement leads to synthesis of *E. coli* gene products at relative rates determined by the λ promoter.

The hybrid phages seem to make available a new way of looking at the regulation of synthesis, assembly and function of the bacterial flagellar organelle.

We thank Jeff Velten and John Abelson for help, Vickers

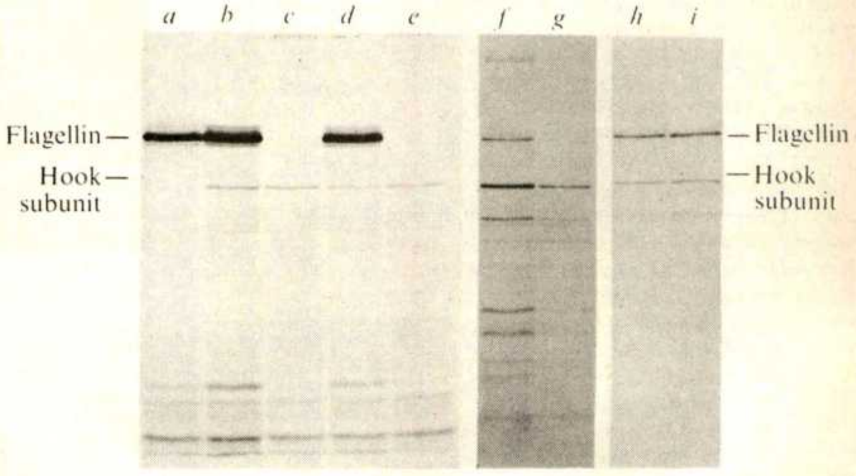

Fig. 3 Electrophoresis of proteins synthesised in ultraviolet-irradiated bacteria infected with hybrid λ phage. The infection of ultraviolet-irradiated cells was performed exactly as described by Jaskunas *et al.*[10,11]. After the infected, irradiated cells were labelled, they were pelleted and resuspended in sodium dodecyl sulphate (SDS)–gel sample buffer (3% SDS, 5% 2-mercaptoethanol, 10% glycerol and 0.06 M Tris–HCl, *p*H 6.8), heated for 1 min at 100 °C, and electrophoresed. Radioactively labelled marker proteins were used and the samples were loaded on to a 12.5% polyacrylamide gel slab containing 0.1% SDS. After electrophoresis the gels were dried and subjected to autoradiography. The host strain was either *E. coli* K12 strain 159 carrying λ (obtained from Dr H. Murialdo)[19], or mutants derived from this strain by mutagenesis and selection with bacteriophage chi. The chi-resistant mutants derived from 159 λ were screened by complementation and strains carrying *hag* (MS6101), *mot* (6106) and *fla*I (6103) mutations were chosen. Samples *a*, *b*, *c*, *d*, and *e* show the results of infection of 159 λ with: *a*, λ*fla*14 (*hag*); *b*, λ*fla*18 (*fla*B, *hag*); *c*, λ*fla*115 (*fla*B, *fla*N); *d*, λ*fla*117 (*hag*, *fla*N); *e*, λ*fla*110 (*fla*B, *fla*N). These autoradiograms were incubated with film for 5 d. The strains carrying flagellar mutations were infected with λ*fla*I at a multiplicity of approximately 10. *f*, *hag* (MS6101), a clear band corresponding to flagellin is seen. *g*, *fla*I (MS6103), no apparent flagellin material was found. *h*, *mot* (MS6106), a flagellin band appeared. *i*, *hag* (MS6101) was infected with λ*fla*14—another λ phage carrying the flagellin gene at a multiplicity of approximately 10. These autoradiograms were incubated with film for 1 d.

"Non-rigid" nucleotides in tRNA: a new correlation in the conformation of a ribose

WE have reported the three-dimensional structure of yeast tRNA^{Phe}, determined by fitting a skeletal wire model to an electron density map at a resolution of 2.5 Å, phased by the method of isomorphous replacement[1]. Atomic coordinates have been published for the unrefined structure[2]. We are in the process of refining our structure using difference Fourier techniques together with the real-space refinement procedure of Diamond[3]. The crystallographic residual (R) at 2.5 Å is 0.31, a value comparable to that found for proteins at a similar stage.

On the basis of a survey of the known nucleotide and nucleoside structures, several groups have suggested that the conformational angles are naturally confined to a few narrow ranges[4,5], and this concept has been embodied in the term "rigid nucleotide"[5]. The essence of this idea is that although a single nucleotide unit in a polymer or oligomer has six main-chain dihedral angles, the two on either side of the phosphorus atom (ω and ω') are the only ones which are free to vary, the others being confined to a narrow range. By applying this concept to folded nucleic acids, attempts have been made to predict the structures of non-helical regions[5,6]. Refinement of the tRNA structure tests to what extent these ideas and predictions are correct. We have found that the polynucleotide chain is able to explore many more conformations than are implied by the rigid nucleotide hypothesis, and thus that most previous energy calculations (for example ref. 7) and structural speculations have too limited a basis.

While we were building the wire model to fit the isomorphous replacement density map, it became clear that some ribose rings had to adopt the C2′-*endo* conformation (in contrast to the more usual C3′-*endo* found in RNA double helices), to fit the density for the pendant base and the phosphate groups on either side. This change in the sugar pucker implies a change of the dihedral angle ψ' (Fig. 1) from 83° to 146°, and thus has a considerable effect on the course of the chain. Most of the loops and extended regions in tRNA involve several such unusual sugars.

As well as changing the sugar pucker, we were obliged, in fitting the map, to change the conformation at the C4′–C5′ bond in a number of places. The normal conformation here (Fig. 1*a*) is the so-called *gauche*$^+$ (g^+, also called *gg*) in which the angle ψ (O5′–C5′–C4′–C3′) is +60°. (The sign convention is that, looking along the C5′–C4′ bond, a rotation of the nearest bond clockwise by 60° leads to an eclipsed conformation.) In addition to a number of residues in which conformation about the C5′–C4′ bond, is *trans* (*t* or *gt*), with $\psi=180°$, we found four instances in which the value of ψ is $-60°$ (the rare g^-, or *tg*, conformation). In all four of these cases, the ribose ring has the C2′-*endo* pucker. The reason for this correlation is clear: in a C3′-*endo* ribose with $\psi=-60°$ (g^-), the distance between O3′ and O5′ would be only 3.04 Å. By changing the ring pucker to C2′-*endo*, this unfavourable electrostatic interaction is relieved, the O3′–O5′ distance increasing to 3.96 Å (Fig. 2).

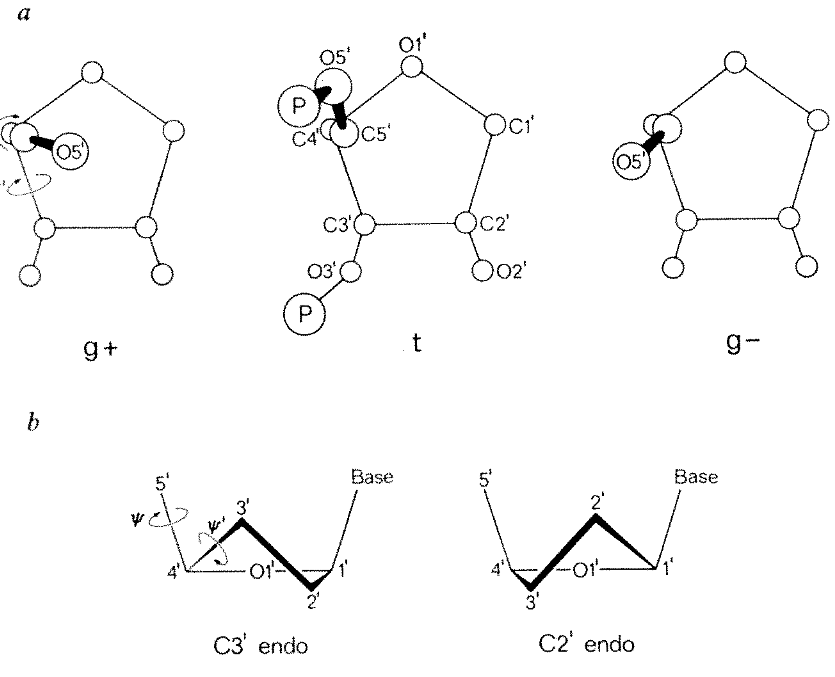

Fig. 1 Schematic diagrams of the ribose ring showing the approximate conformations at (*a*) the C4′–C5′ bond, torsion angle ψ, and (*b*) the C3′–C4′ bond, torsion angle ψ'. In *a* the ribose is viewed face on, and in *b* edge on with the pucker exaggerated.

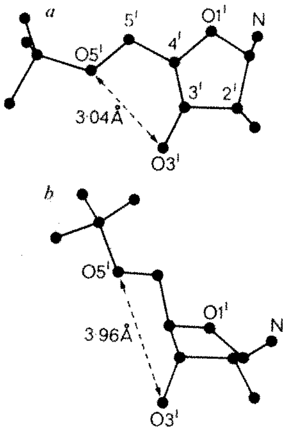

Fig. 2 Projection of a nucleotide on to the plane O3'–C3'–C2' in the two conformations g^-, C3'-*endo* (*a*) and g^-, C2'-*endo* (*b*). Most of the base has been omitted for clarity.

The *t* conformation at C5'–C4' is quite common in nucleosides and 3'-nucleotides and may occur in "kinked" DNA double helices[8]. In tRNA, we believe it occurs at the riboses on either side of the guanine residue involved in the G–U "wobble" base pair[1]. The g^- conformation, however, is much rarer, having been found in only seven nucleoside crystal structures[5,9]. On inspection of these structures, we find, in agreement with our results on tRNA, that in all seven, in which nine crystallographically independent molecules are represented, all the ribose rings have either the C2'-*endo* or the closely related C1'-*exo* conformation. In one of the cases (5'-bromo-5'-dA)[10], the O5' atom is replaced by bromine; in all of the others for which full details are available, the O5' can form intermolecular hydrogen bonds, and this presumably provides the driving force towards the unusual structure. Although no known nucleotides have the g^- conformation, the further interactions occurring in polynucleotides (for example base-stacking and intercalation) may sometimes favour the unusual staggered forms.

It is clear that loop formation in folded nucleic acids is not as straightforward as hitherto supposed; although all the ω–ω' pairs in our refined tRNA structure fall in energetically favourable regions of the ω–ω' plot[7], we must take into account the two extra factors of sugar pucker and rotation about C5'–C4' when considering loop formation. The anticodon loop is the only example in which the folding is achieved by varying only ω and ω'.

Coordinates for the same tRNA molecule in a different crystal form have been published recently by another group[11]. These coordinates are based on a refinement against X-ray data at 2.7-Å resolution. In contrast to our results, their ψ values show all the ribose groups to have the g^+ conformation about C5'–C4'. A second set of coordinates for the orthorhombic crystal form[12] does contain some sugars in conformations other than g^+, but generally not in the same places as we find. Although we cannot yet be certain that we have all our ribose conformations correct, most of them have been sustained during refinement. The correlation we have found between g^- and C2'-*endo*, with its simple physical explanation, argues strongly in favour of our interpretation.

Production of nerve growth factor by the mouse adrenal medulla

PREVIOUS studies in our laboratories[1] have demonstrated that nerve fibres from explanted chick embryonic sensory ganglia become preferentially orientated towards fragments of mouse sarcoma 180 or adrenal medulla. It was suggested that this orientation was mediated by the release from the tissues of nerve growth factor (NGF). Direct experimental evidence for this hypothesis was not presented but the effect could be duplicated by using a capillary tube containing a solution of purified NGF instead of the tissue fragment, thus establishing that the protein could exert a directional effect on the growth of nerve fibres *in vitro*. Independently, Burnstock and coworkers[2] have reported similar orientation effects for rat sympathetic ganglia grown in proximity to a range of rat and other tissues. These results are potentially of considerable importance since they suggest that the orientation of peripheral nerves *in vivo* may be regulated, at least in part, by the release of NGF from the end organ. We report here the results of further experiments which confirm that NGF, as identified by biological activity and specific immunological properties, is produced and released by the adrenal medulla in culture.

Table 1 Orientation of nerve fibres towards and away from explants of adrenal medulla in tissue culture

Score	Towards adrenal	Away from adrenal
0	54	133
0.5	57	16
1	19	3
1.5	16	2
2	6	0
2.5	2	0

Frequencies with which the stated scores (on the accepted arbitrary scale) were obtained. From these data the mean scores ± s.e.m. are 0.57±0.05 (towards) and 0.09±0.02 (away). The frequency distributions are significantly different ($\chi^2 = 179$, $P < 0.001$). For experimental details, see text.

The orientation of nerve fibres promoted by the mouse adrenal medulla is evident from the results given in Table 1. Cultures were set up essentially as previously described[1] and the fibre outgrowth assessed on the accepted arbitrary scale[3]. The effect was investigated further by maintaining intact adrenal glands (4–5 per preparation, 578 total) from fully mature male mice (Swiss albinos) as organ cultures essentially by the method of Trowell[4]. The culture medium was changed at the half-way stage of the experiment (24 h) and the total medium collected and pooled. Parallel control experiments without tissue were carried out simultaneously. The recovered media were then concentrated (~ 20 times) by ultrafiltration (Minicon concentrators, 15,000 MW cutoff, Amicon). The adrenal glands were recovered at the end of the experiment and the water-soluble material was extracted and lyophilised. A comparable extract from freshly dissected glands (546 total) was also made. The samples were then tested for NGF activity in the standard bioassay[5,6]. The adrenal glands were found to contain no detectable activity before the organ culture but released biologically active material into the culture medium and thereafter contained significant levels of the factor. (Tables 2 and 3.)

The immunological properties of the active material were then examined to establish that the observed effects were due specifically to NGF and not to some other, general growth-promoting agent. Two main types of NGF have been isolated; those from mouse salivary gland and from snake venom[7,8]. The factors are immunologically distinct[9,10] as shown by different titres with homologous and heterologous antisera (see also Table 4). NGF of the immunological type found in snake venom is not confined to this species but occurs also in mammalian sera[9]. The active material from the mouse adrenal medulla was now found to have identical immunological properties (within the limitations of the test) to the NGF from mouse salivary gland (Table 4). Further, the orientation effect described above was blocked by similarly high dilutions of the antiserum to the salivary protein (Table 4).

Table 2 NGF activity in concentrated organ culture media from preparations of adrenal medulla

Score	Experimental	Control
0	12	79
0.5	34	3
1	22	0
1.5	7	0
2	1	0

Cultures were maintained in a water-saturated atmosphere of 95% oxygen and 5% carbon dioxide in a pre-selected medium (1–1.5 ml per preparation, all components from Gibco-Biocult) consisting of RPMI 1640 (80%), foetal calf serum (10%), tryptose phosphate broth (10%), penicillin (100 units ml^{-1}), streptomycin (100 μg ml^{-1}) and L-glutamine (2 mM). The table gives the frequencies with which the stated scores (on the accepted arbitrary scale) were obtained for the concentrated media cultured with (experimental) and without (control) tissue. From these data the mean scores ± s.e.m. are 0.68±0.05 (experimental) and 0.02±0.01 (control). The frequency distributions are significantly different ($\chi^2 = 432$, $P < 0.001$). For further details, see text.

These results do not, however, distinguish between the *de novo* synthesis of NGF in culture and the activation and release from the gland of a potential precursor. Such an activation might be achieved by proteolytic cleavage, possibly resulting from the action of a native esterase as has been tentatively suggested for the NGF from mouse salivary gland[11]. To test this hypothesis, a soluble extract of mouse adrenal glands (470 glands, 15% w/v in water) was incubated (37 °C, 24 h) in the presence and absence of the purified γ (esteropeptidase) subunit from the mouse 7S NGF (ref. 12) and some of the esterase-active and other fractions from the purification of the latter protein[13]. In no case was NGF activity detectable (at 0.5 mg ml^{-1} lyophilised extract) in bioassay. A further possibility, apparent in all studies on the biosynthesis of NGF *in vitro*, is that the tissue releases an ezyme which causes the formation of NGF from a precursor in the culture medium. This precursor would presumably be located in the serum component of the medium. The adrenal clearly does not normally contain such an enzyme, however, since the standard bioassay of the soluble extract (which gives negative results) involves incubation of the material in a tissue culture medium essentially similar to that used in the organ culture experiments. More importantly, the NGF detected in the present study is immunologically identical to the protein from mouse salivary gland and is therefore more likely to be derived from the mouse adrenal medulla than from foetal calf serum. We have shown previously[9] that the growth factors present in human and mouse sera are immunologically distinct from the salivary protein and Oger *et al.*[14] have reported that foetal calf serum does not contain immunoreactive NGF as judged by a highly sensitive phage assay based on this protein.

Table 3 NGF activity in soluble extracts of adrenal medulla before and after culture

Score	Cultured adrenals	Fresh adrenals
0	0	20
0.5	9	1
1	4	0
1.5	5	0
2	2	0

Glands (cultured or fresh) were homogenised in distilled water (30% w/v) and the extract centrifuged (48,000*g*, 60 min) and lyophilised. In general 1 g wet weight of tissue gave ~15 mg of lyophilised extract. Samples were assayed at a final concentration of 5 mg ml^{-1}: the table gives the frequencies with which the stated scores (on the accepted arbitrary scale) were obtained. From these data the mean scores ± s.e.m. are 1.00±0.12 (cultured) and 0.02±0.02 (fresh). The frequency distributions are significantly different ($\chi^2 = 27$, $P < 0.001$). In addition, preparations of microsomes (both before and after treatment with 1% Triton X-100 to liberate any membrane-bound protein) from uncultured adrenals were inactive. For further details, see text.

Table 4 Immunological properties of the NGF from mouse adrenal medulla

	Antibody	
Antigen	Mouse submaxillary gland NGF	*Vipera russelli* NGF
Mouse submaxillary gland NGF (purified)	6,000	15
Vipera russelli NGF (purified)	<3	6,000
Adrenal medulla, orientation effect	3,000	15
Adrenal medulla, concentrated organ culture medium	6,000	15

The maximum dilution of the appropriate antiserum which will block the effect of 1 BU of the NGF preparation (on the accepted arbitrary scale) or completely inhibit the production of nerve fibres in orientation experiments.

Our results then suggest that the level of NGF in the normal adrenal is < 1 biological unit (BU) per g wet weight, the limit detectable by bioassay under the conditions used. This finding is in sharp contrast to those of Hendry[15] and Johnson *et al.*[16] who obtained by radioimmunoassay values of 100–300 BU g^{-1}. To reduce the possibility of interference in the bioassay, a soluble extract (200 glands) was fractionated by ion exchange chromatography as previously reported for mammalian sera[9] but again no activity could be detected. A possible explanation of these differences is that the adrenal contains NGF in a form which is biologically inactive but capable of combining with antibody. To test this hypothesis, the homologous antiserum titre for salivary NGF was determined in the presence and absence of adrenal extract (0.5 mg ml^{-1}). The titres were the same in both cases, however, showing that the extract did not contain significant amounts of material capable of competing with NGF for antibody. According to the data from radioimmunoassay, a change in titre of up to tenfold would have been expected. These findings may reflect the reported difficulty[17] in obtaining NGF in sufficiently highly purified form to permit valid immunochemical studies. This is particularly relevant for studies based on radioimmunoassay, which is an extremely sensitive procedure.

There have been a number of reports on the synthesis *in vitro* of NGF by cell lines and tissues[14,18–22]. We believe, however, that we are the first to demonstrate the production of NGF *in vitro* by an organ that does not normally contain the protein *in vivo*. Our findings may relate to those of Hendry and Iversen[23] who showed that after sialectomy in the mouse, which apparently removes the major site of synthesis of NGF in the animal, other unidentified organs begin to secrete the factor. The adrenal gland may be such an organ. Alternatively, our findings may imply that the adrenal begins to synthesise NGF in culture in response to the artificial conditions of the experiment. In this event, any attempt to extrapolate from the production of NGF *in vitro* to the situation *in vivo* must be made with great caution. This may be particularly relevant since preliminary studies show that the synthesis of NGF in culture is not restricted to the adrenal medulla but may be a general property of mouse and rat tissues.

We thank the Science Research Council for the award of a Postgraduate Studentship to G.P.H., Dr D. C. Edwards (Wellcome Research Laboratories) for the gifts of antisera and mice and Dr S. J. Walter (Charing Cross Hospital Medical School) for providing the fractions from mouse salivary gland.

A paradox in the lateralisation of the visual evoked response

THE average evoked response in man to stimulation of the visual field with a reversing checkerboard pattern and recorded from the scalp over the occipital region has a waveform which is consistent both within and between subjects. The most characteristic feature for full-field stimulation is a major positive component at about 100 ms which is recorded maximally 5 cm above the inion in the midline and is distributed fairly symmetrically over both sides of the head (Fig. 1). The pathways from the retina to the visual cortex undergo partial decussation in the chiasma, so that information presented to the left half of the visual field passes to the right hemisphere, whereas the left hemisphere receives signals from the right half of the visual field. Consequently, it might be predicted that stimulation of one half field will produce an evoked response which is maximal over the contralateral hemisphere. The data presented here show that, contrary to this prediction, the maximal response occurs at the scalp electrodes situated over the hemisphere ipsilateral to the field stimulated.

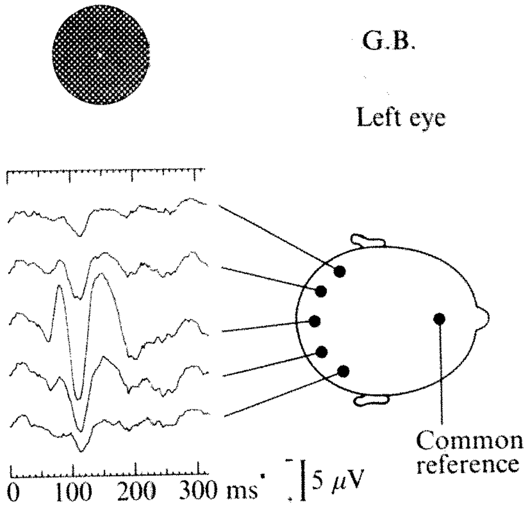

Fig. 1 Monopolar recording of the response to stimulation of the whole field (out to 16°) for the left eye of subject G.B. The positive large component at about 110 ms is seen maximally at the midline electrode and falls off fairly symmetrically in amplitude on the two sides of the head. Time scale in 10, 50 and 100 ms marks.

The average evoked response to stimulation of the left and right half fields for each eye of nine healthy individuals (age range 19–29 yr) was recorded from a chain of chlorided silver cup electrodes 5 cm up from the inion. The central electrode of the chain was in the midline and the other electrodes were spaced 5 cm and 10 cm laterally on either side. Each electrode was referred to a common midfrontal electrode 12 cm above the nasion and in the midline. A black-and-white checkerboard pattern was back-projected on to a translucent screen which was masked to produce a semicircular field extending 16° out from the fixation point for a subject sitting 1 m from the screen. The subject was instructed to fixate a constantly illuminated spot of light at the centre of the vertical diameter of the stimulus field. Each square of the checkerboard subtended an angle of 50′ and the brightness of the white squares as seen by the subject was 227 cd m^{-2}, whereas that of the black squares was 8.2 cd m^{-2}. The checkerboard pattern was reversed twice per second and the electrical activity at the five electrodes was sampled at 400 Hz for 320 ms after each reversal. The average evoked response for 200 complementary pattern reversals was recorded with a PDP-12 computer.

The monopolar records in Fig. 2 show that, paradoxically, the response to stimulation of a half field is recorded maximally from the midline and from electrodes over the hemisphere ipsilateral to the field of stimulation, whereas the response on the contralateral side is comparatively flat. This ipsilateral positivity was recorded consistently in every subject for each half field and for stimulation of either eye. The bipolar records in Fig. 2 show the distribution of responses recorded with the five occipital electrodes connected as a bipolar chain rather than linked to a common midfrontal reference; the maximal response is now apparently recorded over the contralateral hemisphere. Comparison of

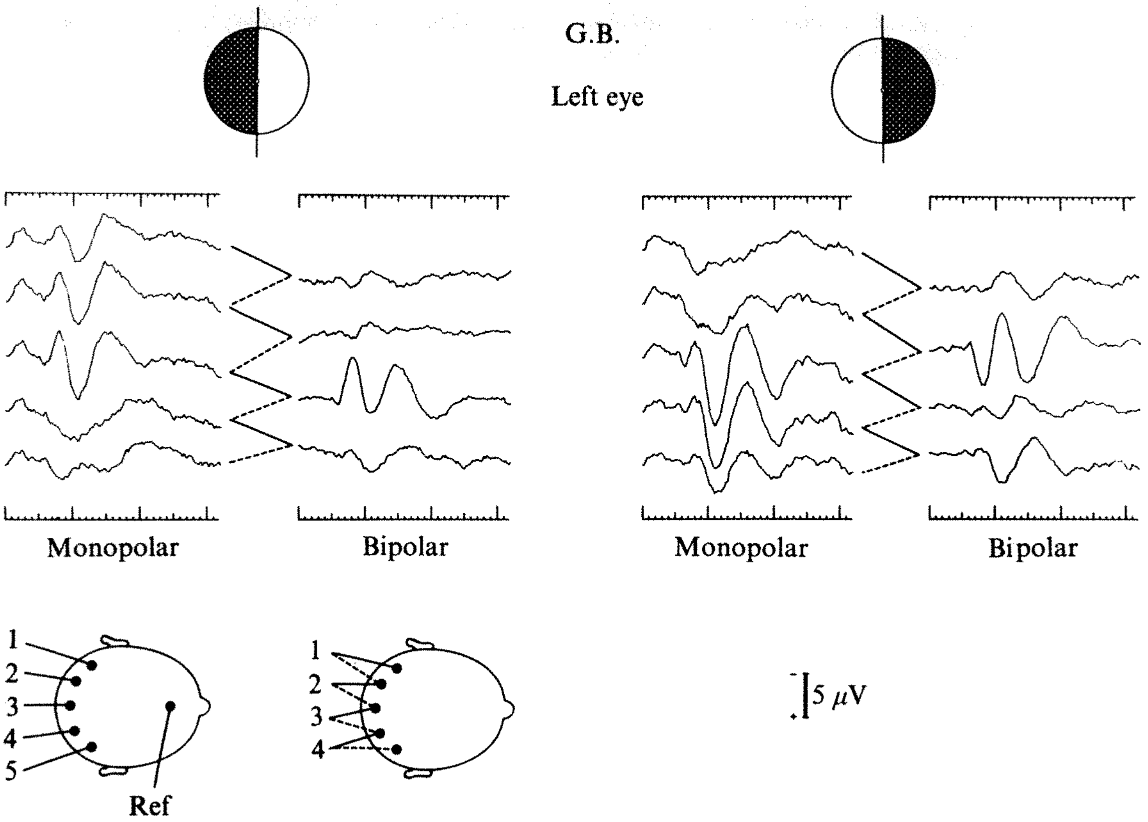

Fig. 2 Monopolar and bipolar records for stimulation of the two half fields for the left eye of subject G.B. In the monopolar record the large positive component at about 110 ms is seen at the midline electrode and at the electrodes ipsilateral to the stimulated half field, whereas the contralateral channels are relatively flat. In the bipolar record, which reflects voltage gradient, the ipsilateral channels show little or no response, whereas the midline–contralateral channel shows the maximum response.

the monopolar and bipolar records, however, shows that it is erroneous to conclude from such a bipolar record that the response is largest contralaterally; although the maximum voltage gradient is indeed between the midline electrode and its neighbour over the contralateral hemisphere, it is the response at the midline electrode that has the greater amplitude, as the monopolar record shows. The bipolar recording shows a comparatively flat response on the ipsilateral side, not because there is little or no activity, but because there is equally high amplitude activity at all electrodes on this side of the scalp. Similarly, on the contralateral side, there is low amplitude activity at both electrodes, not the high amplitude activity that would be expected if the maximal response occurred over this hemisphere.

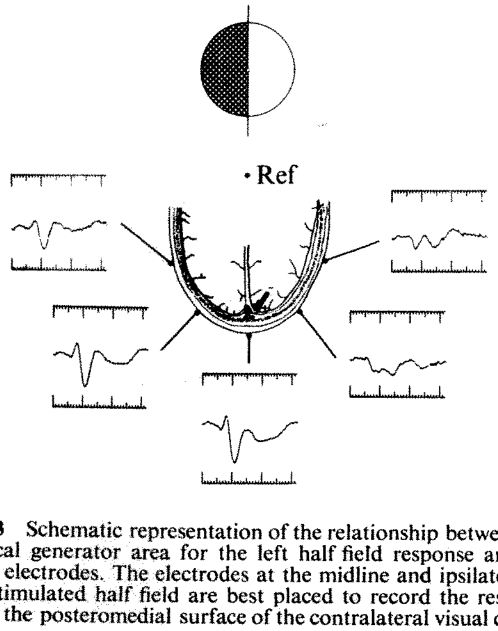

Fig. 3 Schematic representation of the relationship between the cortical generator area for the left half field response and the scalp electrodes. The electrodes at the midline and ipsilateral to the stimulated half field are best placed to record the response from the posteromedial surface of the contralateral visual cortex.

A possible explanation of this unexpected lateralisation of the evoked response is that the cortical generator areas for the pattern stimulus are largely situated on the medial and posteromedial surface of the visual cortex where the neurones are transversely oriented. Thus, electrodes over the hemisphere ipsilateral to the field stimulated are optimally placed to record the response from these generator areas, whereas electrodes over the contralateral hemisphere are not so placed. The schematic representation of this hypothesis in Fig. 3 shows that the electrodes on the left side of the head are best placed to record a response from the medial surface of the right visual cortex evoked by pattern stimulation of the left half field. The electrodes over the right hemisphere, however, are approximately perpendicular to the axis of the generator area and therefore record very little response.

The paradoxical distribution of the evoked response to stimulation of the visual half fields has important implications for the interpretation of recordings made in cases of hemianopia. The findings in healthy subjects can be used to predict the type of response asymmetry to be expected in cases of either homonymous or bitemporal hemianopia. In homonymous hemianopia the asymmetry of the evoked response recorded to whole-field pattern stimulation is the same for both eyes ('uncrossed' asymmetry) and the 'blind' field will be contralateral to the side over which the response is maximally recorded. In bitemporal hemianopia (that is, where the fibres from the nasal retina of each eye are damaged) the asymmetry is opposite for the two eyes ('crossed' asymmetry) and the maximal response will be seen on the right side for the left eye and on the left side for the right eye. Recordings made from patients with hemianopia support these predictions[1].

In the present experiments a half field stimulus extending out to an eccentricity of 16° has been used, but a similar ipsilateral distribution of the major positive component of the pattern reversal response can also be recorded when stimulating smaller segments of each half field. It is still clearly demonstrable when only the central 0–4° are stimulated. When stimulation is confined to the macular area itself (0–2°), however, the response becomes less well lateralised and may even have a contralateral predominance. This is what would be predicted on the scheme illustrated in Fig. 3, as the cortical representation of the macula is at the posterior pole of the occipital lobe and the generator neurones are here facing posteriorly rather than medially.

Synaptic vesicle recycling in synaptosomes *in vitro*

PINCHED-OFF presynaptic nerve terminals (synaptosomes) prepared from rat brain homogenates[1,2] retain many of the functional properties of intact neurones[3,4]. They can accumulate K$^+$ and extrude Na$^+$ against concentration gradients[5,6], and their membranes seem to develop K$^+$ diffusion potentials which behave like the membrane potentials of most neurones[7]. Furthermore, the isolated terminals exhibit an increased rate of Ca^{2+} accumulation[8] and Ca^{2+}-dependent transmitter release[8–10] when exposed to depolarising agents such as veratridine or an increased external K$^+$ concentration ([K]$_0$). The latter findings are consistent with the 'calcium hypothesis' of depolarisation–secretion coupling[11]. The calcium which enters the terminals during depolarisation seems to trigger the release of transmitter from intraterminal vesicles by an exocytotic process involving transient fusion of the vesicle membrane with the surface membrane[12–14]. This hypothesis is supported by experiments with electron-opaque extracellular markers; the appearance of the markers within intraterminal vesicles, after stimulation, has been taken as evidence for vesicle recycling[15–17]. Here we report similar observations on synaptosomes incubated *in vitro*, showing that synaptosomes function like intact terminals in this respect as well.

Synaptosomes were prepared from whole rat brain homogenates by a slightly modified[18] Gray and Whittaker procedure[2]. The standard ('Na+5K') synaptosome incubation solution contained (mmol l^{-1}): NaCl, 145; KCl, 5; CaCl$_2$, 1.2; MgCl$_2$, 1.3; NaH$_2$PO$_4$, 1.2; glucose, 10; HEPES, 20; the solution was titrated to *p*H 7.6 at 20 °C with Tris base. In some instances, part of the NaCl was replaced mol-for-mol by KCl (='K-rich' incubation media; see below).

Synaptosomes from the sucrose gradient[2] were equilibrated[7] with ice-cold Na+5K, and centrifuged at 9,000*g* for 5 min at 4 °C. The supernatant was discarded, and the pellets resuspended in Na+5K (approximately 2 mg synaptosome protein ml^{-1}) and incubated for 12 min at 30 °C. Additional aliquots of Na+5K or of K-rich solution (to give a final [K]$_0$ of 35 or 50 mM) were then added. In most experiments the incubation solutions also contained sufficient colloidal thorium dioxide (Thorotrast, a 25% suspension, from Fellows Testagar, Anaheim, California, a gift from Dr A. Enders) to give a final concentration of 3.3%, or horseradish peroxidase (HRP, type VI, Sigma, St Louis, Missouri, previously dialysed[15] against Na+5K) to give a final concentration of 5 mg ml^{-1} after dilution.

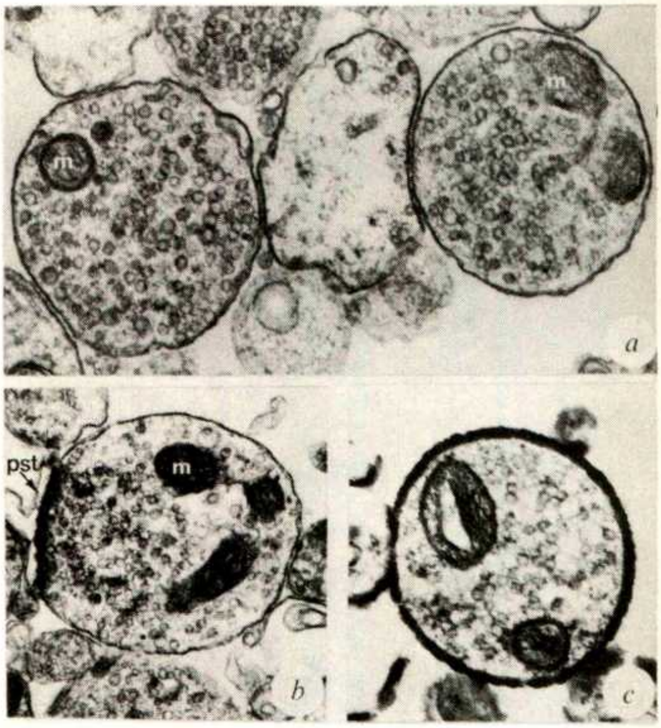

Fig. 1 Morphology of synaptosomes incubated in standard Na+5K. *a*, Vesicle-filled terminals with intraterminal mitochondria (m). No extracellular marker present. ×43,000. *b*, Similar to *a*, with a clearly demarcated postsynaptic thickening (pst). ×33,000. *c*, Synaptosome fixed and stained after 30 min incubation in Na+5K containing 5 mg ml^{-1} HRP. Note halo of HRP reaction product around synaptosome, and absence of product in the cytoplasm. ×39,000.

The diluted suspensions were incubated at 30 °C for an additional 2–30 min. Aliquots were then diluted with one volume Na+5K plus two volumes Karnovsky's cacodylate-buffered fixative[19], and refrigerated overnight; the samples were then centrifuged, and the supernatant solutions discarded. The HRP-treated pellets were reacted with H$_2$O$_2$ and diaminobenzidine[16] for 2 h at room temperature, and washed several times in cacodylate buffer[16]. All pellets were stained with potassium ferrocyanide-reduced osmium tetroxide[20], followed by osmium tetroxide. They were dehydrated in increasing concentrations of ethanol and embedded in Araldite. Thin sections were examined electron microscopically.

Most synaptosomes appeared more-or-less circular in cross section (Figs 1 and 2). Those fixed after incubation in Na+5K were generally filled with uniform-sized vesicles (about 400–500 Å in diameter; Fig. 1*a–c*), although occasional larger vesicles were seen. The terminals also usually contained mitochondria (Fig. 1). When exposed to HRP, the terminals incubated in Na+5K were surrounded by a halo of HRP reaction product (Fig. 1*c*); the apparent lack of HRP penetration into the cytoplasm implies that the surface membrane had resealed. In some terminals (see Fig. 2*c*), however, the extracellular marker was distributed diffusely throughout the cytoplasm, but was excluded from the synaptic vesicles; this presumably occurred in terminals which had not completely resealed, or which were subsequently damaged. The morphological markers may therefore be useful for the quantitative assessment of synaptosome integrity.

After exposure to media containing 35 or 50 mM K, the intraterminal vesicles appeared much more variable in size, and large vacuoles (cisternae[16]) were found in many terminals (Fig 2*a* and *c*). Coated vesicles[16,21] were observed in some of the terminals exposed to elevated $[K]_0$, (Fig. 2*b*). Even after prolonged (15–30 min) incubations in K-rich media, the terminals were not markedly depleted of vesicles.

When incubated in HRP-containing K-rich media, vesicles filled with electron-opaque material (presumably HRP reaction product) were seen in some of the terminals; this is illustrated in Fig. 2*b*, which also shows a coated vesicle filled with HRP reaction product. This latter finding fits with the hypothesis[16,21] that one of the steps in the vesicle retrieval process may involve coated vesicles. Further evidence of synaptic vesicle recycling was obtained with Thorotrast-treated terminals, where both vesicles and large vacuoles contained the marker even after a short period of incubation in a depolarising solution[22] (Fig. 2*c*).

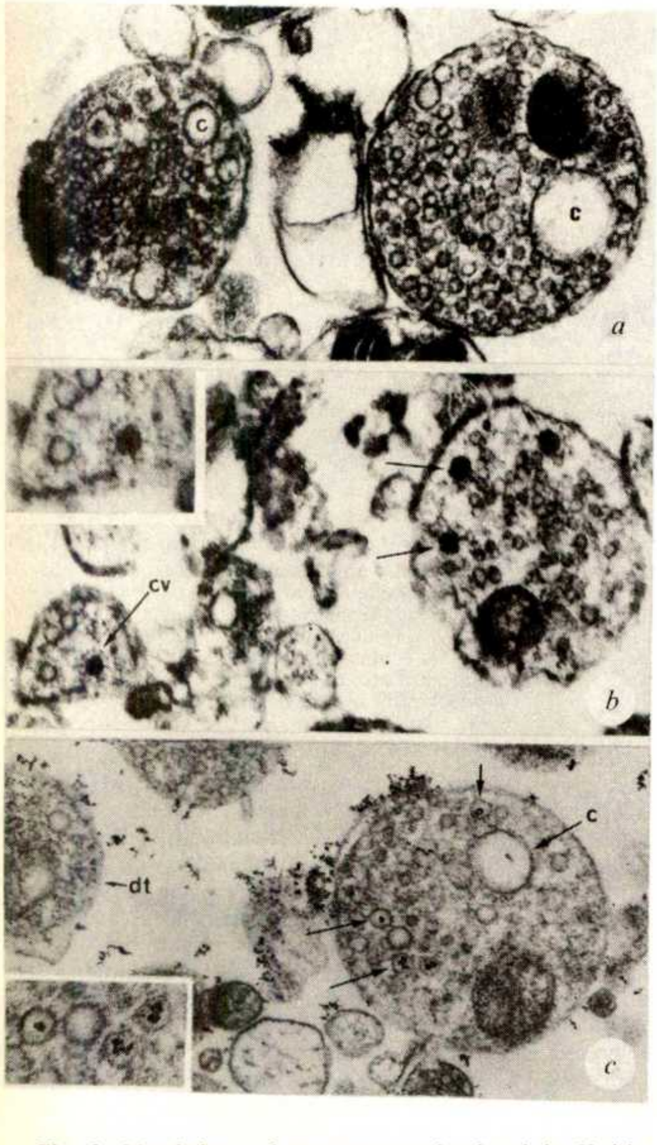

Fig. 2 Morphology of synaptosomes incubated in K-rich media. *a*, Synaptosomes incubated in 100 Na+50K solution, without extracellular marker for 15 min. Note marked heterogeneity of synaptic vesicle size and presence of large vacuoles (c). ×41,000. *b*, Synaptosomes incubated in 100 Na+50K containing 5 mg ml^{-1} HRP, for 30 min. Note HRP-labelled coated vesicle (cv); unlabelled arrows indicate two other HRP-labelled synaptic vesicles. ×45,000. Inset: coated vesicle at ×71,000. *c*, Synaptosomes incubated for 2 min in 115 Na+35K containing 3.3% Thorotrast. Unlabelled arrows indicate some of the Thorotrast-containing vesicles. A Thorotrast-containing large vacuole (c), and a damaged terminal (dt) with diffusely distributed Thorotrast are also seen. ×50,000. Inset: higher magnification of Thorotrast-labelled vesicles. ×88,000.

We have repeatedly observed that the tracer-labelled vesicles (Fig. 2*b* and *c*) are usually larger than most vesicles in 'control' synaptosomes (Fig. 1). Preliminary evidence (unpublished) indicates that the initial step in membrane retrieval seems to involve the pinching-off of these large vesicles from the plasma membrane. The further implications of large vesicle formation are being investigated.

Our observations are consistent with a mechanism involving transient plasma membrane fusion and recycling of synaptic vesicles. They suggest that synaptosomes behave like intact terminals with respect to the mechanism by which they release vesicular contents. Thus, synaptosomes may be useful for the study of transmitter release and vesicle recycling processes in the central nervous system.

We thank J. A. Arndt, W. dePalma and T. McKenzie for assistance, Drs M. B. Bunge and Y. Fukami for guidance with the electron microscopy, and Drs N. C. Kendrick, D. Purves and C. M. Rovainen for suggestions regarding the manuscript. Supported by NIH. R. C. F. was a Grass Foundation undergraduate fellow.

Extremely low frequency, weak electric fields affect schedule-controlled behaviour of monkeys

THE effect of weak electric fields on behaviour of orgasnims has potentially important implications for basic neurophysiology and evaluation of environmental hazards (chronic exposure to weak 60-Hz electric fields has become a way of life). We have demonstrated[1] that weak (approximately 7 V m^{-1} p–p), extremely low frequency (7 Hz) electric fields could modify a lever-press response in monkeys. We summarise here data[2] confirming that finding for a larger group of animals with more replications and presenting evidence for a dose-dependent relationship for

7-Hz fields. In addition there are indications of a threshold of 10–56 V m^{-1} p–p for field frequencies higher than electroencephalogram (EEG) range (1–32 Hz). Adey[3] has hypothesised that since these field levels are clearly too low to trigger synapses in the fashion prescribed by classical neurophysiology, more subtle membrane sensitivities may be functioning as central nervous system mediators of the observed behavioural effects. One possible mediator is the degree of calcium efflux across the membrane[4].

We have explored possible behavioural effects of fields at frequencies from 7–75 Hz and voltages from 1–56 V m^{-1} p–p, together with a preliminary study at 100 V m^{-1} p–p. Five female *Macaca nemestrina* monkeys (3–6 kg) were trained on a Skinner[5] conditioning schedule. The animals had to wait 5 s between lever presses and to press within a 2.5 s 'limited hold'; each response recycled the 5-s delay period—an inter-response time (IRT) schedule (IRT > 5 s; < 7.5 s). The analysis of behaviour in terms of IRT has been widely used to evaluate behavioural effects of low doses of drugs (for example, ref. 6). For details, see Fig. 1, which shows an example of the histogram of IRTs across three voltage levels (1, 10 and 56 V m^{-1} p–p) for the 7-Hz condition.

Our data analyses are limited to voltage levels of 1–56 V m^{-1} p–p because preliminary data at the 100-V m^{-1} level suggested that fields of this strength affected the randomly interspersed control days—that is, there seemed to be a 24-h 'carry-over' effect. Evaluation of possible effects at this level awaits further experimentation.

For fields with voltages from 1–56 V m^{-1}, the *a priori* hypothesis of shortened IRTs was tested with t tests (Fig. 2). Since our previous data[1] had indicated that low voltage ($\sim$7 V m^{-1}) low frequency (7-Hz) fields resulted in shorter times between responses than control no-field conditions, it was possible to examine the present data with this specific statistical hypothesis. At 1 V m^{-1} none of the observed differences between field and no-field mean IRT$\pm$s.d. was statistically significant. There is evidence for a frequency-specific (7-Hz) threshold at 10 V m^{-1} p–p. The difference observed is small ($\sim$0.1 s) but significant at the 0.05 level. This low threshold for 7 Hz may reflect the fact that this frequency is in the range of normal brain wave activity (hippocampal theta) for performing monkeys. At 56 V m^{-1}, both 7-Hz and 75-Hz fields produce large ($\sim$0.3 s) and statistically significant reductions in IRT. Note that these data suggest a dose-dependent relationship for 7-Hz fields; mean IRT differences increase systematically across the three voltage levels from 0.07 s at 1 V m^{-1} to 0.12 s at 10 V m^{-1} to 0.29 s at 56 V m^{-1}.

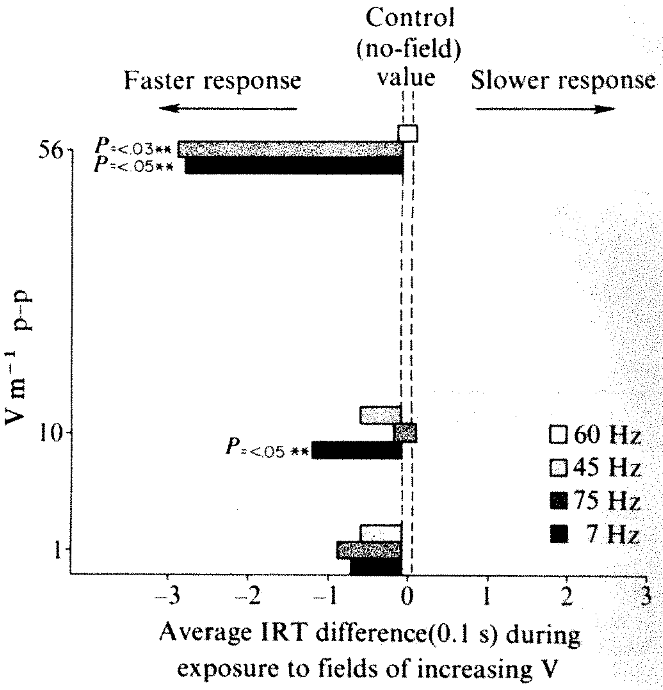

Fig. 2 Faster response (reduced IRT) as a function of frequency and voltage of applied electric field. Asterisks denote statistically significant shifts. All data are based on four repetitions of each experiment for each of 4–5 monkeys. Note the low voltage threshold (10 V m^{-1}) for 7 Hz, a frequency which is relevant to normal brain activity.

These results substantiate our earlier finding that the 7-Hz field was associated with a very low voltage threshold of

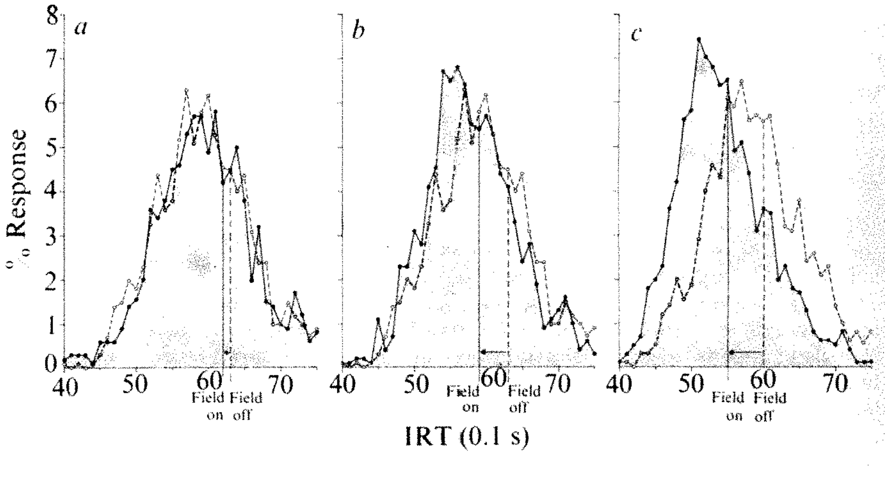

Fig. 1 An example of the IRT distributions observed for one 4-h experiment for one unimplanted animal at 1 (*a*), 10 (*b*) and 56 V m^{-1} p–p (*c*). Field frequency = 7 Hz. Exposure to this field resulted in a small shift towards faster IRTs at 10 V m^{-1} and a much larger shift at 56 V m^{-1}. The average difference observed over all monkeys for this field configuration was 0.07 s at 1 V m^{-1}, 0.1 s at 10 V m^{-1} and 0.3 s at 56 V m^{-1}. Field (●) and no-field (○) distributions are contrasted. Number of responses and $\bar{x}$ for field on: *a*, 1,024 and 62; *b*, 1,026 and 59; *c*, 973 and 55. Field off: *a*, 1,505 and 63; *b*, 1,505 and 63; *c*, 987 and 60. Histograms for both field and no-field conditions are a good approximation of the normal distribution. Four such histograms were generated for each frequency–voltage combination for each animal. About 300 field and no-field experiments were carried out. Correct responses were reinforced with small quantities of fruit juice; water deprivation was used during the initial stages of training but was not necessary during testing. No external cues (lights, bells) signalled availability of the reinforcer; the animal was required to respond to the lapse of time following the occurrence of its own preceding response. After 80–100 d training, stable performance (70–80% correct) was achieved and a random series of field/no-field tests carried out. Three animals were implanted with EEG electrodes and two were not, so that possible 'antenna' effects due to the presence of the electrodes could be assessed. Four 4-h replications of each field condition and each control condition (no-field) were analysed for each monkey. Field conditions included frequencies of 0, 7, 45, 60 and 75 Hz, and voltage levels of 0, 1, 10, 56 and 100 V m^{-1} p–p. One animal died from accidental causes at the conclusion of the 10 V m^{-1} experiments so n was reduced to 4 for the experiments at 56 and 100 V m^{-1}. Experiments were carried out in a double-bronze mesh screened enclosure; a.c. conductors (except for a shielded camera) were excluded. Monkeys sat in plastic chairs between parallel field plates (1 m^2 50 cm apart) centred in the enclosure. The fields were measured with a specially devised fibre optic probe, and were found to be satisfactorily uniform and balanced[7]. Current from the imposed field flowing to ground through the implanted electrodes was measured in a phantom head at slightly less than 0.9 nA at 10 V m^{-1} p–p. IRT was tape recorded and analysed by computer in 0.1-s intervals. Responses longer than 17.5 s were excluded to avoid skewing the distribution with occasional very slow responses.

Table 1 Summary of t tests for mean IRTs ±s.d. (no-field minus field differences, across voltage levels)

Voltage (V m^{-1} p–p)	Frequency (Hz)	No. of monkeys	Average no. of responses	Mean difference ±s.e.d. (10th s)	P	s.d. difference ±s.e.d. (10th s)	P
1	7	5	3,299	0.70±0.69	<0.20	0.12±0.97	<0.50
	45	5	4,229	0.55±1.35	<0.40	−0.28±1.04	<0.45
	75	5	3,360	0.94±0.62	<0.15	−0.20±0.66	<0.40
10	7	5	3,560	1.18±0.48	<0.05*	1.60±0.52	<0.03*
	45	5	3,982	0.55±0.61	<0.25	0.10±0.41	<0.45
	75	5	3,560	0.00±0.60	—	−0.12±1.06	<0.50
56	7	4	2,764	2.88±1.27	<0.05*	1.78±0.35	<0.01*
	60	4	2,662	−0.03±0.70	<0.50	0.58±0.28	<0.10
	75	4	2,862	2.90±0.72	<0.03*	2.25±0.69	<0.03*

*Statistically significant shifts.

approximately the same level (7 V m^{-1} previously and 10 V m^{-1} here) and indicate much higher thresholds for frequencies which are not relevant to normal brain wave activity. For 75 Hz, the threshold is between 10 and 56 V m^{-1}; for 60 Hz it may be higher.

Numerical data and t tests for the mean IRT±s.d. for voltage levels from 1–56 V m^{-1} p–p are summarised in Table 1. No effect is observed at 1 V m^{-1}. At 10 V m^{-1}, the 7-Hz field was associated with a significantly smaller s.d. At 56 V m^{-1} all field frequencies were associated with s.d.s smaller than the no-field values. These differences were statistically significant for 7 and 75 Hz, and reach a borderline level ($P<0.10$) for 60 Hz.

Data for individual animals reflect the orderliness of the average values. At 1 V m^{-1} the mean IRTs varied randomly across the field conditions. At 10 V m^{-1}, the 7-Hz condition was associated with the fastest mean IRT and smallest s.d. of all field conditions for every animal tested. At 56 V m^{-1} all field-associated s.d.s were smaller than the no-field condition for every animal. All mean IRTs, except those associated with the 60-Hz field, were faster than no-field means at 56 V m^{-1} for every animal tested.

Table 2 Analysis of variance of implanted compared with unimplanted animals at 1 and 10, 56 and 100 V m^{-1}

		Mean IRTs ±s.d.					
Voltage		1 and 10 V m^{-1}		56 V m^{-1}		100 V m^{-1}	
Source		F	P	F	P	F	P
Group	$\bar{x}$	0.048	0.84	0.770	0.47	0.708	0.49
	σ	0.378	0.58	0.014	0.92	1.469	0.35
Replication	$\bar{x}$	0.953	0.46	0.769	0.55	0.497	0.70
	σ	0.412	0.75	0.865	0.51	2.434	0.16

Analysis of variance of IRTs for implanted compared with unimplanted animals revealed no significant effects (Table 2). Thus, it is improbable that the observed effects can be attributed to the presence of EEG recording electrodes in the brain (the so-called 'antenna' hypothesis). Additional analyses of variance were carried out for IRT data across frequency and voltage levels to look for possible information secondary to the initial effect of shortened IRTs. These analyses revealed no unexpected findings. Field exposure contributed significantly to the variance of the s.d.s of mean IRTs at low voltages (1 and 10 V m^{-1} exposures, $F=2.59$, $P<0.05$), but not to the average IRTs —probably because of the small n. At 56 V m^{-1} both s.d.s and average IRTs were associated with significant F values ($F=5.75$, $P<0.02$ and $F=5.22$, $P<0.03$, respectively). Replications did not contribute significantly to the variance at any of the voltage levels tested.

Ethological studies of electric and magnetic fields lend support to the behavioural data presented here. Keeton[8] demonstrated that weak magnetic fields can affect the homing of pigeons; certain species of fish utilise weak electric fields to detect their prey[9]; and 10-Hz electric fields (25 mV cm^{-1}) can alter circadian rhythms of activity in man[10]. Laboratory studies to date have provided only equivocal evidence[11-15]. Absence of a clear-cut picture may be related to specific attributes of the separate experiments in such factors as field frequency, voltage, duration of exposure and behavioural assay. Keeton's pigeons ignored the presence of an imposed magnetic field if the Sun were available as a homing cue. Similarly, weak electric fields may not affect performance on demanding behavioural tasks with multiple stimuli inherent in them. An animal carrying out such a task may be able to 'ignore' the presence of the field.

On the basis of studies on calcium binding in cerebral tissues[16,17], which have paralleled the present studies on behavioural effects of weak electric fields, and taking into consideration the physical model conceived by Grodsky[18], we propose that the potential for sensitivity to weak electric fields exists in all organisms whose nervous system is characterised by: slow electrical waves in the extracellular space; and a system of macromolecular sensors on the membrane surface which is capable of transducing components of the extracellular field by altered ion binding and an associated conformational change. In animals in which field detection is not intimately linked to survival, sensitivity can probably only be revealed in innocuous experiments of the kind described above which are characterised by long exposure duration, little external stimulation and low motivational requirements.

We thank the Naval Electronics System Command, Office of Naval Research and the Bureau of Radiological Health, Washington, DC, for support; and J. Frane of UCLA Health Sciences Computing Center for advice on the statistical analyses.

Antivenom activity of rattlesnake blood plasma

MANY species of venomous snakes have a high resistance to their own venoms and to those from other individuals of the same species and other species[1–4]. The resistance is not absolute but it increases as the size of the snake increases, and varies also with the type of venom. Blood plasma or sera of several species neutralise the venom of the same species and of other species both *in vivo* and *in vitro*[5–11]. As Clark and Voris[10] reported, the whole serum of the eastern diamondback rattlesnake (*Crotalus adamanteus*) neutralises lethal doses of *C. adamanteus* venom in mice and the protective capacity of the serum is associated with the serum albumin fraction. Mixtures of *C. adamanteus* serum and venom show no evidence of precipitation, such as occurs when serum from animals hyperimmunised with *C. adamanteus* venom is mixed with *C. adamanteus* venom. The nature of the factor(s) in rattlesnake plasma, which neutralise rattlesnake venom toxins, and the mechanism of neutralisation are unknown. We have found that both western and eastern diamondback rattlesnake (*C. atrox* and *C. adamanteus*) blood plasma contain antivenom factor(s) and have a neutralisation capacity (NC), not only for *C. atrox* venom but also other rattlesnake venoms. The antivenom activity of *C. atrox* plasma is sufficiently potent, compared with commercial immunoglobulin antivenin, to be potentially useful in the management of snakebite.

Before testing for *C. atrox* plasma antivenom activity, we heated the plasma at 56 °C for 30 min to detoxify it[12]. The intraperitoneal toxicity (LD_{50}) of unheated *C. atrox* plasma in mice varied from 2.6 mg per 20 g mouse to 9.0 mg per 20 g mouse for plasma from 25 individual specimens of *C. atrox*. Pooled plasma (LD_{50}, 5 mg per 20 g mouse) from 100 captive *C. atrox* was used. Heating removed the toxicity ($LD_{50} > 40$ mg per 20 g mouse) and all subsequent experiments were carried out with heat-treated plasma. Biuret[13] assay was used to estimate protein content of plasmas and venoms and showed a protein content of about 40 mg ml^{-1} or about 50 mg ml^{-1}, when corrected for dilution by citrates for pooled *C. atrox* plasma. All antivenom and toxicity assays were done on a protein weight basis.

We found that both *C. adamanteus* and *C. atrox* plasma were potent antivenoms for several rattlesnake venoms (Table 1). The neutralisation capacity of both plasmas was compared with that of commercial antivenin by injecting mice with 5 mg of plasma protein or antivenin intraperitoneally and determining the LD_{50} of the venom in the antivenom-treated mice compared with that of untreated mice. Both plasmas had significantly higher neutralisation capacity values for various rattlesnake venoms than did antivenin, except in the case of South American rattlesnake venom (*C. durisus terrificus*) and the mohave rattlesnake venom (*C. scutulatus scutulatus*, brown variety). We found two varieties of *C. scutulatus scutulatus* readily distinguished by the toxicity of their venoms and the capacity of antivenoms to neutralise each venom. The two varieties are distinguished also by their colour. The yellow variety has more toxic venom and lower neutralisation capacity values for antivenoms than the brown variety.

Rattlesnake venoms are neutralised also when premixed *in vitro* with either rattlesnake plasma or commercial antivenin. A visible precipitate occurs with immunoglobulin antivenin but not with plasma.

To test the hypothesis that the antivenom activity is due to antigenic protein or multiple proteins in *C. atrox* plasma, rabbits (New Zealand White) were injected with heat-treated *C. atrox* plasma and Fruend's complete adjuvant and the resultant antisera were collected 1 week after a booster injection of *C. atrox* plasma and adjuvant 4–6 weeks after the initial injection. The antivenom activity of *C. atrox* plasma was removed completely when a 5-ml sample was treated three times with 1 ml of antisera and the resultant precipitates were removed by centrifugation. Addition of unimmunised rabbit serum to *C. atrox* plasma did not diminish the antivenom activity.

Clark[10] found the antivenom activity of *C. atrox* serum in the albumin fraction after chromatography on Sephadex G-100. Our results of polyacrylamide gel electrophoresis (PAGE)-immunodiffusion studies indicate that the antivenom activity is due not to albumin or some small molecule bound to albumin, but to separate antigenic proteins in the plasma.

Plasma proteins were fractionated on gradient (4.5–8% acrylamide) gel slabs using the discontinuous basic buffer system described by Ortec Inc. Each slab was cut into three sections and minced; the protein was extracted into saline and filtered through a 1-μm Millipore filter. Extract from each gel section was assayed for antivenom activity. The

Table 1 Capacity of four antivenoms to neutralise lethal toxicity of rattlesnake venoms

Venom	Neutralisation capacity			
	Pig plasma	Antivenin	*C. adamanteus* plasma	*C. atrox* plasma
C. adamanteus	1.3	4.5	7.7	6.5
C. atrox	1.4	2.7	3.5	4.3
C. viridis concolor	1.3	6.4	9.8	9.0
C. durisus terrificus	1.1	9.5	8.1	8.3
C. scutulatus scutulatus, brown	1.3	10.2	9.0	10.1
C. scutulatus scutulatus, yellow	1.1	2.7	5.8	6.4
Naja naja kaouthia	1.1	1.0	1.0	1.0

Venom lethal toxicity (LD_{50}) was assayed using Swiss–Webster mice (18–20 g). Twenty to thirty mice were used for each assay and the LD_{50} dose was calculated according to the method of moving average interpolation[14–16]. Venoms from rattlesnakes and cobras were obtained from our captive specimens by mild electrical stimulation of the mandibulae compressor glandulae muscles surrounding the venom gland[17]. Venoms from several healthy individuals, strictly of the same species, were pooled and centrifuged to remove cellular debris, then lyophilised and stored at −20 °C as a batch. Venoms handled in this manner can be stored for years without measurable loss of lethal toxicity. Neutralisation capacity is the ratio of the intraperitoneal LD_{50} of venom in mice treated with antivenom (5 mg protein given intraperitoneally) to the intraperitoneal LD_{50} of venom in untreated or saline-injected mice. A neutralisation capacity of 1 means that the antivenom had no effect on the LD_{50} of venom in mice in 24 h. The greater the neutralisation capacity the more potent was the antivenom. Pig plasma was obtained from a local slaughterhouse from blood collected in trisodium citrate (3.8%, 4 parts blood: 1 part citrate). Antivenin was Crotalidae polyvalent, equine, North and South American antisnakebite serum (Wyeth). *C. atrox* and *C. adamanteus* plasma were obtained from specimens in our serpentarium, either by heart puncture under anaesthesia[18] or by decapitation. The plasma was separated from individual citrated bloods and then pooled, centrifuged and stored frozen (−20 °C). Plasma was taken and stored in this manner to avoid serum clots. The antivenom activity of plasma and serum was the same.

Table 2 Effectiveness of *C. atrox* plasma compared with antivenin on mean survival times of New Zealand White rabbits (~2.7 kg) injected with *C. atrox* venom (6 mg kg^{-1})

Treatment	Antivenom pretreatment time (h)							
	−12	0	24	48	72	96	120	144
None	22±4	22±4	—	—	—	—	—	—
Pig plasma (1,000 mg)	20±4	22±4	22±4	—	—	—	—	—
Antivenin (200 mg)	24±4	30±4	24±4	—	—	—	—	—
C. atrox plasma (heated) (200 mg)	24±4	S	32±4	22±4	—	—	—	—
Antivenin (400 mg)	26±4	50±4	22±4	—	—	—	—	—
C. atrox plasma (heated) (400 mg)	26±4	S	45±5	28±4	22±4	—	—	—
Antivenin (800 mg)	26±4	S	22±4	—	—	—	—	—
C. atrox plasma (heated) (800 mg)	26±4	S	S	S	S	S	50±8	25±5

Each group consisted of three rabbits. Antivenom was injected intravenously either at the same time as the venom (intramuscularly) (that is pretreatment time = 0) or before the injection of venom at several pretreatment times (24–144 h). The first column minus 12 h (−12) refers to injection of venom 12 h before injection of antivenom. S indicates that all animals survived for several weeks until they were killed. Survival times are in hours.

activity was found in the middle gel cut separate from albumin. Analytical PAGE of the extract revealed four protein staining (Coomassie blue) bands 1.5–2.5 cm behind the albumin band. This group of proteins also stained strongly for carbohydrate.

To determine whether the antivenom activity of *C. atrox* plasma is potent enough to be of potential value in snakebite therapy, we compared its effectiveness with that of antivenin. The plasma was more effective in increasing survival time than any dose of antivenin (Table 2). This is remarkable as whole *C. atrox* plasma was used and, as shown by PAGE, only a small amount of the total plasma protein has antivenom activity. In contrast antivenin is a purified horse serum immunoglobulin preparation. Thus *C. atrox* plasma is a very effective antivenom.

We also found that *C. atrox* plasma activity against *C. atrox* venom was maintained for up to 4 d *in vivo* (Table 2), whereas antivenin rapidly loses its effectiveness (6–12 h) *in vivo* (rabbits).

We found the same antivenom pretreatment effect in mice by determining neutralisation capacity against *C. durisus terrificus* venom as a function of pretreatment time. There was a steady decline in neutralisation capacity during 3 d after a single intraperitoneal injection of antivenom (10 mg protein). The curve is somewhat steeper for *C. durisus terrificus* venom compared with that of *C. atrox*.

In these experiments, treated rabbits and mice showed markedly less tissue damage and haemorrhage than untreated animals. Isolation and characterisation of the antilethal factor(s) in *C. atrox* and *C. adamanteus* plasma may show that it is similar to the antihaemorrhagic factor found in Habu (*Trimeresurus flavoviridis*) venom reported by Omori-Satoh[11].

Even though immunoglobulin antivenin, prepared from sera of horses immunised against venom, is the most effective agent used in the management of snakebite, there are many serious problems associated with its use; for example, allergic reactions and the length of time from the bite to the effective administration of antivenin. Perhaps an antivenom prepared from snake plasma or a synthetic product based on antivenom factor(s) in snake plasma would be useful and safe for both the first aid and medical management of snakebite.

We thank the Charles Conners family, Broken Bow, Oklahoma and the Junior Chamber of Commerce, Okeene, Oklahoma, for health specimens of *C. atrox*, and Mr Don Bennett, Oklahoma City, for *C. atrox* plasma. We also thank Mr Phil Garn and Mr Robert Larsen for assistance.

Erratum

In the article "Calcium activation produces a characteristic response to stretch in both skeletal and cardiac muscle" by R. L. Moss, M. R. Sollins and F. J. Julian (*Nature*, **260**, 619; 1976) there were the following errors: on p. 619, line 16 should have read . . . able to interact with thin filament sites . . . and not as printed. On p. 620, second column, line 27 should have read . . . cium (*p*Ca about 9). Little if any short range elastic response . . . and not as printed.

Nature Index and Binders

The **Index** for 1975 is now available, price £2.25. Copies of the 1974 index are still on sale, price £3.00. **Binders** for the journal are also available at £7.00 for four (a year of *Nature* fits into four binders).

Postage is included in the above prices. Orders should be sent, accompanied by remittance to Macmillan Journals Ltd, Brunel Road, Basingstoke, Hampshire, England.

Symbionts or parasites?

Fred Dainton

The Force of Knowledge: The Scientific Dimension of Society. By John Ziman. Pp. ix+374, (Cambridge University: Cambridge and London, April 1976.) £7.50.

FRANCIS BACON firmly believed that natural philosophy could be organised for the benefit of mankind and no doubt good rational men holding power in an authoritarian state might entertain this hope. But both science and society change and so do their interactions. In his book, which arrived on the 350th anniversary of Bacon's death, Professor Ziman traces the changes in this relationship in the period from Bacon to the present day.

It is difficult to encapsulate the author's thesis in a few phrases but he seemed to be saying that knowledge—that is, science—is only useful if it leads to the creation of new knowledge or the solution of social problems or the acquisition by a society of physical power over resources and energy; and for all these purposes it must be communicated between men. But new ideas came from the sifting, re-arranging and assessing sceptically facts and earlier concepts in the minds of individuals. So in the first few chapters we are given glimpses of individual scientists, their styles of work, how their institutions for discourse and intercourse developed from clubs to learned societies and professional associations in response primarily to the increasing need (and difficulty) to communicate.

His characters are skilfully chosen and his vignettes are beautifully drawn: there is the restless, questing intellect of Leonardo; the convergent, introvert Cavendish drawing solitary satisfaction from precise observation and measurement; Ramanujan, the untutored genius; Wegener the inspired advocate of continental drift admitting only the evidence favourable to his belief; the courageous, pugnacious, rational, iconoclastic ideologue J. B. S. Haldane and the brilliant but conservative all-rounder Fermi forced by the social significance of the work he initiated to face up to his social responsibility. All this and much else besides is offered to the reader in felicitous evocative prose accompanied by beautiful illustrations; but I found it curious that such an author should stress the cognitive at the expense of the affective in his subjects. Thus we read nothing of their frequent passion for music and mountains. From the intercommunication of scientists it is a short step to their communication with laymen where, oddly, the roles of the Extra-Mural Departments of Universities, the Open University, of the Literary and Philosophical societies and other mutual improvement movements receive no mention.

Photo: California Institute of Technology

Einstein—personal authority accorded by his own republic of learning

Professor Ziman is at his best in showing us how personal authority whether accorded by the state—for example, as to Lindemann and Oppenheimer—or by their own republic of learning—for example, as to Darwin and Einstein—is in the long run the enemy of progress in science. Healthy science requires the maintenance of a vigorous scepticism in its practitioners, who should not be obedient priests but democratic and critical republicans. But alas scientists are human too and the revolutionary of yesteryear tilting at authority is easily turned by success into the established figure of today resisting the attacks on his ideas, position and influence. After a brief glance at medicine—taken principally, one feels, to illustrate the fundamentally reactionary nature of craft guilds and trade unions exerting powers they have wrested from rather than been willingly awarded by society—the reader moves to stories of industrial innovation (zips, jet engines, nylon, penicillin, float batteries) which the author believes to be "one of the dominant social processes of our time". It may well dominate less in future as such innovation makes further inroads on our resources of energy and raw materials; an aspect which like pollution (*pace* a brief reference on p279) is one of the outcomes of 'science in action' which is completely disregarded.

By now (chapter 9) the reader has been brought to the third quarter of the twentieth century, the scientist is transmogrified from the independent researcher to the more or less willing member of a large team, completely institutionalised, serving the military or civil ends of the state or the commercial ends of a corporation or 'big science'; or, if he is 'academicised', behaving in the ritual research fashion to enliven his teaching and to earn the approval of his senior colleagues which he esteems for its own sake and/or because it aids his promotion. Next follows a look at the transplantation of science from Western to alien soil in Australia, Japan, India and in that hypothetical but so clearly recognisable and authentic newly emerged Republic of Saturnia and the tragi-comic outcome of this dislocation. We proceed to a child's guide to the social sciences where controlled experiments are impossible, all systems are multivariate (and not independent variables at that!) and people still persist in the exercise of 'free will', the greatest 'joker' in the pack. So by way of the rarely felt moral dilemma of scientists, employed in increasing numbers in the war game, we come to the final chapter which is really an essay in the necessity of scepticism of authority. True as this is, it hardly seems to get to the roots of the scientists' social responsibility and it is a pity that Professor Ziman did not allow the current of his fluent prose to carry him to some deeper commitment.

This said we must remind ourselves that the book is the result of his preparing himself, as his conscience dictated he must, "to introduce the theme of the social relations of science and technology" to the average second year university student of natural science. In this aim he has succeeded brilliantly. Such students with 'A' levels in physics and chemistry should be able fully to understand the scientific, technological and engineering content. Moreover, based either on my own recollections of myself 40-odd years ago or on conversations with present-day students I am convinced that the style, topics and sentiments displayed in the book should have a strong appeal to the sense and sensibilities of young adults. They should find it as fascinating as a good novel, replete with characters whose individual and collective attributes are mirrored in many of their seniors and who face issues of great contemporary relevance and importance. I hope that they will put it down with the feeling that their generation has to meet the challenge of how the scientist is to be the critical symbiont of the larger society of which he is a part, helping to shape its purposes rather than becoming either the parasite or the passive helot of a society to whose aims he is indifferent if not hostile.

There is yet another reason why, were I still a professor, I would strongly recommend this book to my students and more particularly to their nonscientific contemporaries. It is simply that the book conveys in a lucid and lively manner the essence of the attitudes of scientists and by marked contrasts of style and matter jolts the reader into new thoughts. Thus it is serious in intent but impish in style, reverant and irreverent by turn, and popular—almost shallow treatment of some matters nevertheless often contain implicit or explicit insights of some depth. They serve to give the book a touch of human frailty seeming to put the author on the same level as the readers and thus encouraging them to think critically rather than be the passive receptors of the dispensed, predigested pabulum of scientific authority proffered to them in the textbooks. But scholars will sigh over inaccuracies and over-simplications or exaggerated phrases, and twice I narrowly escaped apoplexy. No reader will be indifferent and the young will be stimulated as the author wanted them to be. All that remains to be asked for is a paper back at half the price of the hard copy.

Sir Frederick Dainton is chairman of the University Grants Committee of the UK.

Unexpected treasures

The Compacted States of Vitreous Silica. By William Primak (Studies in Radiation Effects in Solids, Vol. 4.) Pp. xv+184. (Gordon and Breach: New York, London and Paris, 1975.) £10.70.

CONSIDERING the terrestrial abundance of silica and the crucial position it holds in several fields of technology, our understanding of its structure and solid-state chemistry is deplorably vague. An excuse can be given—that the solid states of SiO_2 are many and complex and have frustrated many conventional attacks— but the response of science has been lax. Pure scientists, instead of mounting more unconventional attacks, can be accused of generally turning away from the problems and letting the technologist flounder. A short list of technological uses of silica includes transmitting and reflecting optics, ceramics, piezoelectric devices, crucibles, passivating and insulating films; some unusual thin-film cantilever structures are now being used for displays and other purposes. In many of these applications, vitreous silica is used and yet, because conventional crystallography cannot work on such amorphous structures, ignorance of this state of the material is the greatest.

Primak's book-length review article presents a highly individual view of the structure of this amorphous material, based on physical measurements which can certainly be classed as unconventional but were superbly adapted to the problem. Compaction is an effect which occurs only in non-crystalline solid networks (perhaps even only in oxide networks but Primak omits to tell us if any non-oxide glasses will compact); it is produced by pressure-cycling, high temperature, shock waves or radiation and can so alter the vitreous silica network that density is permanently reduced as much as 15% for pressure, and 3% for the others. Alkali silicate glasses will compact even more. This behaviour is so foreign to our concepts of immutable lattice constants that it is scientifically important; technological uses are, of course, also conceivable. Primak's own work, mainly on radiation-induced effects, is a classic of well-performed experimental study, augmented by careful but not hidebound interpretations. His hypothesis for the compaction was startling in that it went clean against the instinctive feeling of other workers that an increase in density implied an increase in order (fused silica is less dense than quartz).

He supplies ample evidence that silica can reduce its volume by the formation of a 'kink' in the large (say twelve-atom) rings of the silica network so that a 'void space' which was previously empty is newly occupied and order thereby decreased. But why should the kink be retained? The wider, new idea comes in the proposal that the silica network is in "a microscopic state of balanced stress" and that an excitation, producing one kink, causes the whole local structure to rearrange, perhaps in the form of a "network segment" which re-configures its quota of non-bridging oxygen atoms. Although Primak does not elaborate the model with any theoretical solid-state physics, it is still a very meaty and useful hypothesis. The book is a pursuit of its proof through every scrap of evidence available (there are over 350 references). Although the book was conceived nine years ago and largely finished six years ago, the central hypothesis and the suggestions for further investigations remain valid. Appendices embrace new research up to 1973.

Only occasionally does the relaxed personal style lead to vagueness; for example, the author never tells us the best estimate for the Si–O–Si bond angles and lengths in the seven main phases of silica, and this sort of thing does detract from the introductory value. Later chapters are packed with intense and creative reasoning. Parochialism sometimes shows up here—for example in the lack of use which Primak has made of the electronic–optical disciplines of solid-state physics—for example, he does not explain the relevance of infrared spectra, or more than quote a few measurements. His only definite error in the electronic field is to say that "vitreous silica has no proper band structure", a common but unfortunate misconception, disproved by Di Stefano and others; the field of colour centres is dismissed as a "morass" and, although work on thin silica films is mentioned in passing, he has failed to note a valiant attempt made in 1969 by H. L. Hughes to explain γ-ray-induced surface-state generation in such films, using a compaction model correlating his and Primak's data. One feels that great benefit would have been bestowed on the world if the author had wandered a bit further in these fields.

The book does give people interested in silica a chance to revel in a refreshing minor tributary of knowledge which may yet do great things for the mainstream. By his pleasant but creative style the author indicates some of the unexplored creeks which could yield unexpected treasures from the most abundant material in the earth's crust.

Andrew Holmes-Siedle

Aphids

Aphids. (Invertebrate Series.) By Roger Blackman. Pp. 175. (Ginn: London and Aylesbury, 1975.) £3.00.

THE main reason why aphids have not attracted the attention they merit is the lack of simple accounts of their biology and taxonomy. Roger Blackman in 175 pages presents such a comprehensive, highly readable and extremely well illustrated account of aphids. The book's main asset is Chapter 10, 'Aphids in Britain'. This chapter makes available to amateur entomologists, for the first time, a workable key in English to the more common genera of aphids in Britain. The excellent colour plates by Hilary Burn, which illustrate this chapter, serve to bring some of the aphids to life. Unfortunately the colour photographs in plate 1 are so badly reproduced that they are useless; an additional colour plate would have been preferable.

The other 10 chapters deal with the structure and physiology of aphids, natural enemies, relationship with ants, population dynamics and techniques of study. This last chapter is a useful source of ideas for student projects.

In future editions Fig. 3 could be omitted, or revised, as it confuses rather than clarifies the discussion of an aphid's powers of multiplication; and Fig. 33 modified, as not all host-alternating aphids can produce and mature sexual morphs on their secondary hosts. The complex terminology of the various morphs of aphids has deterred many biologists from studying aphids, and it is therefore surprising that Dr Blackman did not use the simpler terminology proposed by Hille Ris Lambers (*A. Rev. Ent.*, **11**, 47–78, 1966). Unqualified statements such as aphids produce large numbers of offspring to counteract the losses they incur (p34), and that crowding is self induced (p78) unfortunately support Janzen's (*Science*, **182**, 1125–1126, 1973) contention that aphid biology is in need of a solid dose of evolutionary biology. Apart from these criticisms this book can be warmly recommended as an excellent introduction to a fascinating group of insects.

A. F. G. Dixon

Controversial texts

Techniques of Applied Quantum Mechanics. By J. P. Killingbeck. Pp. 224. (Butterworth: London and Boston, Massachusetts, November 1975.) £9.

OF the five chapters in this book two are directly relevant to the title—chapter four on "Perturbation and Variational Methods" and chapter five on "Group Theory", both topics in which the author has had practical experience. It is a pity that chapter four did not begin at the beginning—clearly a reader is supposed to have already read a standard book on quantum mechanics including the section on perturbation theory. The book would have been better if these chapters had been preceded by a conventional description of the principles of quantum mechanics. Instead we have a chapter called "Review of Basic Principles", which makes derogatory remarks on other textbooks, gives instructions to teachers of quantum mechanics and tells us about dyadics, but fails to review the basic principles. It is too nebulous in intent to be useful and is inconsistent in what is required of the reader—for example, if he needs to be told the meaning of operators commuting he should not be expected to be familiar with Dirac bra/ket notation. We then have two chapters on "Modern Mathematics" and "Operator Theory". In fact the mathematics of the second chapter is not in any sense modern. As a summary of some, mainly algebraic, topics these two chapters are adequate and probably useful. They are, however, essentially a list of definitions and theorems. Little is actually done with the concepts discussed and there are no proofs. It is hard to see how any student can really learn a subject from this type of treatment.

When the author is writing about "Applied Quantum Mechanics" he writes well and it should be said that the relevant two chapters constitute more than half of the book. In other places he is less convincing and one detects a certain 'propaganda' aspect to to the book, inappropriate in a textbook. On p10: "One of the basic problems is that of communication between the different types of scientist working on the subject; many a physicist has tried to follow up some interesting point which he suspects may have a practical application, only to give up in frustration at the large number of unfamiliar theorems and erudite subtleties which are taken for granted by the average mathematician's writings on quantum mechanics". Presumably it is "lack of communication" not "communication" that is alleged to be a problem. But is it a problem? What is the evidence?

On p38 we are told "The embedding of the real numbers in the complex numbers which is involved in this calculation is usually not commented on at all in texts concerned with quantum mechanics". Presumably these textbooks, contrary to the one under review, also omit to tell us that ±i is "more exactly 0 ± li". Maybe their authors know something! **E. J. Squires**

More to coral reefs . . .

Biology and Geology of Coral Reefs. Vol. 3 (Biology 2). Edited by O. A. Jones and R. Endean. Pp. xxi+435. (Academic: New York, San Francisco and London, 1976.) $49.00; £25.00.

FOR the second biological volume of this composite work on coral reefs, the editors have assembled a highly competent team of collaborators. There are chapters dealing with the more important groups of associated organisms and others covering aspects of the ecology of both reefs and coral cays. (For a review of volumes 1 and 2, see *Nature*, **248**, 809, 1974.)

From the unique wealth of his long experience, F. R. Fosberg discusses coral island vegetation which, in its limited but widely distributed species, gives, as he concludes, an insight into the nature and complexity of vegetation generally, while itself forming the basis of the rightly famed beauty of coral islands.

A. J. Bruce reviews our present knowledge (to which he has contributed so extensively) of the numerous shrimps and prawns around coral reefs. Aspects of the ecology of coral reef fishes are similarly discussed by B. Goldman and Frank Talbot, again on the basis of much personal experience on One Tree Island in the Capricorn Group. A further chapter deals with the natural toxicity of certain coral reef fishes.

The highly vexed problem of ciguatera is the province here of its major investigator, A. H. Banner. This disease, which may unpredictably follow human consumption of coral reef fishes in the Indo-Pacific and the Caribbean, forms a major hazard in the developments of fisheries. We know the nature of the toxin but not the conditions controlling its appearance.

The factors responsible for the destruction and recovery of reefs are very suitably reviewed by R. Endean; there are further chapters on echinoderms, on intimate associates of reef corals and on birds and on turtles, the last from Robert Bustard who has contributed so much to our knowledge of those around the Great Barrier Reef.

Altogether this is an exceptionally valuable book to be studied and, if possible, possessed by the growing numbers of those fascinated by the innumerable problems presented by a living coral reef.

C. M. Yonge

obituary

Robert Franklin Mehl, Professor-Emeritus of Metallurgy at Carnegie–Mellon University, who died in Pittsburgh on January 29 at the age of 77 was undoubtedly one of the greatest academic metallurgists of the American scene. After studying at Franklin and Marshall College, Princeton and Harvard Universities, he went to the Naval Research Laboratory in 1927 as Director of the newly formed physical metallurgy laboratory. In 1932, after a brief period in industry, he became the first Director of the Metals Research Laboratory at the then Carnegie Institute of Technology, and launched on what was to be his greatest achievement. He collected around him an extremely talented group of physicists, chemists and metallurgists who in the next decade were to make outstanding contributions to physical metallurgy, particularly in the fields of diffusion, phase transformations and precipitation hardening. But perhaps Mehl's greatest contributions were towards a basic understanding of the various reactions involved in the heat treatment of steels, in particular the formation of ferrite from austenite and the pearlite and bainite reactions which he and his colleagues analysed so thoroughly that they elucidated many of the principles from which the physical metallurgy of steels has developed.

In 1935 Mehl also became Chairman of the Department of Metallurgy, instituting scientifically based courses of high standard which in a few years made Carnegie Tech. a premier place for the study of metallurgy which had a large impact not only on the local steel industry but also throughout the United States. During World War II his laboratory was thus well placed to carry out work which greatly aided the production of guns and armour, though Mehl was often frustrated by reactionary attitudes in industry towards scientific endeavour!

After the war, he continued to stimulate the activities of the Metals Research Laboratory over an extremely wide range until 1960. Possessed of a very strong personality, he wielded his influence far and wide; inevitably his scientific contributions were now made with a broad brush rather than a rapier; however, the rapier was always ready at hand to deal decisively with anyone who might venture to take an opposite viewpoint. Numerous names of scientists in the MRL during the period 1945–60 now adorn the faculties of many well known departments of metallurgy and leading industrial laboratories, a constant reminder of the high standards on which Mehl insisted.

He became a familiar figure in Europe between 1960 and 1966 when he was European consultant to the US Steel Corporation. The combined role of ambassador and interpreter of the European metallurgical scene suited Mehl at this stage of his life, when he was already one of the grand old men of metallurgy; he returned, however, to the USA in 1966 to become visiting professor at the University of Delaware and later at Syracuse University. Latterly, retired in Pittsburgh very close to his beloved University, he suffered severe ill-health, but set a fine example by his great courage, and by maintaining an active interest in his subject to the last. A paper he wrote in 1975 for the Annual Review of Materials Science is an excellent summary of his scientific career and is spiced with his own unmistakeable philosophy. It is indeed a fitting epitaph.

R. W. K. Honeycombe

Appointments

Dr Mart de Groot as Director of the Armagh Observatory.

Dr Thomas Anthony Connors as Director of the MRC Toxicology Unit.

Dr Peter Cardwell Elmes as Director of the MRC Pneumoconiosis Unit.

Dr R. R. Dils as Professor of Physiology and Biochemistry at the University of Reading.

Dr A. F. G. Wyatt as Professor of Physics at the University of Exeter.

PhD in evolution

EIGHT months ago the Science Research Council (SRC) produced a report on postgraduate education which by the standards which generally prevail in the academic world was decidedly radical. The working party, headed by SRC chairman Sir Sam Edwards, proposed amongst other things that greater emphasis be placed on graduate students taking a wide range of courses, particularly in their first year. A high proportion of broadly based compulsory course work leading to an examination for a Master's degree or equivalent qualification was suggested. The option of continuing for a further two years, the report went on, should only be open to students who had passed the Master's course and demonstrated real aptitude for research. The example of MIT was clearly well to the fore in the working party's deliberations.

The background to this needs little rehearsing. In the 1960s PhDs were being signed up with enthusiasm, not least by the new universities which then proceeded to generate even more PhDs of their own. These days universities no longer recruit, emigration is less of an option, the civil service does not grow in size, so PhDs find themselves applying for a job, somewhat reluctantly maybe, to those same industries to which they might have applied three years earlier. But industry's view of a PhD is by no means one of universal approbation—indeed, those in industry who think that PhDs are of little use to their needs have been getting much of the attention in the last year or two. Small wonder then that SRC decided that some spring cleaning was necessary of the ideas surrounding the PhD.

In the past two months a form of participatory democracy has been in operation. SRC had already received many written submissions on its report, but it decided to take to the road as well so that the report could be discussed more informally in regional gatherings of university science staff and industrialists. That exercise, which took the SRC to Cardiff, Birmingham, Glasgow, Leeds and London, is complete; now the SRC must try to see whether anything like a coherent policy can emerge from the consultative process. The general conclusions that can be drawn seem to run as follows:

- Industry does not speak with anything like a unified voice in its views about the relevance of the PhD. Even within the same company it is possible to find, say, research directors and personnel managers who would differ in their assessment of the value of the degree.
- Whilst most academics support, or at least don't oppose, the idea of more taught courses, the idea that these should be compulsory has had a very mixed reception.
- The idea that the courses should be concentrated in the first year of postgraduate education has come in for some criticism.
- The nature of the assessment at the end of the first year has caused some alarm, not surprisingly amongst students who fear another year of being tyrannised by examinations.
- Many people have expressed doubts about the feasibility of doing a good research project for a PhD in two years rather than three.

Some of these points will undoubtedly result in a softening of the SRC's approach; more than once the council was urged to encourage evolution rather than impose revolution, and such changes as spring from the exercise are likely to emerge slowly over the next decade. For it is not at all clear that the SRC should use the muscle that it has, in the way of discretion over grant money, to force the pace. Maybe the very fact of the report and the chance to air views will have generated enough momentum.

The one thing that the SRC should not soften on, however, is its conviction that there is not a "correct" duration of three years of research for the PhD. A fairly common view amongst academics was that a period of less than three years in the laboratory is inadequate for students to make a research contribution. If the student is being trained to write papers or know more about some particular subject than anyone else in the world, this may have some element of truth in it. But industry does not usually hire its PhDs for either of these reasons; it hires them for their potential to work in a broadly based team. And the PhD who stays in the academic world is going to have plenty of time to develop the necessary expertise later.

Moreover, it is a poor comment on the quality of postgraduate course work if it doesn't make a significant contribution to helping students to be more effective researchers, by pointing them in the direction of key literature, by exposing them to the ethos of research and by allowing them the luxury of sampling different staff members before having to make a final choice. A year of coursework could easily be worth two of research. ☐

US takes up the issues . . .

The nuclear exporters meet again soon. **Colin Norman** reports on the debate now taking place in the United States

NEXT month, representatives of present and potential nuclear exporting countries are scheduled to meet in London for a second round of secret talks aimed at curbing the proliferation of nuclear weapons. With international trade in nuclear goods now estimated to be well in excess of $1,000 million a year and growing rapidly, and with several particularly risky transactions in the works, the talks are considered by many to be critical for the future stability of the world.

They will take place against a background of growing demands in the United States for extraordinary measures to prevent potentially dangerous nuclear transactions from taking place. Though some of the strongest demands are coming from Capitol Hill, the issue of nuclear proliferation has even been raised in the Presidential election campaign, and some Administration officials are also taking an increasingly hard line in urging the adoption of strict international safeguards to prevent the diversion of peaceful nuclear technology to weapons production.

Two recent developments are, however, likely to be particularly influential in next month's talks. On May 14, the Senate Foreign Relations Committee approved a foreign aid bill containing a little-noticed provision which would cut off all US aid to countries buying or selling uranium enrichment or nuclear reprocessing plants without adequate safeguards. And, in the same week, the Senate Government Operations Committee approved a bill calling on the President to negotiate a "binding agreement" with other nuclear exporting countries to prohibit the sale of enrichment or reprocessing technology to individual countries which do not already possess nuclear weapons. The bill also specifies, that the agreement should prohibit the sale of any nuclear facility—including a power reactor—to a country which refuses to place *all* its nuclear activities under international safeguards and inspection.

Moreover, Senator Abraham Ribicoff, the chairman of the Government Operations Committee, has on several occasions called for strict sanctions against West Germany and France if those countries go ahead with plans to sell reprocessing plants to Brazil and Pakistan respectively.

Thus, with Congress breathing heavily down its neck, the Ford Administration is likely to take a tough line in next month's talks. Because some participants in the talks have insisted on strict secrecy—France is said to have threatened to pull out of the first round if the discussions were made public—Administration officials are reluctant to discuss that matter in detail. Nevertheless, it is clear that there is likely to be continuing friction between the United States on the one hand, and France and West Germany on the other.

The first round of the talks, which included representatives from the United States, the USSR, Britain, Canada, France, West Germany and Japan, ended in January with general agreement on principles for international safeguards. According to assorted reports and Administration sources, the agreement would allow nuclear technology to be sold only to those countries which promise not to use it to produce explosives, and it would provide for the adoption of common standards to guard against theft or clandestine diversion of nuclear materials.

The agreement fell far short, however, of the strict controls urged by the United States. The Secretary of State, Henry Kissinger, for example, said in Congressional testimony on March 9 that the talks had simply ended in a "general understanding about restraint", and he suggested that the United States would press for "something more binding" in the next round. The Ford Administration is particularly concerned that the agreement is weak in dealing with the critical issue of the sale of uranium enrichment and fuel reprocessing plants.

Because enrichment plants are capable of producing weapons-grade uranium, and reprocessing plants separate plutonium—another potential bomb ingredient—from spent reactor fuel, they are the key links in a weapons fabrication process. By themselves, reactors present a smaller proliferation hazard since neither the uranium fuel nor the reactor wastes can be used directly to make explosives. Thus reactor sales to non-nuclear weapons countries are usually made on condition that the fuel going into and coming out of the reactor is closely monitored, and that it is not enriched or reprocessed by the purchaser.

The International Atomic Energy Agency (IAEA), the Vienna-based body established in 1957, is responsible for policing most nuclear transactions to ensure that no diversion of weapons-grade material takes place. IAEA keeps records of fuel passing through reactors under its supervision, and it also has a small corps of inspectors authorised to make spot checks at individual installations. The Nuclear Non-Proliferation Treaty (NPT), which came into force in 1970, binds all signatories to place future nuclear transactions under IAEA supervision.

A number of recent events have, however, shattered hopes that such a loose system of controls can be completely relied upon to prevent the insidious spread of nuclear weapons around the world. The most significant event by far was the detonation in 1974 of an explosive device by India. Using plutonium reprocessed from spent fuel from a Canadian-supplied reactor, India abruptly ended the nuclear hegemony of the United States, the USSR, Britain, France and China. Though Indian officials insisted that they would only use nuclear explosives for peaceful purposes, that piece of semantic juggling does not disguise the fact that India is now a nuclear power.

The other chief unsettling events were the negotiation last year of an agreement between West Germany and Brazil for the sale of an entire nuclear system, including enrichment and reprocessing facilities, followed by a deal between France and Pakistan involving the sale of a reprocessing facility. A third transaction, the sale of a French reprocessing plant to South Korea, was scotched earlier this year when South Korea pulled out under heavy pressure from the United States. (In a press briefing in Washington last

Dr Fred Iklé, Director of the US Arms Control and Disarmament Agency week, however, the French President, Valery Giscard D'Estaing, said that he had personally vetoed the sale.) West Germany, in addition, is widely believed to be negotiating to supply reactors, and possibly a reprocessing plant, to Iran.

Those deals mark a significant qualitative shift in international nuclear trade, since they would transfer directly the means for producing weapons-grade materials. What makes them particularly worrying is the fact that none of the recipients, except for Iran, is a party to the NPT. They have all been bitterly opposed by the United States, and US officials from Dr Kissinger down tried in vain to dissuade France and Germany from going through with them.

Aside from sales of enrichment and reprocessing technology, there has also been considerable doubt expressed recently about the adequacy of present safeguards on reactor sales. For one thing, many reactors have already been sold without IAEA safeguards—the Canadian sale to India provides a particularly vivid example, and similarly the sale by France of a small research reactor to Israel in the early 1960s is widely believed to have provided Israel with the means to produce weapons. According to a recent CIA analysis, Israel has taken up that option and now possesses between 12 and 20 plutonium bombs.

And the IAEA safeguards themselves do not provide an insurmountable barrier against diversion of fissile material. In a speech on May 13, Dr Fred Iklé, Director of the Arms Control and Disarmament Agency (ACDA) and one of the more outspoken Administration officials on nuclear proliferation, warned that the IAEA is understaffed, relies chiefly on information supplied by the country under safeguards, has no power to impose sanctions against violators and cannot investigate unsafeguarded plants. IAEA safeguards, Iklé said, provide "a burglar alarm, but not a lock", and it is a "fallacy" to believe that we don't have to worry about facilities under IAEA safeguards.

The United States itself, moreover, is not entirely blameless. In 1974, then President Nixon promised to sell nuclear reactors to Israel and Egypt, two antagonists who have not ratified the NPT. (Negotiations concerning those reactors are not yet complete.) And last week it became known that the General Electric Corporation has applied for a licence to sell two 1,000 MW reactors to South Africa, together with 1.4 million pounds of slightly enriched fuel. According to Administration sources, that deal is likely to be officially approved, even though South Africa has not signed the NPT and is believed to be interested in joining the nuclear weapons club.

That is the background against which the talks between the nuclear exporting nations will resume next month. Aside from the seven original participants, they are expected to include representatives from the Netherlands, Sweden, Belgium, East Germany, Italy and Poland. The critical issue is again expected to be the sale of enrichment and reprocessing technology, with the United States arguing against deals which would place such plants in the hands of individual purchasers, whether or not they are placed under IAEA safeguards.

The chief American argument is simply that reprocessing is not necessary at this time, and there is no economic need to sell either enrichment or reprocessing plants. Dr Iklé, for example, noted in his May 13 speech that separating plutonium from spent fuel and recycling it "could replace at most about one third of the fuel required, and far less in a rapidly growing nuclear power system. Hence, recycling would not bring independence from imported fuel". He added: "Before we plunge into a plutonium fuel economy, let us look very closely at the risks and our ability to control them . . . spreading plutonium should be avoided if possible, and with the current generation of reactors it can be avoided at no economic cost".

If it proves impossible to curb the desire for reprocessing plants, the Administration will probably continue to urge that instead of selling such plants to individual countries, nuclear exporters should consider placing such technology under multinational control. Iklé noted that the United States is now studying the feasibility of "multinational fuel centres for storage of fuel, waste management, and other services when needed".

The United States' arguments are, however, likely to fall foul of the desire,

Passage to India?

THE Nuclear Regulatory Commission (NRC) announced last week that it will hold public hearings to decide whether or not the United States should supply slightly enriched uranium to India, for the Tarapur Atomic Reactor located near Bombay. The hearings, the first ever to be held on a nuclear export licence application, graphically underline the fact that because the United States is the world's major supplier of reactor fuel, it is in a strong position to force many countries to accept strong safeguards against the diversion of peaceful nuclear technology to weapons production.

The hearings, set for June 2, will be held in response to a petition from the Natural Resources Defense Council, the Sierra Club and the Union of Concerned Scientists. The United States has supplied India with fuel for that reactor in the past, but the petitioners are essentially suggesting that NRC should use the application to supply another 40,000 pounds of uranium as a way to force India to accept extra safeguards.

The Tarapur reactor and its fuel supplies are all under the supervision of the International Atomic Energy Agency (IAEA), and those facilities were not the source of plutonium for India's nuclear explosives.

But the petitioners have pointed out that India hasn't signed the non-proliferation treaty, that a clash between India and one of its neighbours might disrupt present safeguards at the plant, that the United States has not required India to place all its other nuclear facilities under international safeguards, and that the United States has not required India to accept bilateral safeguards in addition to the IAEA controls. The implication is that the United States should threaten to shut off fuel supplies to India unless it accepts those additional safeguards. The concept could clearly be applied to other countries.

At present, only the United States and the Soviet Union export enriched uranium fuel, and their dominance of the fuel export market is expected to last at least until the mid-1980s. Some observers have therefore raised the possibility of a joint US–USSR agreement that future fuel supplies should carry strict safeguards agreements, in addition to IAEA controls. Senator Abraham Ribicoff, for example, has even suggested that the United States should refuse to supply nuclear fuel to West Germany and France if those countries persist in selling enrichment or reprocessing plants. But Henry Kissinger has forcefully ruled out such "blackmail", suggesting that a pact with the Soviet Union against America's NATO allies would have "the gravest foreign policy consequences".

As for the proposed fuel shipment to India, the NRC has announced that it will decide whether to issue the licence before the end of June, and it has suggested that it might even act on the matter before the conclusion of the hearings "if it finds a need for greater expedition". The hearings would, however, carry on with an examination of the broad policy issues involved in United States' fuel exports.

particularly on the part of France and West Germany, to earn maximum export dollars from nuclear trade, and of deep European suspicions of American motives. According to some observers, there is concern in Europe that American attempts to prevent the German–Brazil deal, in particular, were chiefly designed to protect the United States' commercial interests there.

Such suspicions were given a blast of fertiliser last year by an incident which occurred just as the United States was applying pressure on West Germany not to conclude its fuel technology agreement with Brazil. According to published accounts, a representative of the Bechtel Power Corporation, a major US nuclear manufacturer, met in March last year with Brazilian officials to discuss the possibility of building fuel facilities there, leaving the impression that the US government would sanction such a deal. Though the incident was probably simply a product of poor communications between industry and government in the United States, it clearly left a sour impression in Europe. Moreover, it should be noted that while Dr Iklé has been arguing that there is no economic incentive for recycling plutonium at present, the US nuclear industry has been urging the government to allow plutonium recycling in the United States.

If the provision in the foreign aid bill survives the rest of the Congressional mill intact, however, it would greatly stiffen the administration's policies in trying to dissuade the sale of enrichment and reprocessing technology. Proposed by Senator Stuart Symington, it would cut off nearly all US aid to the buyers and sellers of such technology, unless they have agreed to "place all such equipment, materials, and technology, upon delivery, under multilateral auspices and management when available", and unless the recipient agrees to place all its nuclear facilities under IAEA safeguards. The latter provision is intended to prevent the recipient from either duplicating the reprocessing or enrichment technology, or separating plutonium from an unsafeguarded reactor in the transferred reprocessing plant. The amendment is not, however, included in the House version of the bill, and its prospects are uncertain.

As for safeguards on the sale of power reactors, the Administration's policy is that controls should be applied uniformly among the supplying countries rather than imposed unilaterally, the argument being that if the United States insists on excessively strict safeguards on its own sales, potential purchasers will simply look elsewhere. Key issues in next month's talks are likely to include ways to bring presently unsafeguarded reactors and facilities into the IAEA safeguards system, methods to ensure that promises not to use imported nuclear technology for weapons production are made binding, and strengthening of the IAEA safeguards and inspection system.

Aside from the suppliers' conference, Mr Jimmy Carter, the leading candidate to be the Democratic Party's Presidential nominee, has called for a UN-sponsored World Energy Conference to discuss worldwide energy problems and alternatives to nuclear power. Calling nuclear proliferation a "fearsome prospect", Carter also urged a ban on sales of reprocessing and enrichment technology, and he called for a pact among purchasers of nuclear technology to buy only from suppliers who require proper safeguards. "The hour is too late for business as usual", he said. So far, nobody else has talked about those issues in the campaign.

The outcome of the exporters' conference is clearly going to be of immense importance. As Denis Hayes, a researcher with the Worldwatch Institute noted in a recent study on nuclear power, if a few more nations acquire nuclear weapons, there will come a point at which the "dam will break and the world will go nuclear". And, in Congressional testimony earlier this year, David Lilienthal, the first chairman of the US Atomic Energy Commission called for an immediate, unilateral halt to all US nuclear exports because of the dangers of proliferation. "I'm glad I'm not a young man", he said, and "I'm sorry for my grandchildren". □

... Canada makes up its mind

Canada announced last week that further nuclear cooperation with India was impossible.

David Spurgeon in Ottawa gives the background

THE Canadian government is just emerging from some serious soul-searching about the moral, political and economic questions involved in nuclear assistance and reactor sales abroad — particularly to developing countries. In the Canadian House of Commons last week, where the subject has been under debate for some time, the External Affairs Minister, Mr Allan MacEachen, announced that the government had decided that it will not resume supplies to India of nuclear equipment and technology. The two countries have failed to agree on safeguards against the use of the materials supplied by Canada for nuclear explosions.

The decision marks another step in the development of Canadian nuclear policy. The whole subject—which an MP described in one session as "perhaps the most important ever raised on an opposition day"—originally arose in the House as a result of government negotiations to resume nuclear assistance to India. In March these negotiations were conducted with India in New Delhi by Ivan Head, foreign policy adviser to the Prime Minister, Pierre Trudeau, and Michel Dupuy, an assistant under-secretary in the external affairs department.

This had followed the suspension of assistance after India's explosion of what it called a peaceful nuclear device in May, 1974. The device used plutonium from the Canadian-design CIRUS research reactor, and the suspension had been ordered because, in the words of MacEachen, "the carrying out of that explosion was in clear violation of the understanding that had been reached between Canada and India".

The latest news probably means that the efforts to reach international understandings on nuclear exports have suffered something of a setback. But the Canadian government has meanwhile been pursuing its chosen path in negotiations with other countries. Canada hopes to obtain an agreement with Pakistan not to use plutonium from a Canadian-designed nuclear power plant, and in January concluded agreements to build 600 megawatt power reactors in Argentina and South Korea. An Atomic Energy of Canada Ltd (AECL) spokesman has said there is the prospect of building second units in Argentina and South Korea in future, and preliminary discussions have been undertaken with other countries, including Mexico. Canada is also involved in licensing negotiations with Italy and Romania. Altogether, expected exports of CANDU reactors between 1974 and 1983 have been estimated by the federal department of industry, trade and commerce to amount to $3,000 million.

The debate over the propriety of Canada's selling nuclear reactors and technology when world powers are concerned about the proliferation of nuclear weapons has gone beyond Parliament. The Prime Minister has received delegations from the Canadian Council of Churches, the United Church of Canada, and the Quakers, and he has been urged to call a halt to the sales. The irony is that the CANDU nuclear reactor has turned out to be one of the most successful in the world at a time when confidence in reactor reliability is waning throughout the world and construction starts are falling off. Canada went it alone with its design (the CANDU is moderated by heavy water and fuelled with natural uranium), and finally appears able, as a result of worldwide interest, to recoup some of its huge investment made over the years.

Critics of the government's policy have expressed fears that CANDU reactors will be used to recover plutonium (produced as a by-product) for the making of nuclear weapons. In the eyes of T. C. Douglas, the former leader of the New Democratic Party, for example, "Canada has greater special responsibility than any other country"; the CANDU reactor, he points out, produces twice as much plutonium as light-water reactors, and spent-fuel rods containing plutonium can be removed daily without shutting down the reactor. On the other hand, Frank Maine, a Liberal MP with a PhD in organic chemistry who is one of the few members of the House with a background in science, has claimed that there are "technical reasons why the CANDU does not contribute to the proliferation of nuclear weapons."

The argument was put in these terms. Since the CANDU is fuelled with natural uranium it converts a lot of its primary fuel component, Uranium 238, into Plutonium 239 and Plutonium 240. Plutonium 239 is used primarily to make bombs, but Plutonium 240 is not very useful for bomb-making. The operating conditions for bomb-making and electricity-generation, however, are contradictory in a CANDU reactor: the longer the fuel is left in the reactor, the more plutonium 240 is made; the shorter the time, the more plutonium 239; but the longer the reactor is left running without changing fuel, the more economic it is. To make plutonium for a bomb, the fuel rods must be left in the reactor for perhaps 600 megawatt days per tonne; but if economic electricity production is wanted, the rods must be left in for 6,000 megawatt days.

Thus, said Dr Maine, the CANDU system is "a total design":

> It is designed to be fed the fuel continuously, and the feeding of the reactor is such that the uranium will be irradiated to the 6,000 megawatt days per tonne level.
>
> If you change it by a factor of ten, either you have to redesign your system completely . . . or else you will have to shut the system down to take out the fuel . . . if you want to generate electricity you use the CANDU system, but if you want to make bombs you do not use the CANDU system.

Dr Maine's technical arguments had little effect on the debates. What bothered many of the opposition members was what they considered a secretive attitude on the part of the government concerning its negotiations with India. Mr Douglas complained that when newspaper reports first appeared about the Delhi delegation and inquiries were made, the Secretary of State for External Affairs "said that the delegation was in India and until it returned he was not in a position to say what agreement it might be discussing". When the delegation did return, "he said the matter was before Cabinet and he could not discuss it until a decision had been made."

Another aspect that bothered critics was that they felt they did not know exactly what was decided at the meetings in London of the "Group of Seven". The Government's position has been that it cannot in good conscience withhold from developing countries the technology they need to help supply their power requirements. Mr MacEachen has also claimed that Canada has had considerable influence in upgrading nuclear standards among the suppliers, and that if Canada withdrew from the export market it would lose this influence. There would also be domestic consequences, such as a radical dislocation of the uranium mining industry. "If we want to succeed in the task of ensuring non-proliferation, we must cast the net wider", Mr MacEachen told the Commons. "We must consider the causes of international tension and do something about the disparities that exist in the world. We must do something to bring about a better and more equitable international economic system."

In addition to the CIRUS research reactor from which India obtained the plutonium for its nuclear explosive device, Canada has helped to build two reactors known as RAPP-I and RAPP-II. Completion of the second has been held up by Canada's decision not to

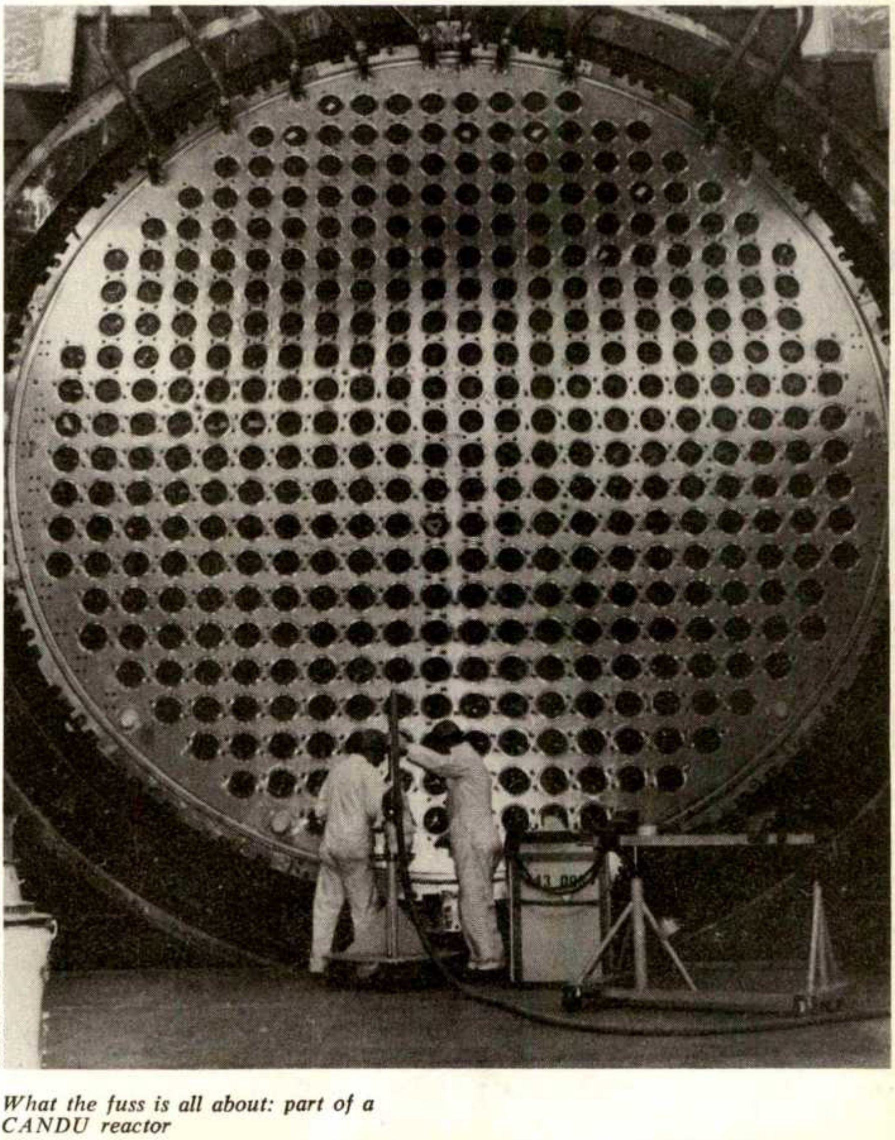

Photo: IPC

What the fuss is all about: part of a CANDU reactor supply further nuclear assistance without assurance that plutonium coming from it will not be used for further nuclear explosions. It is the lack of that assurance which is chiefly responsible for last week's announcement. The Canadian government has wanted to upgrade the safeguard system which already exists on RAPP-II, which India is capable of finishing alone, though it will take longer without Canadian help.

According to Mr MacEachen, the question the government has been faced with is whether it is better in the interests of non-proliferation to get out of nuclear co-operation with India completely, risking a collapse of current safeguards, or to complete the project while upgrading the RAPP-II safeguards. The crucial point, however, concerns the absence of safeguards on the very reactor that produced India's first nuclear explosion—the CIRUS. CIRUS would not have been covered by the agreement, Canadian officials apparently thinking it unimportant because it produces only enough plutonium to make one or two bombs a year. Furthermore, future reactors now being built or planned by India to Canadian design would not have been safeguarded by the terms of the Canadian agreement.

Before the latest decision the rationale that the government was using seemed to ignore the very rationale Frank Maine had put forward to defend it: that, because the RAPP reactors are designed to produce power, they could only be used to produce weapons-grade plutonium at the expense of power production. On the other hand, a research reactor like CIRUS is ideal for producing fissile material. That, in fact, is what was done two years ago.

Another question critics asked was how much Canada could rely on safeguards even if they were agreed to. Canada thought it had agreement from India that she would not explode a nuclear device before she actually did so. "Safeguards," said T. C. Douglas, "are worth nothing unless the people who give them are the kind of people on whom we can rely." Robert Stanfield, the former opposition leader, wondered if "the government and those who are advising the government are not acting on the premise that these potential customers are going to get the bomb anyway, and Canada might as well get the business".

There has been some indication that a firm stand by Canada does have some effect. South Korea cancelled a fuel reprocessing plant under pressure from the United States and Canada when Canada threatened to cancel construction of its nuclear plant. Pakistan has contracted with France to buy a processing plant—for reasons unsatisfactory to Canada—and Canada was hoping that if its agreement with India was successfully concluded it would obtain a similar agreement with Pakistan. Such an agreement would prevent Pakistan from using explosive devices from waste fuel from a Canadian-designed plant in Karachi. Until it receives a commitment, Canada will not supply Pakistan with a plant to make fuel bundles for the Karachi reactor, and has threatened to hold back delivery of fuel made in Canada.

What the Canadian nuclear export critics have been saying is that Canada should undertake a moratorium on sales of nuclear materials for a period, during which pressure should be exerted on other exporting countries to agree on adequate safeguards, with sanctions. With respect to India at least, the Cabinet has now made a decision, and through its external affairs minister the Indian government has already expressed its regret and disappointment. The full background behind the Canadian announcement has yet to emerge—India quickly disclaimed any responsibility on her part—and the forthcoming meeting of the "Group of Seven" has now taken on added interest. ☐

CHEMICAL WEAPONS

Slow progress to disarmament

Atttempts are being made to reduce, through international understandings, the chances of chemical warfare. John Stares outlines some of the problems

Drawing up an international treaty banning chemical weapons ought to be a simple matter. Chemical warfare has been illegal for more than 50 years. No chemical weapons have been manufactured, at least in the West, for almost 10 years, and some countries have begun to dispose of their obsolete stocks. Admittedly a new generation of chemical weapons—the binary weapons—is being developed in the United States, but the US Congress has so far refused to grant funds for their manufacture. And yet, in almost 10 years of international negotiations, the Conference of the Committee on Disarmament (CCD) in Geneva has failed to produce a chemical disarmament treaty.

As time goes on, the need for a chemical warfare (CW) treaty becomes more urgent. Details of the chemistry of CW agent production are widely known, and there is a growing risk of the proliferation of chemical weapons. Advances in our knowledge of biochemistry, and developments in genetic engineering, bring with them the danger of the development of new CW agents. It may only be a matter of time before the US Congress does grant procurement funds for binaries. If proliferation, the development of new agents or procurement of binaries does become reality, the problems of reaching agreement on chemical disarmament will increase considerably. But in a major speech to the CCD last month, the US delegate, Joseph Martin, indicated that agreement is still a long way off.

Ambassador Martin said that there are several issues where, in the US view, "an adequate basis for forming judgments already seems to exist, and where agreement may be possible in the relatively near future". On the question of the scope of a CW treaty, he said that "the complete prohibition of chemical weapons cannot be realised in a single comprehensive agreement", and that therefore there should be a phased approach to chemical disarmament. A step-by-step approach is not a new idea, but while in the past the aim was to concentrate initially on the most dangerous "supertoxic" CW agents, such as the nerve gases, it is now generally agreed that an initial CW treaty should encompass all lethal CW agents.

Thus the phased approach to chemical disarmament should be based on the activities to be included in the ban. Initially attention should be focused on banning the production of all lethal CW agents, and on reducing existing stockpiles, although exactly what measures should be applied to stocks—whether, for example, the treaty should require destruction of all, or only part, of the stocks—is still a matter for debate.

On the question of the definition of CW agents, it is the "tentative view" of the USA that it might be adequate to rely on a general purpose criterion—perhaps along the lines of the formulation in the 1974 Japanese draft CW treaty, where CW agents were defined as chemicals "of types and in quantities that have no justification for protective or other peaceful purposes"—and on lethal toxicity standards. Other criteria, such as representative lists of agents, or structural formulae, could perhaps be used as well, if necessary.

To have taken five years to reach a consensus that, in an initial CW treaty, production of all lethal CW agents should be banned, that lethal CW agents can be defined satisfactorily, and that some, as yet still unspecified, measures should be applied to existing stockpiles, is not exactly impressive progress—particularly when there is still no agreement on how to ensure compliance with such a treaty. Verification remains the major stumbling block to the conclusion of any CW treaty, partial or otherwise.

In recent years, a mass of detailed information on technical methods of verification has been produced by SIPRI, Pugwash and other groups, and presented in the CCD. It has been suggested that therefore all the elements necessary to build an effective CW treaty are now available, and that all that is needed is a political decision to conclude the treaty. But Ambassador Martin stressed that the USA does not share this view, maintaining that effective solutions to the problems of verification have not yet been found.

A first stage CW treaty would require a verification system capable of providing adequate assurance that CW agents are not being produced, and that the destruction of stockpiles actually complies, qualitatively and quantitatively, with the provisions of the treaty. There are two broad aspects of verification. First, the methodology. The methods studied include, for example, statistical monitoring of data on the production, transport and use of phosphorus and phosphorus compounds, a technique aimed at detecting possible diversion of phosphorus from civilian industry to military uses; and sophisticated scientific analytical techniques capable of detecting organophosphorus compounds in air, water or soil samples (and thus of detecting production of nerve agents), and of monitoring destruction activities, from remote locations. In addition, reconnaissance satellites might be used to observe mothballed production facilities and hence warn of any resumption of activity.

These methods are certainly not foolproof. But, as Martin admitted, 100% effective verification is not necessarily essential: : what is needed is a system capable of setting the difficulties of evasion high enough to deter treaty violation. These methods, especially when used in combination, could form a useful basis for such a system. And the methods are constantly being developed and refined: SIPRI, unfortunately, seems to have lost interest in chemical disarmament problems, but other groups, such as the Pugwash Chemical Warfare Study Group, are actively engaged in studies on this question.

The other aspect of verification is the implementation of the system. This is a purely political decision, involving an assessment of the adequacy of the degree of assurance that could be provided by the technical verification methods. Martin made the US view quite clear, that in order to obtain adequate assurance of compliance with the provisions of a CW treaty, there must be provision for supplementing the technical verification methods with on-site inspection of production and destruction facilities, whether on a mandatory or a challenge basis.

On-site inspection has always been a politically sensitive issue, and it is unlikely to be resolved until there is a considerable improvement in international trust and confidence. Of course, in many ways, this is a circular argument: the greater the degree of international confidence, the easier it would be to implement a verification system including on-site inspection, while at the same time the need for extensive verification would decrease. Nevertheless, there is a point at which the degree of international mutual confidence is such that a given level of verification, including on-site inspection, is both perceived to be necessary, and is acceptable, politically, by all sides.

The international chemical disarmament negotiations therefore seem to have reached the stage where, all the technical elements of a verification system being available, the emphasis is on building international confidence. In this context, Ambassador Martin made the valuable suggestion that it "might be useful to consider the feasibility and utility of technical exchange visits to selected chemical production and disposal facilities in different countries". This was an idea that had been emplanted last year within the US administration, and those of other countries, by the Pugwash Chemical Warfare Study Group. It is encouraging that its public endorsement by Ambassador Martin coincided with the Group's latest Workshop, held in London and attended by experts from 11 countries, East, West and non-aligned.

There have been indications, unofficially, that other countries, including the Soviet Union, would respond favourably to this idea. If a programme of visits could be arranged, at which it would be possible to test the methodology of verification in practice, this would represent a significant step forward in the chemical disarmament negotiations. ☐

ASBESTOS

Tiny straws in the wind

Recent events in Britain have raised anew questions about the true extent of the asbestos health threat. Allan Piper reports on signs that white asbestos may, after all, be just as dangerous as the blue variety, and that the hazards stretch beyond the risk of asbestosis on the factory floor

THAT asbestos is a threat to health is nothing new—the progressive respiratory disease known as asbestosis led to the first asbestos regulations for industry fully 45 years ago. But the latest controversy in Britain has done more than raise questions about the adequacy of the regulations now covering its industrial use; it has also served to publicise the possibility that asbestos poses a threat to the public at large.

For asbestos does not just cause asbestosis. It is also a carcinogen. Minute asbestos fibres, if inspired, can pierce individual cells to cause both cancer of the lung and mesothelioma, a particularly malignant, inoperable cancer which attacks the lining of the pleural cavity. There is also emerging evidence that fibres can migrate across internal membranes: they have been detected in cancerous liver tissue, and may also be able to infiltrate the gastrointestinal tract.

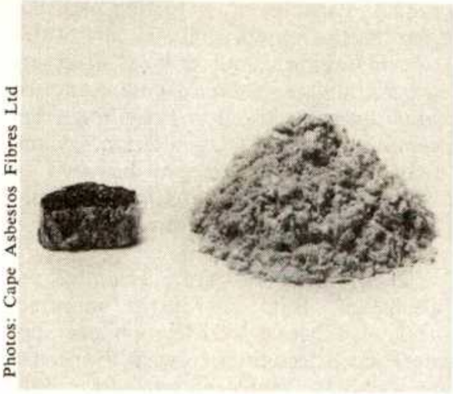
It was only at the end of last month that some of the crucial issues became fully public, when an eight-year-old Department of Health (DHSS) report (together with a revised version) was suddenly made available in the Parliamentary Library following a question in the House of Commons. The report, which was prepared for the DHSS Standing Medical Advisory Committee by a working party it established under the Chairmanship of Sir Richard Doll (then Director of the Medical Research Council's Statistical Unit in London, and now Regius Professor of Medicine at Oxford), clearly states that minimal levels of exposure to asbestos pose a real cancer hazard. According to the report the dangers are not necessarily limited to the naturally fine, blue asbestos, crocidolite, as has hitherto been maintained; they probably extend also to the extensively used white asbestos, chrysotile, which is now milled far more finely than in the past—thus posing a far more widespread threat than previously believed (a possibility which the report clearly acknowledges).

In that light, the official view that the dangers of asbestos have remained confined to industry seems complacent. Even regarding the situation within industry, the suggestion that the cancer threat was removed with the exclusion of crocidolite under the updated Asbestos Regulations of 1969 seems worrying now that the DHSS report has identified chrysotile as a possible hazard. Moreover, the report also called for a review of the issues once the 1969 regulations had been in force for five years. That dateline came up last May, but the review is only now getting under way—and not because of the report itself.

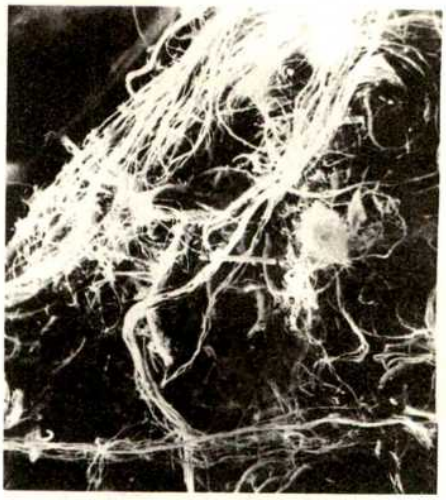
How far the authorities should have moved towards enforcing more stringent regulations remains somewhat arguable, however, if only because the broader scientific community can provide few helpful clues which might finally determine the true extent of the dangers of asbestos. A major difficulty arises because there have been few sufficiently long-term studies. Asbestos fibres can only be detected in diseased tissue using electron microscopy, and the complication means that until now they have been sought only in cases known to be associated with asbestos. Consequently, epidemiological studies—investigations of disease patterns throughout the population—are lacking. In fact, the situation remains so unclear that different interpretations of such data as exist are leading to a rift within the involved scientific community.

Extremes of opinion about the report's claims are easily found. One Medical Research Council (MRC) scientist told *Nature* there was "no evidence at all" of any cancer risk to the general population as suggested in the DHSS report. He was also sceptical of the suggestion that chrysotile may be as dangerous as crocidolite. These rejections came even though a colleague at the same unit has published data showing that of 120 mesothelioma cases in a single study, 23—the largest single statistical unit—were attributable to chance exposure to minimal levels of chrysotile.

On the other hand, a research worker in London fully backed the DHSS report, and even went on to suggest that glass fibres and commercially available talcum powder should also be studied as possible carcinogens. These materials could pose a cancer threat similar to that presented by asbestos since it is the size of the fibres, rather than any chemical agent, which is suspected of inducing cancer. In fact, a recommendation on minimum fibreglass diameters has already gone out to industry from one MRC unit. *Nature* was also told that asbestos fibres in the form of anthophyllite have already been detected in studied samples of talcum powder, but a member of the MRC's Pneumoconiosis Unit at Penarth refutes this, claiming that extensive studies on talcs from all over Europe have failed to reveal a single fibre.



Photos: Cape Asbestos Fibres Ltd



White asbestos or chrysotile (above), and (right) Stereoscan photograph of Chrysotile fibre (magnification ×4500)

The hope is that the ongoing research effort will help resolve the controversy. In Britain work at six MRC units ranges from a major co-operative programme with the Ministry of Defence (into asbestos hazards in naval dockyards), to studies of the aerodynamic properties of fibres. Further MRC laboratory studies of glass fibres are also planned to accompany research already in progress under the sponsorship of the DHSS Health and Safety Executive (HSE), while a major, year-long epidemiological study of all mesothelioma cases should soon be under way at Penarth. In addition, several projects are supported in British universities. On the international front the World Health Organisation's Agency for Research on Cancer announced plans last January for a coordinated epidemiological study on fibre glass workers in Europe; and when its Advisory Committee on Asbestos Cancers meets later this year more research recommendations can be expected.

But while the research efforts continue, the outstanding need for new legislation, and suitable enforcement, remains. The DHSS report underlines the inadequacies of the 1969 regulations, which do not cover the public beyond factory workers and do not recognise the newly defined cancer hazard. Yet no new legislation is planned beyond a marking scheme to cover do-it-yourself asbestos materials. The current review may recommend more, and even the adoption of the recommendations of the DHSS report would represent a considerable move towards eliminating the general dangers. It would mean the eventual disappearance of crocidolite (which still enters Britain inside manufactured goods), the early introduction of suitable asbestos substitutes, tight controls over the sale, use and disposal of asbestos, and possible checks on general emission levels by the Alkali Inspector.

One difficulty is that the official statistics do not reinforce the case for such action. DHSS figures show only 800 recorded cases of asbestosis, while recorded cases of asbestos cancer and mesothelioma are negligible. But whether the numbers mean very much is questionable on several counts. In the first place, past ignorance of the general danger has ensured that many asbestos cases are attributed to something else (or interpreted as secondary cancers). Industrial settlements out of court provide another distortion. And then there is the hidden factor arising because mesothelioma can take up to 50 years to develop, whereas the asbestos dangers have become significant only during the past 30 or so.

The industry disputes these arguments, and points to a national factory survey by the Health and Safety Executive under existing regulations. Critics regard that move scornfully, particularly after the recent Parliamentary Commissioner's report questioning the vigilance of the Factory Inspectorate at Acre Mill in Yorkshire, the site of an asbestosis tragedy. But they are confronted by a powerful and well-organised industrial lobby, and equivocal union attitudes.

Meanwhile, many unacknowledged asbestos victims (or their families) go uncompensated. Questions about the dangers of asbestos, and about how to minimise them, have been asked and almost forgotten before. At least now it looks as though the latest resurgence of concern could be sustained until answers are found. ☐

IN BRIEF

Nuclear trade . . . continued

The trends in international nuclear trade were further emphasised by developments last week. South Africa apparently hopes to place the $1,000 million dollar contract for its proposed twin reactor nuclear power station by the end of the month. A consortium including General Electric of the USA, Brown Boveri of Switzerland and Rijn-Schelde-Verolm of Holland is the leading candidate if credit guarantees can be arranged—a matter now troubling the Dutch coalition government.

Following agreement in principle three months ago in Nice, France and West Germany have now agreed on the practical details under which the French Atomic Energy Commission and the German companies Interatom and Kraftwerk Union will exchange ideas and expertise for a standard marketable design for a fast breeder reactor. Little progress has so far been made on cooperation in the high temperature reactor field, however. Japan–USSR cooperation in the nuclear field, first mooted in discussions last year, has taken a step forward with the news that Japanese nuclear plant manufacturers are to submit estimates for a proposed Soviet project.

Among other developments: Westinghouse has reportedly signed a letter of intent to sell Egypt one of the two nuclear reactors contained in last year's US–Egypt deal; Kuwait is to seek tenders for a 40–60 MW training reactor as part of its programme for twin 1300 MW stations eventually to provide electricity and desalinated water; and Korea has confirmed that it has not so far approached Britain on nuclear cooperation. Meanwhile, 13 members of the 19-nation International Energy Agency have agreed to exchange information to help insure nuclear reactor safety.

Britain's uranium difficulty

The worldwide scramble for scarce uranium supplies has landed the UK Government in the centre of an embarrassing controversy over a 1970 contract to import an annual 1,500 tonnes of uranium from Rio Tinto Zinc's Rossing mine in the politically-sensitive territory of Namibia. Under strong UN pressure to cancel the deal, the Labour Gogernment is also burdened by a promise to withdraw which it made while in opposition during 1973. Namibian uranium is arguably crucial to Britain's nuclear future: projected 1980 requirements for the UK's first and second generation reactors stand at over 2,000 tonnes a year, and on this point the debate concerns whether, in the face of fierce international competition, UK demands can be met as cheaply or reliably by alternative producers.

Canada's energy moves

In a drive towards energy sufficiency by 1985 Canada is to introduce incentives to boost exploitation of gas and oil reserves, change its licensing system and give the state-owned company Petro-Canada preferential powers over other companies.

Organised research

KENNETH MELLANBY

ALEXANDER Solzhenitsyn is generally admired as a writer, and as the winner of a Nobel Prize for Literature. His political views are more controversial. In Western countries some of those who have watched his recent interviews on television say they want action at once, to combat the dangers of Soviet imperialism and communist infiltration; others think his views exaggerated and irrelevant to democratic countries. His novel *The First Circle* deals with the political situation in Russia under Stalin in 1950, but it also contains something which may be relevant to the debate about the organisation of scientific research, a debate which is continuing today in Britain, in many European countries and in North America.

The book describes the Mavrino Special Prison, which is in effect a government research laboratory. Many of the inmates are distinguished scientists and technicians who are alleged to have collaborated with the Germans when prisoners of war. In addition there are "free" workers, mostly in junior positions. The establishment is under the direction of scientists who have not yet incurred the displeasure of the regime, with close supervision from government ministers with more or less scientific experience. The purpose of the research is mostly highly practical, generally aimed at improving the surveillance of those suspected of ideological deviation, though sometimes the research workers may become involved in scientific problems and forget how their results may be applied. It is generally understood that any prisoner whose work is successful will have his sentence remitted; this is intended to ensure his "motivation".

Much of *The First Circle* concerns politics and the problems of insecurity and intrigue in Stalinist Russia, and is thus not, we hope, directly relevant to laboratories in other countries. Yet the organisation of the research has, in some instances, a disquieting resemblance to the system now being developed in Britain and elsewhere—though in most cases the resemblance is that of an obscene caricature. However, such caricatures have sometimes given a foretaste of future developments.

Thus at Mavrino we see bureaucracy encroaching everywhere, and an obsession with paperwork. Instead of getting down to actual research, the organising scientists are concerned with "plans, plans, promises and more plans". The scientists as a whole have little influence on the choice of the subject to be investigated, and are often compelled to devote their efforts to topics they know to be worthless. The research programmes are controlled by rigidly described "projects" with an exact—and often impossible—timetable for their completion. When, as is often inevitable, the required results are not forthcoming, a crash programme (described by one of the participants as "heads down and charge") is mounted. As a result we read of "the rushed, sloppy, careless style of work which was the rule" at Mavrino. The whole system is seen to be remarkably inefficient, unable to produce even short term results.

Notwithstanding (or even because of) Solzhenitsyn's gloomy predictions, we may avoid the political fate he warns us against. But I think we can also learn from his account of Stalinist scientific research. Changes in the organisation of science in Western countries seem to be introducing many of the methods used at Mavrino. Can we be sure, even under a democracy, that they will not reduce even further our scientific originality and productivity?

correspondence

Jukes on food

Sir,—Thomas H. Jukes, writing on nutrition (May 13, page 92), tried to be funny at the expense of accuracy. To give but one example, his response to the recommendation from the Royal College of Physicians' Working Party that less butter should be eaten, is that it is "just as logical" to place a warning on "every nubile woman, for human milk contains fats similar to those in cow's milk and we are told the pre-arteriosclerotic changes can start at a very young age".

Really, Mr Nature, this sort of stuff will not do. Cow's milk is suited to body growth, with three times as much protein and mineral as human milk which, by contrast, is suited to brain, vascular and organ biochemistry. Human milk contains between 4–7 times the amount of essential polyunsaturated fatty acids of 18 carbon chain length, and some 8–12 times the amount of long-chain polyunsaturated fatty acids (C20–C22), which are the principal essential fatty acids found in the brain, artery, endocrine and reproductive systems of the body. Perhaps Thomas Jukes had not noticed that the brains and arteries of the human are somewhat differently developed as compared with those of the cow.

The Zoological Society of London

Government and industry

Sir,—Since you have dealt editorially (April 29) with the difficult question of salary comparisons between industry and the civil service, I would seek space to make only two points in reply to Harold Turner (April 8, page 472).

First, I agree with him that the problems of British industry are not primarily technological, but economic and managerial. My article (February 12, page 436) was intended to be a constructive contribution to solving these more serious problems. Second, the CBI has devoted considerable thought to defining the optimum relationship between government and industry in the field of research and technology, and last October sent a fairly lengthy, and generally well-received, document on the subject to appropriate parts of the government machine.

There is no simple formula, but essentially the CBI sees the need to develop government–industry technological relations through such mechanisms as the Requirements Boards of the Department of Industry, and to establish links between these Boards and the Economic Development Committees which operate under NEDC in order to relate technological to economic factors.

D. W. Budworth
Confederation of British Industry

Isolative sound-change

Sir,—Your correspondents Alan Ross (April 22, page 664) and Ian Hurrell (May 13, page 93) discuss the problem of vowel-shifts with particular reference to the evolution of the English language. We must first of all be certain that a problem exists.

"Anglo-Saxon" is the name given to the miscellany of people who migrated to the British Isles from all of the coastal regions around the North Sea—from what is now Flanders to northern Scandinavia. The languages and dialects of these peoples, which fused to become the dialects of the Anglo-Saxon language, were related but diverse. Both Anglo-Saxon and Middle English were highly heterogeneous languages, even when only the literary forms are considered (compare the language of *Beowulf* with that of the Exeter Book in the Anglo-Saxon, or compare the original language of *The Canterbury Tales* with that of *Piers Ploughman* or of *Sir Gawain and the Green Knight*, all three of which were written in the late fourteenth Century).

As England became united and contact between dialect groups increased, some words from each dialect would survive but most would vanish, a process that has continued to this day. The literary language at any one time was a reflection of the region of medieval England which was dominant at that time. Either of these two factors would give the impression, judging only from the literary forms which have survived, that well defined shifts in pronunciation had taken place, whereas the changes that did occur were due to chance.

In order to show that a problem in "psycho-linguistics" exists and that the explanation is not trivial, one must show that:

- all dialects of the language, not merely the literary form, changed in the same direction at the same time
- all words in any one dialect with a particular vowel sound changed to another sound (for example, ā→ǭ)
- these changes were not related to political changes, especially with respect to the region of origin of the royal household.

Tropical trees

Sir,—May suggested (*Nature*, **257**, 737–8; 1975) that "relatively stable tropical environment(s)" tend to produce plant species of high competitive ability (K-selected) as opposed to opportunists (r-selected species) which he considers are favoured by "relatively vagarious, temperate climates". This generalisation is misleading. It overlooks the class of trees, also well-represented in tropical rain forest, known as pioneers which *are* opportunists. These are the species which colonise gaps. They possess a whole syndrome of features which equip them to this niche in the ecosystem.

In brief, they possess small, easily (wind or animal) dispersed seeds which have dormancy and are produced more or less continuously; are extremely fast growing, unable to regenerate under shade, and have pale wood of low density. Balsa (*Ochroma lagopus*) of Latin America is the classic example. Appreciation of the existence of two classes with strongly contrasting biology is vital to an understanding of both the ecology and silviculture of tropical rain forest. For example, it has been realised for some time that the most valuable African rain forests in which timber species of Meliaceae (African mahoganies) dominate are a late seral stage, not replacing itself but altering to a forest with less valuable and smaller trees of different families; and the *Campnosperma* and *Terminalia* forests which are the main natural resource of the Solomon Islands are stands of near-pioneers.

Pioneer species are the ones foresters nowadays mainly plant. Their biology and timber properties suit modern conditions. The humid tropics are well-suited to rapid timber production and in fact tropical pioneer trees will be one of the world's main timber sources by the turn of the century. It is therefore important to correct any misconception that there are no pioneers in tropical rain forest.

Viral infection mimicking genetic patterns

from Arie J. Zuckerman

THE recognition of hepatitis B surface antigen (originally known as Australia antigen or Au antigen) and its homologous antibody as two specific markers of infection with hepatitis B virus resulted in considerable progress in the understanding of the epidemiological, clinical and immunological behaviour of this infection. A major public health problem that has emerged from the results of numerous surveys is the remarkably high prevalence of persistent carriers of the hepatitis B surface antigen in many areas of the world, resulting in an estimate of over 110 million carriers. For practical purposes, a persistent carrier had been defined as an individual in whom the surface antigen has been detected repeatedly for more than three months. The duration of carriage may be many years (Zuckerman and Taylor, *Nature*, **223**, 81; 1969) but some carriers may lose the antigen after a shorter period of time (Szmuness *et al.*, *Am. J. Epidemiol.*, **98**, 104; 1973).

The reported percentage of carriers varies widely in different geographical areas, from less than 0.1% to as many as 20% of the apparently healthy population. The carrier rate is higher in warm-climate countries than in the temperate zones, higher among males than females, higher among children and adolescents than among adults, and higher among urban than among rural communities. The underlying mechanisms for the establishment of the persistent carrier state have remained largely unknown, although the subject of many investigations. Blumberg and his colleagues (*Proc. natn. Acad. Sci. U.S.A.*, **62**, 1108; 1969) proposed that susceptibility to persistent asymptomatic carriage of hepatitis B surface antigen was based on a simple autosomal recessive gene (Au^1), once infection with hepatitis B virus had occurred. This gene was considered to be common in tropical areas but rare in temperate zones. Individuals homozygous for this gene (Au^1/Au^1) would have persistent antigen without overt manifestation of hepatitis, although they remain as carriers of the associated virus, whereas heterozygotes (Au^1/Au^0) and individuals without the gene (Au^0/Au^0) would not remain as carriers. This hypothesis has evoked considerable controversy (*Nature*, **248**, 377; 1974). Data now obtained by Stevens and Beasley (*Nature*, **260**, 715; 1976) and Mazzur (this issue, page 316) are not compatible with this simple genetic hypothesis. Stevens and Beasley determined the rates of hepatitis B surface antigenaemia among children in Taiwan, which is a high prevalence area, in families with two antigen carrier parents and compared the rate with those with a carrier mother and an antigen-negative, antibody-positive father. The results suggest that all the children could become antigen carriers, regardless of the genetic background. Furthermore, acquisition of the carrier state was probably influenced by the dose of virus received by the babies (Stevens *et al.*, *New Engl. J. Med.*, **292**, 771; 1975) and the age of infection (Szmuness and Prince, *Am. J. Epidemiol.*, **94**, 585; 1971). From Mazzur's data on the children of matings between two carriers or between one carrier and one non-carrier the genetic hypothesis can also be rejected. In this study there were, for example, three families in which both parents were antigen carriers, yet only 2 of the 13 children in this group were carriers. Three of the children had antibody and therefore they had been infected with hepatitis B virus but they did not become carriers, which is clearly incompatible with the genetic theory. The remaining eight children had no serological evidence of infection. All four children in another family were carriers, although the antigen was not detected in either of the parents. The probability of this occurrence according to the simple genetic hypothesis was calculated as 1 in 256.

More complex genetic explanations have also been proposed, including a link between heterozygosity for Gm antigens and increased susceptibility to persistent antigen carriage. Homozygosity for Gm antigens on the other hand leads to an increased probability of developing surface antibody when infected with hepatitis B virus (Blumberg *et al.*, *Nature*, **236**, 28; 1972). This aspect was not supported by the investigation of Schanfield *et al.* (*Nature new Biol.*, **243**, 81; 1973) in normal blood donors. In a subsequent multicentre study, Schanfield and associates (*Int. Symp. Viral Hepatitis. Devl biol. Standard*, **30**, 257–269, S. Karger, Basel, 1975) found no association between the Gm phenotype and susceptibility to hepatitis B virus, using the surface antigen or the ability to make antibody to it as a marker. It was concluded that variation in the distribution of Gm haplotypes did not seem to be a feasible explanation for variation in surface antigen and surface antibody frequencies in a series of multiply transfused populations in the United Kingdom, Cyprus, Greece and Sardinia.

Another possible genetic association has been described more recently, however. Boettcher and colleagues (*J. Immunogenet.*, **2**, 151; 1975) established an association between an HLA antigen and the presence of hepatitis B surface antigen in a group of Australian aborigines. There was a statistically significant deficiency of W 15 among carriers of the antigen and this was explained in terms of linkage disequilibrium between W 15 and an immune response gene involved in clearing the surface antigen from the body. Although it was pointed out that the hypothesis that becoming a carrier is largely genetically determined is an oversimplification, it was accepted that the potential for becoming a carrier is a recessive condition controlled by a single autosomal gene. It was proposed that if the antigen W 15 is a (hepatitis B) virus receptor on cells, and it is disadvantageous to have viruses located on these receptors on certain cells, it would be of selective advantage also to possess the immune response gene responsible for clearing viruses from the receptors. In these circumstances, association of W 15 and the hepatitis B surface antigen immune response gene would be of selective advantage. Indeed, the major complex of histocompatibility antigens has been shown to be closely associated in animals and in man with the immune response genes. This could explain the association of immunological diseases with HLA antigens, for example on the basis of a possible receptor role of HLA antigens or the "molecular mimicry" between viruses and HLA antigens. Vladutiu (*Lancet*, **ii**, 288; 1974) pointed out, however, that lymphocyte-defined determinants have been shown to exhibit a stronger association with diseases than serologically-defined determinants. He also noted that the enthusiasm generated by the idea of association of HLA antigens with various diseases is not unanimous, and although there is a strong association with a few diseases, the underlying mechanism remains unknown. Vladutiu stressed that there are many pitfalls when searching for such associations and that the principal source of errors is the statistical analysis. Another example cited is the association of many diseases with HLA 1 and HLA 8. Although these antigens are absent in Japanese, diseases known to be associated with them are seen among the Japanese population. It is apparent, therefore, that further studies and experimental models are necessary.

Finally, it is widely recognised that family clustering may be entirely a function of an increased risk of exposure to an infecting virus rather than genetically determined susceptibility; particularly if a parent is excreting the virus and more so if the mother is the transmitter. Mazzur notes that persistent infection with hepatitis B virus may be representative of other infections which may also mimic genetic patterns. Indeed she suggests that perhaps polygenic birth defects and other diseases, which the currently accepted as genetically determined because of family clustering may also be caused by perhaps as yet unrecognised infectious agents. This suggestion merits considerable further investigation and careful evaluation of the results. □

Theileria in the laboratory

from F. E. G. Cox

THE increasing problem of protein shortage in Africa has once again concentrated attention on the parasitic diseases of cattle and although recent attempts at vaccinating animals against these diseases give grounds for optimism (*Nature*, **260**, 380; 1976) much basic research still remains to be done. East Coast Fever, caused by a protozoan *Theileria parva* and transmitted by a tick *Rhipicephalus appendiculatus*, still kills up to 40% of calves over a wide area of Central and East Africa. The parasite develops through two cycles of multiplication in lymphocytes before entering red blood cells and becoming infective to the tick. Only cattle, buffalo and Indian water buffalo can support the infection through to its final infective stages and research has been limited by the non-availability of a suitable laboratory host. In 1970 some progress in the maintenance of *T. parva in vitro* was made (Malmquist, Nyindo and Brown, *Trop. Anim. Hlth Prod.*, **2**, 139; 1970) when it was shown that the early stages of the parasite in lymphocytes could be grown in a bovine cell line but the infection did not proceed through to the blood forms. More recently the use of interspecific heterokaryons formed by the virus-induced fusion of cells has found favour (Irvin *et al.*, *Int. J. Parasitol.*, **4**, 519; 1974) but still no invasion of blood cells has been recorded.

In this issue of *Nature* (page 311) Danskin and Wilde describe how they have been able to grow all stages of *T. parva* up to the blood forms in culture. Their technique is simple; they use the modified Eagle's medium described by Malmquist *et al.* with 20–30% foetal calf serum (instead of 10%) and in addition 5–10% bovine lymph. The usual macroschizonts and microschizonts developed and bovine blood cells added after 18–66 h became infected but not those added after 90 h. The number of cells infected, 0.1%, was low but cattle are infective to ticks at this level of parasitaemia.

The next stage will be to infect ticks from cultures and considerable progress has been made on an understanding of the feeding biology of *R. appendiculatus* by Tukahirwa (*Parasitology*, **72**, 65; 1976). The larvae and nymphs require 8–9 d after hatching or moulting before they can feed and this they do for 4–6 d. The adults cannot feed for 6–9 d after moulting but eventually feed for 7–9 d. On *Theileria lawrenci* (a parasite closely related to *T. parva*, so realistic comparisons are possible) adult *R. appendiculatus* infected as nymphs become infective to cattle 3 d after beginning to feed and remain so for the next 6 d (Young *et al.*, *Parasitology*, **71**, 27; 1975). These authors were able to correlate infectivity with morphological criteria of parasite maturity in the ticks' salivary glands so it should be possible to infect nymphs from cultures, allow the nymphs to moult, let them feed on rabbits and collect infective stages to initiate further cultures after 3–4 d using the morphology of the parasites as a guide to infectivity. Experimental cattle should no longer be needed and basic research will not necessarily have to be done in Africa. This should please the growing number of scientists who are concerned about excessive animal experimentation.

Diseases caused by *Theileria* are not confined to Africa and in India considerable progress is being made in the understanding of the biology of *T. annulata*. Bhattacharyulu, Chaudri and Gill (*Parasitology*, **71**, 1; 1975) have confirmed that *Hyalomma anatolicum* and other ticks transmit this disease, that the infection passes from larvae to nymphs and nymphs to adults and that the infection is transmitted during the first 24 h after feeding. Of considerable interest is the finding that if infected larvae are fed on cattle as nymphs the adults are not infective whereas if the nymphs are fed on rabbits which are not susceptible to infection with *T. annulata* the adults are infective. It seems as if the infective stages are "used up" during feeding on an appropriate host. This may call for some reappraisal of the experimental procedure of using "susceptible" and "non-susceptible" hosts almost randomly in various fields of research into piroplasmosis. The use of cultured parasites would avoid this problem. □

Of gods and men

from David W. Hughes

STARS were first named by the herdsmen, hunters, sailors and travellers who lived along the banks of the Euphrates and Ganges, and it was these people and not the learned and scientific who were the sideronomists. The star names used today have been gradually accumulated over the last three thousand years or so. They have come in the main from Greece, Rome and the nomadic and scholarly tribes of Arabia. Castor and Pollux (α and β Geminorum)—the heavenly twins; Regulus (α Leonis)—the ruler of the affairs of the heavens; Betelgeuze (β Orionis) from *ibt al jauzah*, the armpit of the central one, Algol (β Persei) from the Arabian's *Ra's al Ghul*, the Demons head, are a few examples.

Today naming stars has gone out of fashion and astronomers make do with rather dry titles such as V1057 and L789-6. However naming say, Jovian satellites and the features of planetary surfaces that have recently been revealed by imaging devices on space craft is very much in the news and a subject of some controversy.

Carl Sagan (Laboratory for Planetary Studies, Cornell University) discusses this problem in his recent paper in *Icarus* (**27**, 575; 1976). In 1967, confronted with enormous amounts of new data relating to the near and far side of the Moon, Commission 17 of the International Astronomical Union set up a subcommittee on lunar nomenclature. They decided to extend the previous system of nomenclature to the reverse side of the Moon and to name craters after deceased scientists, special attention (and presumably preference) being given to astronomers. It was also proposed (*Trans. IAU*, **XIIIB,** 103; 1967) that the nomenclature should be widened to include people associated with the present space effort and particularly cosmonauts and astronauts and others who have lost their lives in space vehicles. It was also thought that named craters should be at least 18 km in diameter. Conservatism and caution were stressed, the committee members pointing out that the names would be permanent, so only names of permanent renown should be used, revision and reassignment being thought undignified. Features below the minimum size were to be designated accordingly to the Mädler system, capital Roman letters being used for craters, valleys and other depressions, lower case Greek letters being used for hills, mountains and other eminences. In 1973 (*Trans. IAU*, **XVA,** 205; 1973) the working group went so far as to suggest that small features with diameters less than 100 m should have "given names" such as John, Mary and Nikolai, followed by the name of the nearby major feature. Scientists whose names were similar in sound to others and so omitted earlier were now to be given craters. So Born who had not been included because of his similarity to Bohr, Rutherford—Rutherfurd, Lawrence—Lorentz, were now in luck. In 1973 the qualification for a place in the nomenclature was also broadened but still the working group emphasised that they would "exclude all political figures, national heroes, religious figures, and modern philosophers. Ancient philosophers and various legendary figures will be accepted, however". The people responsible for Martian nomenclature (*Icarus*, **26,** 85; 1975) broadened their outlook still further bringing in biologists, geologists, atmospheric physicists and even science fiction writers concerned with the lore of Mars. The major sinuous channels were named after the name of Mars in a variety of other, largely non-IndoEuropean, languages.

Sagan advocates that the craters of Mercury should be named after great poets, authors, composers and other scholarly or artistic figures who were not physical scientists. He puts forward a large list of candidates containing such worthies as Dostoyevsky, Bertrand Russell, Picasso, Tschaikowsky and Hiram Bingham. The end result of the nomenclature should be a non-provincial distribution of nationalities, epochs and occupations; to quote Sagan "a distribution that our great-grandchildren can be proud of. It is just conceivable that some of them will be living in the places under discussion".

In the more specific cases of the satellites of Jupiter the IAU Working Group for planetary nomenclature have proposed a set of names for satellites V to XIII (*IAU Circular*, No. 2846; 1975). The Galilean Satellites are named after lovers or consorts of Zeus, the father of the gods in Greek mythology. The nomenclature group have tried to continue this tradition, naming the remaining satellites after friends of Zeus (all human, with the exception of Amalthea who was the goat which suckled the infant god). Sagan points out that the names proposed for VI, Himalia, and XII, Ananke don't fit the scheme, Ananke's being the mother of the Fates placed in judgment over the Olympian gods and not a friend of Zeus at all. Also Elara (VII), Lysithea (X), and Carme (XI) are thought, by Sagan, to be a touch obscure. He also finds it surprising that the most prominent remaining consorts seem to have been omitted and suggests that Maia, Leto, Semele, Demeter, Alcmene, Hera, Latona, Aegina, Pasiphae, Themis, Metis and Eurynome should be afforded due consideration.

The best chance for a place in the nomenclature for mere mortals, however, still remains the discovery of a comet or asteroid. □

Plant pathology changing direction?

from M. S. Wolfe and J. A. Barrett

A conference on the Genetic Basis of Epidemics in Agriculture was held in New York on April 5–8, 1976 under the auspices of the New York Academy of Sciences.

In 1970, disaster struck the American corn crop in the form of southern corn leaf blight, a fungal disease which reduced the total yield by 15% and thus rocked the world grain markets. In the same year, and for similar reasons, another cereal pathogen caused much greater suffering, but was less publicised: downy mildew of pearl millet in India reduced the yield of the "poor man's crop" by 30% and directly caused hunger and starvation. The similarity between the two disasters was the development of advanced forms of hybrid varieties which, in each crop, were dependent on a single type of male sterile cytoplasm and this provided the perfect uniform environment for the explosive development of the two pathogens.

One result of the corn epidemic was the instigation of an American survey of crop uniformity around the world, to determine the extent to which modern methods of agricultural production might be increasing the vulnerability of food production to pest and pathogen epidemics. Superficially at least, the result was alarming in that not only do the world's major crops comprise very few species, but that within each of these species production is dominated by very few varieties, which may often be related to each other.

The meeting was held to assess more critically the risk to world food supplies through the relationship between crop uniformity and disease and pest vulnerability, and the kinds of solutions which could be readily utilised. The general consensus was that since 1970, crop uniformity had, if anything, increased. In the developed countries, this was largely the result of demands by producer, processor and consumer for uniform products. In the developing countries, the main influence was the widespread introduction of breeding material from centralised sources which, at least in the recent past, has had a limited genetic base, and which squeezes indigenous material out of production, thus reducing available genetic resources.

In a comprehensive survey of the evolution of disease problems in tropical crops, I. Buddenhagen (International Institute for Tropical Agriculture, Ibadan) pointed out that increases in crop uniformity did not necessarily lead to problems, and that control in some cases could be effected by straightforward programmes of breeding for resistance. For example, downy mildew of sugar cane in Australia had been eliminated in this way, and in a similar way in Britain, it seems unlikely that eyespot disease of cereals will ever be a very serious threat because of the background of resistance built into cereal varieties grown in the United Kingdom.

For many diseases, however, notably those caused by the leaf pathogens of cereals, increased uniformity of crop production does place us on a knife edge with regard to disease and pest vulnerability. The problem was graphically illustrated by K. M. Safeeulla (University of Mysore) in relation to past and potential problems with the cereal varieties of the Green Revolution introduced into India. The core of the meeting was concerned with this problem and quickly revealed the wisdom and foresight of the organisers, P. R. Day, J. G. Horsfall and Otto Frankel, in bringing together those who are showing increasing interest in the genetics, epidemiology and mathematical interpretation of the dynamics of the host-parasite interaction as it occurs in the field. As with the early fusion of any range of scientific disciplines, opinions were many and varied, but two general trends could be discerned. First it was likely that there was no universal answer for dealing with all host–parasite problems: different strategies would be optimal for different situations depending on the balance between the level of disease risk and the price that plant breeders and growers are willing to pay to contain that risk. For example, the complete turn-away from crop uniformity by employing mixed varieties or multilines, which are heterogeneous for disease resistance and other characters, may be of advantage only where there is severe and continuous disease present. Second, there was a general, but not unanimous, movement towards the conclusion that no form of host resistance or its manifestation could produce an endlessly stable situation. The aim should be to slow down the rate of pathogen or pest response to the control measures so that it becomes virtually imperceptible, whilst maintaining constant vigilance.

The consideration that the host–parasite interaction could be stabilised, by the exploitation of so-called "horizontal resistance", was argued by R. Robinson (FAO, Rome). "Horizontal resistance" is defined as resistance in the host to all genotypes of the pathogen and Robinson suggested that techniques currently being used in an FAO programme under his direction could accumulate such resistance and thus provide permanent protection. Although some of the techniques have considerable practical value, we remained unconvinced by the theory, particularly since the weight of emerging experimental evidence moves us inexorably towards the view that specific qualitative or quantitative variation exists to corespond with all of the host resistances which have been thoroughly investigated. It does not necessarily follow that all of this variation will be of practical significance.

For all the tension which the pathologists and breeders feel with regard to the vulnerability of major crops to diseases and pests, and for all the differences of opinion experienced over the means of relieving that tension, there emerged from the meeting an underlying feeling of excitement and optimism. Plant pathologists have for too long been following behind the disasters, explaining why the patient suddenly became ill, or patching him up with pesticides. In recent years however, attention has been increasingly focused on positive strategies of confronting pathogens and pests with increasingly complex problems, based on sound genetical and epidemiological principles. The organisers of the meeting should feel well satisfied in providing an important signpost in this essential direction. □

Plant production in Pakistan

from D. Boulter and A. Muhammed

A Symposium on Genetic Control of Diversity in Plants was held in Lahore from March 1–6, 1976, organised by Dr Amir Muhammed, Vice-Chancellor, University of Agriculture, Lyallpur, and Dr A. Hollaender of the Associated Universities Inc., Washington, DC and sponsored chiefly by the US National Science Foundation.

THE initial promise of the introduction of new dwarf varieties of cereals and the impact of the Green Revolution have not been sustained in Pakistan; agricultural productivity remains disappointingly low. The Government of Pakistan recognises the first importance of agricultural improvement and has provided funds for buildings and facilities. The Punjab Finance Minister, Dr Abdul Khaliq, pointed out that Pakistan is "doomed", as he put it, to be an agricultural country; the only way out is by recognising the value of research which can bring about the revolutionary changes necessary to improve the general prosperity of the country. Thus, although primarily an agricultural country, only 35% of the gross national product derives from agriculture. Time is of the essence since every 5 minutes an acre of agricultural land is lost because of increased salinity. One major constraint on the improvement of agricultural productivity, is that Pakistani scientists lack channels of communication. Their work is often not recognised among their colleagues, and generally stimulation is lacking. So the Symposium was particularly welcome.

It was organised to provide a forum on the latest developments in the field of crop improvement, both fundamental and applied, including those relevant to the adverse conditions of high salinity and aridity.

O. H. Frankel (CSIRO, Canberra) warned of the drastic reduction in the diversity of crop plants brought about by widespread use of new varieties;

Pakistan with its gene centre of primitive wheats and fruits was an important case in point. The exploration and collection of genetic materials for future breeding programmes and the long-term conservation of seeds, are urgently required. S. A. Qureshi (Punjab Agricultural Research Institute, Lyallpur) made a strong case for the use of varieties developed from local programmes instead of selections from exotic materials, since the latter required inputs, particularly fertilisers, which were not being used effectively probably due to inadequate price incentives.

R. D. Brock (CSIRO, Canberra) stressed the important role of mutation breeding which is much underestimated at present; the best immediate prospects for increasing its specificity lie in the manipulation of the selection environment.

The development of high yielding, disease-resistant varieties of chick pea (*Cicer arietinum*) is an urgent need, since the supply of adequate protein still remains a problem in Pakistani diets especially for the young (A. Muhammed, University of Agriculture, Lyallpur). A. G. Kauser (University of Agriculture, Lyallpur) reported the successful development of reasonably high-yielding varieties with moderate resistance to wilt disease and high resistance to blight. C. M. Akhtar (Punjab Agricultural Research Institute, Lyallpur) reported varietal resistance to the major diseases of wheat, rice, sugarcane and cotton. Genetic resistance has not been observed against root rot of cotton, but biological control of this disease, by adding the antagonistic microorganism *Trichoderma viride*, along with organic substrate, has proved satisfactory but will need further field trials.

Soil salinity is the main problem in Pakistan especially where canal irrigation is practised, and at the moment the battle is being lost. Selection within hybrid rice populations for salt-tolerance appears feasible (M. Akbar, Nuclear Institute for Agriculture and Biology, Lyallpur) since crosses between salt-resistant varieties are more salt resistant than either of their parents and desirable progenies have been selected from F_4 populations. L. Bernstein (International Service Corps, New York) presented evidence that nutritional imbalance due to excess salt can often be corrected by foliar sprays of nutrients.

B. O. Eggum (Institute of Animal Science, Copenhagen) showed that up to 80% of the lysine in the wheat of some chappatis is made unavailable by cooking and that tannins, important constituents of tea, decrease the biological value of proteins. D. Boulter (University of Durham, UK) pointed out the great potential for improvement in the yield of legumes; the alternative strategy of increasing the protein content of cereals would be a difficult task due to the yield/protein content "trade-off". That higher protein content can be achieved without serious yield penalty, however, was illustrated by the results of V. A. Johnson (USDA, Nebraska) and his colleagues, who have recently released a new productive high protein hard winter wheat variety derived from Atlas 66, with genetic potential for 2 percentage points higher grain protein content.

J. Dobereiner (Universidade Federal Rural do Rio de Janeiro) outlined the potential for nitrogen fixation of a number of tropical forage grasses and sorghum, maize and wheat; she reported that the *Spirillum* bacterium responsible is found inside the roots. Exploitation of this potential requires considerable work to identify the limiting environmental factors and develop agronomically feasible practices to overcome them. The difference between cultivars and even ecotypes of some species has been demonstrated and preference should be given to plant breeding; for example, among S_1 lines of maize, several could be selected with nitrogenase activity many times higher than that of the original cultivars.

J. K. Setlow (Brookhaven National Laboratory, USA) looking to the future, thought that genetic transformation with purified DNA would be of limited value in agriculture, but that the use of restriction enzymes had great potential, in generating sites for the insertion of specific genetic material. □

Thermodynamics in biological systems

from a Correspondent

An EMBO-sponsored Workshop on Thermodynamics in Biological Systems was held at the Villa Durazzo at Santa Margherita Ligure under the auspices of the University of Genoa on April 5–9, 1976.

The contributions of thermodynamics in general, and calorimetry in particular, to the study of biochemical and biological processes formed the subject of the workshop.

S. N. Timasheff (Brandeis University) presented a thermodynamic analysis of the aggregation of tubulin which, in the presence of Mg^{2+} at low temperatures, yields cyclic polymers (molecular weight 3×10^6) composed of 26 subunits. Above 37 °C the aggregation to microtubules (molecular weight $\sim 10^8$) is favoured, particularly in the presence of glycerol or sucrose. The thermodynamic and sedimentation data were confirmed by electron micrographs showing the different types of aggregates. A similar treatment, applied to the aggregation of sickle cell haemoglobin, was discussed by P. Ross (National Institutes of Health, Washington), on the basis of the polymerisation of critical nuclei, consisting of about 40 molecules, to helical structures.

With the aid of selective chemical modification of Trp 62 or Glu 36, J. Rupley (University of Arizona) demonstrated the involvement of these residues in the self-association of lysozyme. In the case of insulin, the three dimer-hexamer association characteristic of the crystal state is inconsistent with calorimetric, scattering and sedimentation studies in solution.

The thermodynamics of small molecule binding to biopolymers provided considerable interest. Thus H. J. Hinz (University of Regensburg) showed that whereas isoleucine tRNA synthetase showed a high affinity for isoleucine, compared with leucine or valine, yet ΔH and ΔCp for the binding of all three amino acids are identical, suggesting COO^- and NH_3^+ groups as the interaction sites. M. N. Jones (University of Manchester) reported on the binding of sodium dodecyl sulphate to β-lactoglobulin which indicated two specific, high affinity sites ($\Delta H = -9.5$ kJ mol^{-1}) and 22 non-specific sites ($\Delta H = -3.5$ kJ mol^{-1}). In this context, but on a much more complex level, A. Beezer (Chelsea College) described applications of microcalorimetry to characterise interactions of micro-organisms with drugs. Interpretation of such experiments are frequently complicated by specific interactions with certain buffer ions.

High precision heat capacity measurements on biopolymers over wide temperature ranges (5–500 K) continue to improve our understanding of the unfolding mechanisms. P. L. Privalov (Institute of Protein Research, Moscow) reported on methods of resolving $Cp(T)$ curves from various types of tRNA into several Gaussians which are found to correspond well with those derived from NMR measurements. The existence of "stable" intermediate states is therefore a possibility and the minimum domain size is estimated as about 100 residues. Comprehensive thermodynamic state diagrams, that is, free energies, enthalpies and entropies as functions of pH and temperature for both native and unfolded states, were presented by W. Pfeil (Zentralinstitut für Molekularbiologie, Berlin) for myoglobin, cytochrome *c*, haemoglobin, chymotrypsin and lysozyme. Such diagrams can now provide a thermodynamic base of reference for "unfolded" proteins. J. Brandts (University of Massachusetts) discussed the unfolding of ribonuclease in terms of the possible intermediate states which are clearly indicated by kinetic measurements, although the thermodynamics are compatible with a two-state model, implying that all steps bar one are associated with zero enthalpy changes. This condition is met by the *cis-trans* isomerisation of proline which may therefore account for the rate-determining step, whereas conformational changes are associated with relaxation times of 1–100 ms. The folding/unfolding equilibria of all small proteins appear to be consistent with a rate-determining step corresponding to a *cis-trans* isomerisation.

A description of the dynamic nature of folded proteins presents many topical problems and both R. Lumry and A. Rosenberg (University of Minnesota) stressed the importance of high frequency ($10^8\ \mathrm{s}^{-1}$) conformational fluctuations to the catalytic functions of proteins. The existence of free volume fluctuations is consistent with the high diffusion rates of large molecules (such as acrylonitrile) in folded proteins and with the marked pressure dependence of proton exchange rates which are not observed with homopolypeptides or oxidised ribonuclease.

A thermodynamic characterisation of biochemical processes by itself is not always as interesting as an insight into molecular mechanisms, and this implicitly takes us into the realm of statistical thermodynamics. F. Franks (Unilever Research, Sharnbrook) discussed the combination of thermodynamic data and computational methods aimed at the derivation of a potential function for the hydrophobic interaction. This in turn allows the calculation of the radial distribution function and hence the thermodynamic properties associated with the interaction of apolar particles in water. In a complementary paper, E. Clementi (Istituto Donegani, Novara) outlined a combination of *ab initio* and computer simulation approaches to the study of amino acid hydration. □

Exploding black holes

from P. C. W. Davies

A symposium organised by R. Penrose and D. Sciama was held in Oxford on April 20 and 21, 1976.

BLACK holes are either a French, German or American idea, according to opinion. But if they explode, they are British. At an historic Oxford symposium early in 1974, Stephen Hawking of the University of Cambridge, revealed an astonishing theoretical discovery—black holes are not black after all, but radiate with a characteristic blackbody (thermal equilibrium) spectrum, at a temperature which increases as the mass dwindles, ensuring the eventual demise of these objects in a sudden explosion.

Since then, the analysis of what is now referred to as the Hawking process has become a veritable industry in South East England, with no less than three major relativity groups (Cambridge, London and Oxford) actively studying the details and implications of the new discovery. Hawking's prediction itself was the result of applying quantum theory to black holes. The remarkable conclusion is that the violent distortion of space-time in their vicinity leads to the production of radiation with a definite temperature. The significance of this lies not so much in observation (the temperature of a solar mass black hole is a mere 10^{-6} K) but in establishing important theoretical connections hitherto barely suspected.

It had previously been noted by some relativists that black hole processes bear a superficial resemblance to thermodynamics. As long as the treatment remained classical the resemblance was only an analogy. The key step, which Hawking took, was to apply quantum mechanics. The result has been to provide an amazing underlying connection between quantum theory, general relativity and thermodynamics.

As experts in any of these three disciplines tend to be lamentably ignorant of the other two, it was particularly appropriate that this year's Oxford symposium entailed a programme of lectures and reviews by practitioners of each subject. The conference provided an opportunity for an unusual interplay of ideas, with the Hawking process as a central theme.

Hawking himself delivered some provocative and fascinating extensions of his original idea, by dealing with the conceptual and philosophical aspects of particle production effects. He and G. Gibbons (University of Cambridge) presented arguments in support of the proposal that event horizons cause radiation production under quite general circumstances. In particular, the claim that particle detectors in de Sitter space would also detect radiation seems to be a direct challenge to the conventional understanding of some fundamental aspects of relativity and quantum theory. This challenge was taken up by some of the other participants in fruitful but inconclusive exchanges. Controversy centred around Hawking's claim that much of physics is observer-dependent. Two observers in different states of motion might encounter two entirely dissimilar histories of the Universe, he alleges. In particular, the traditional theoretical procedure of attempting to construct a covariant energy-momentum tensor which is independent of observer is misguided. Ironically, this procedure is precisely what several research groups have been trying to do, with a view to studying how quantum effects react back on the geometry of space-time. According to Hawking, the traditional energy-momentum tensor calculations are wrong. Indeed, they contain so-called vacuum polarisation terms, which he said he did not believe in.

It will take some time for the full implications of these intriguing new ideas to sink in. The more traditional approach was defended by Bryce DeWitt (at present at the University of Oxford). He described some of the conventional energy-momentum tensor calculations, and also presented an interesting model of a particle detector which appeared to conflict with Hawking's radical departure.

Much of the remainder of the conference was devoted to exposition about some of the peripheral aspects of the Hawking process. Some of the review talks were interesting and entertaining in their own right, particularly that of Donald Lyden-Bell (University of Cambridge) who presented a brilliant review of the thermodynamics of classical self-gravitating systems. Other speakers, such as Jergen Ehlers (Munich) who spoke about relativistic kinetic theory and statistical mechanics, and Bernard Schutz (Cardiff), who dealt with stability in relativity, clearly touched on subject matter which will eventually be relevant to the hoped-for unification of quantum field theory, thermodynamics and gravitation. But at this stage only a jumble of half-connected ideas has emerged. Other speakers were John Steward (Cambridge), Robert Thouless (Birmingham) and Oliver Penrose (Open University).

The cross-fertilisation between these subject areas is clearly of great importance in stimulating further research in this new subject. The conference organisers, Roger Penrose and Dennis Sciama, both gave thought-provoking general assessments, tying the strands of the separate topics together. It is hard to resist their own impression that much more lies beneath the surface; many disconnected ideas seem to be associated in some, as yet vague, but intriguing fashion. In this fast-moving field of research, it is probable that another Oxford symposium in the near future will provide still more fundamentally new results, which could well have implications far beyond the specialist topic of black holes. □

The Zoo: 150 years of research

L. Harrison Matthews*

In the 150 years since its inception, the Zoological Society has developed from a collection of curiosities on which only observational research was carried out, to one of the world's most comprehensive collections of animal species, with two attached experimental research institutes. Dr Harrison Matthews traces the evolution of the Zoo from the time when the idea first occurred to Sir Stamford Raffles on a visit to the Jardin des Plantes in Paris.

IN the first quarter of the nineteenth century, towards the end of which the Zoological Society of London was founded, the science of zoology was emerging from the collecting of objects of natural history for the cabinets of the curious to become a discipline as scientific as botany and deserving the attention of people more serious than dilettanti. The works of Cuvier on the relationships of animals stimulated interest in the study of morphology among many naturalists who followed his researches on comparative anatomy and palaeontology. They broke away from the linear concept of classification built on the foundations laid by Linnaeus, who was the first to lecture in a university on zoology and botany as subjects in their own right instead of as adjuncts to medical knowledge. The immense numbers of hitherto unknown animals brought to the notice of European naturalists by the exploration and settlement of distant parts of the world gave descriptive zoology work enough to occupy many in describing and classifying the novelties.

Sir Stamford Raffles, who spent most of his short life in the service of the East India Company, and who was Lieutenant Governor first of Java and later of Sumatra, and was the founder of Singapore, gained a vast knowledge of the plants and animals of the Far East, in particular the natural history of Java, Sumatra and the Malay Archipelago. In 1817, after leaving Java and before going to Sumatra, he was in Europe, and visited Paris where he was greatly impressed by the Jardin des Plantes. Later in the year he returned to England, where he was knighted and published his *History of Java;* but more important for the present subject he discussed with Sir Joseph Banks, then President of the Royal Society, a proposal inspired by what he had seen in Paris for the foundation of a zoological society in England, to be run on similar lines to the Jardin des Plantes.

Although Banks died in 1820 the proposal was kept alive by correspondence with Sir Humphry Davy and others after Raffles went to Sumatra in 1817, so that on his final return to England in 1824 he became chairman of a committee to consider the formation of the society. The committee's prospectus gave the objects of the society as "the introduction of new varieties, breeds, and races of animals for the purpose of domestication or for stocking our farm-yards, woods, pleasure-grounds, and wastes with the establishment of a general Zoological Collection, consisting of prepared specimens in the different classes and orders, so as to . . . point out the analogies between the animals already domesticated, and those which are similar in character upon

Zoological Society

which the first experiments may be made."

After long negotiations and the granting by the government of a site in Regent's Park the Zoological Society was founded in 1826 for the advancement of zoological knowledge and "the formation of a Collection of living Animals; a Museum of preserved Animals; and a Library connected with the Subject", with Raffles as president. Two months later Raffles died suddenly, and in the following year his widow gave the Society's museum his fine collection made in Sumatra; some of it went to the British Museum when the Society dispersed its museum in 1855. In 1829 the Society was incorporated by Royal Charter as "The Zoological Society of London" for the advancement of zoology and animal physiology, and the introduction of new and curious subjects of the animal kingdom—'animal physiology' had not then acquired its present meaning, but covered the feeding, breeding, and acclimatisation of animals. Raffles acknowledged that he himself was more interested in the scientific side whereas Sir Humphry Davy looked more "to the practical and immediate utility to the country gentlemen".

Raffles and Davy enlisted the help of the Aristocracy and Church in founding the Society so that the list of the first committee was full of "top brass" with a tail chiefly of amateur zoologists: in 1929 Chalmers Mitchell, then secretary, wrote that "from the beginning, the Society depended very slightly on the support of professional zoologists, and largely on persons of public importance—a tradition that it has always maintained." The Society's gardens were opened early in 1828, and the normal course of mortality soon began to supply specimens for examination and dissection by the anatomists, or for preservation in the Museum. The type specimens of newly described creatures were stuffed when they died and displayed in the cases; they were given to the British Museum when the collection was discarded but the rest of the contents was sold, some to the British Museum and some to various provincial museums.

Although a lecture was delivered to a general meeting of the Society in 1827 by Joshua Brookes, the proprietor of a private anatomy school, on the dissection of the body of an ostrich which had been given to the Society by George IV after it died at Windsor, scientific meetings did not start until 1830. At the first meeting for scientific business held in the autumn of that year the secretary, N. A. Vigors, an enthusiastic ornithologist, read a paper on the crested quails of America describing and naming two hitherto unknown species. He was followed by Richard Owen who read a paper on the anatomy of an orang-utan that had died shortly after reaching the Society's collection and had been sent to him for dissection. These communications set the pattern followed by scientific meetings for nearly a century, concentrating for the greater part on systematics, faunas, the description of new species, and on morphology and anatomy.

In the 1830s a visiting veterinary surgeon treated sick animals and made occasional post-mortem examinations to find the cause of death in some of the animals that died, but the bodies of dead animals were generally given to such anatomists as were interested, for dissection and study in their own laboratories. It was not until 1865 that Professor T. H. Huxley spurred the Society into providing a dead-house and dissecting room, and to appointing a "prosector" in charge of them. This title was a misnomer, because a prosector is an assistant who prepares demonstration dissections for the lectures of a professor; the name was, however, retained for many years. The duties of the post combined those of pathologist and research anatomist, and the distribution of material to museums and academic workers who had asked for it to be supplied when available. For some sixty years the successive holders of the post gave greater attention to pathology or anatomy as they preferred—a large number of anatomical memoirs was produced by the earlier prosectors. In 1903 a pathologist as well as a prosector was appointed and, after a number of short term or part time workers had held the post, the Society in 1924 joined with the London School of Tropical Medicine and Hygiene, whose new buildings were not yet ready for occupation, in financing a Research Fellowship in Comparative Pathology, to the great advantage of the

Zoological Society

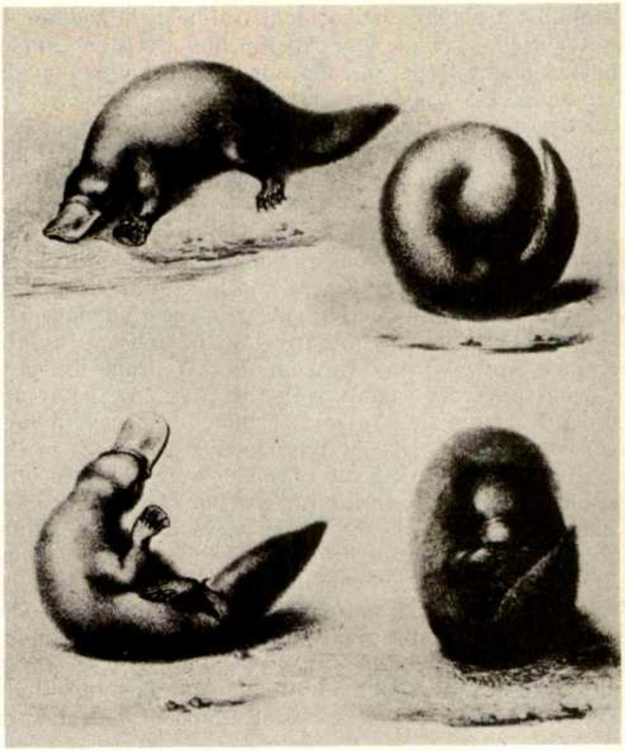
work on the Society's material. This arrangement lasted until 1928, when the Society appointed its own full-time pathologist, a post that continues today. In 1925 the post of prosector was abolished and replaced by a part-time research fellowship—though the title was revived later for a short time. Thus for nearly the first hundred years of the Society's existence the research carried out on its own premises was confined almost entirely to the descriptive anatomy of animals that died in the collection, some descriptive pathology, and the occasional description of new species from animals living in the gardens.

From the first, in 1830, the proceedings of the scientific meetings were published as a journal, which soon became the familiar "P.Z.S.", the *Proc. zool. Soc. Lond.* of reference lists. In its early years it was indeed a report of the proceedings, but as time went on it took the usual form of a scientific journal containing formal papers, some of which had been read in full at the scientific meetings, others only in summary or title, few of them based on work done in the gardens. The title was retained until 1965 when it was changed to the more appropriate *Journal of Zoology*—with a few sentimental sighs from some. In 1833 a second publication appeared, the *Transactions* of the Society, quarto in size to take papers that needed large illustrations; it was issued in parts at irregular intervals. The illustrations, especially those prepared in the last century, are superb, some of them very large folding plates, most beautifully lithographed and often hand coloured. Those of anatomical dissections and of bones, whether fossil or modern, are no less works of art than the illustrations of bright plumaged birds and of butterflies or other insects. Similar plates on a smaller scale were also often used in the *Proceedings.* The cost of producing these publications was great, and until recent decades was subsidised from the general funds of the Society, which thereby fulfilled one of its charter aims, of advancing zoology, in a very material way. With the fall in the value of money this is no longer possible, and the publications have to be financially self-supporting.

The publications were exchanged from their start for those of other learned societies all over the world so that part of their cost was recovered in kind to lay the foundation of the Society's magnificent zoological library. This is one of the largest and most comprehensive in the world, now housed in new premises with an excellent reading room and skilled staff appropriate to the importance and value of such a collection, to which all workers engaged in zoological research can have access.

From time to time the Society made grants towards the expenses of traveller-naturalists, generally with the stipulation that it should receive the living animals collected. Such collecting trips certainly advanced zoology in faunistic knowledge, but scarcely came into the category of academic research.

Apart from its publications the Society's support for research was thus mainly confined to observations on dead animals until the 1930s, when J. S. Huxley became Secretary. He was an early worker on animal behaviour following in the footsteps of Edmund Selous, who invented bird-watching in 1901; his well known paper on the courtship of the great crested grebe was published by the Society in 1914. In the few years before the outbreak of war in 1939 he himself studied animal behaviour on animals living in the Society's gardens, and helped others, among them James Fisher, in similar work. This trend towards the study of living animals is shown in the choice of subject by one of the early holders of the Research Fellowship, the present Secretary, who was appointed to the post as a young man shortly before Huxley joined the staff. Dr Zuckkerman, as he then was, observed and analysed the behaviour of the colony of Hamadyras baboons that made "Monkey Hill" one of the sights of London, approaching the subject "from the deterministic point of view of the physiologist", although he is described as "Anatomist to the Society" on the title page of the book in which he records and discussed his researches. This was what would now be called a seminal work, though its conclusions have been modified in the light of work on animals in less unnatural surroundings and in populations of more normal sex ratio.



Zoological Society

Duckbilled Platypus, *Ornithorhyncus paradoxus.* Taken from volumes of the *Transactions* of the Zoological Society.

The outbreak of war in 1939 put an end to this new approach to research: by 1945 a long list of dilapidations had accumulated, so that neglected repairs, the restoration of bomb-damage, and replenishing the collections took most of the Society's current resources until the 1950s when the present Secretary, now Lord Zuckerman, was appointed. The old sanatorium, and the prosectorium which combined dissecting-room with pathology laboratory, were quite inadequate for any serious work, though they had served well enough in their day. A new and well equipped animal hospital, and modern pathology laboratories were built, a full time veterinary officer and a new pathologist were appointed with a supporting staff of qualified technicians. When vacancies occurred new curators were appointed to the various departments, so that they are now all academically qualified zoologists. A steady stream of research publications has flowed from the work of these officers and from visiting workers in their departments.

The most impressive developments in research, however, are the establishment of two research institutes in the Society's gardens, with splendidly equipped modern laboratories, animal rooms, and ancillary services. The Nuffield Institute of Comparative Medicine, and the Wellcome Institute of Comparative Physiology owe their conception to the foresight of Lord Zuckerman, and their realisation to his genius for fund-raising and to the generosity of several philanthropic foundations and trusts. The work undertaken by the institutes differs fundamentally from the researches formerly sponsored by the Society in being experimental and not solely observational. The latter were necessarily restricted to work that does not need a Home Office licence under the Cruelty to Animals Act, because considerations of public relations and sentiment, in addition to the Act itself, preclude any experimental work on animals exhibited in the Society's collection: the institutes, on the other hand, are licensed. The latest available reports on the work of the Institutes show the wide range of subjects covered, many of them of immediate value in preserving the health and well-being of the collections. In the Nuffield Institute of Comparative Medicine the departments for pathology, infectious diseases, biochemistry, and radiology have investigated numerous problems arising in the collections, as well as more general topics with application to human as well as veterinary medicine. The Radiology Department also maintains the growing and much consulted Wellcome Animal X-ray Museum. The Wellcome Institute has been concerned mainly with the physiology of reproduction in mammals. An investigation of special interest has been carried out on the reproductive physiology of the hystricomorph rodents, some of which were collected during visits to South America for the purpose by members of the staff. Several of the species have bred successfully in the Institute. Other studies include work on the viability of spermatozoa, on the possibility of artificially inseminating African elephants, and reproduction in the Mustelidae. The Institute also contains a growing reference collection of reproductive and endocrine organs.

The Institutes give hospitality to a steady flow of visiting workers, and send members of staff abroad for field work or to visit other institutions, with some of which they have special affiliations. The activity of the Institutes is illustrated by the long list of scientific papers published each year by members of staff and visitors, in the *Journal of Zoology* and the publications of other learned societies.

Since 1959 the Society has held several symposia every year on special topics to bring together workers engaged in research on different aspects of any branch of zoology. The papers and discussions are printed in a special series of Symposia publications which has a wide circulation. The *International Zoo Yearbook,* published annually since 1960 is addressed mainly to those concerned with the housing and husbandry of animals in captivity, but it does contain accounts of research pertinent to those subjects.

Finally, an important publication of long standing must be mentioned. The *Zoological Record,* issued annually since 1864, is an essential tool to all engaged in research on zoology; it is an international bibliography listing all papers published in all branches of zoology for each year, with author, subject, and systematic indexes. The enormous growth in the literature during the past twenty years is reflected in the size of the annual volume, now prepared by a whole-time staff of specialist recorders.

The shades of Raffles and Humphry Davy, could they glimpse the developments at Regent's Park as they stroll through the groves of the Elysian Fields, could surely be surprised to see what they had started, and would be gratified to know that their ideas for the advancement of zoology are being so energetically realised in the researches made possible by their Society.

Evidence is summarised here that trees store a record of atmospheric temperature in their rings. In each ring, the ratios of the stable isotopes of hydrogen and oxygen vary with the air temperature prevailing when the ring was formed. We have shown that the temperature records in three modern trees seem to follow the local mercury thermometer records, and have found that a Japanese cedar indicates a temperature fall of ~1.5 °C in the past 1,800 yr.

LONG TERM isotope changes in precipitation, caused by changes in climatic temperatures, are well documented in polar ice caps —the heavier of the stable isotopes is depleted in ice laid down in the ice age by comparison with present-day ice. In 1970 we extended this concept to trees, suggesting that they are also thermometers, and undertook measurements to test the idea. In trees which use atmospheric precipitation to manufacture their rings, isotope variations in the rings should be climate indicators because the isotope composition in the rain and CO_2 varies with temperature.

Many tree ring sequences can be counted with an accuracy of about one year. Those which are not yet tied to modern sequences by overlapping ring patterns (said to be "floating"), can be dated in favourable cases with an accuracy of about 30 yr, by radiocarbon dating, depending on the age and on the number of radiocarbon measurements which are made. The isotopic compositions of atmospheric carbon dioxide, rain and snow have been shown to vary strongly with atmospheric temperature[1,2]. A non-negligible temperature-dependent isotope fractionation in the formation of wood has been computed assuming thermodynamic equilibrium but is small by comparison with that expected in rainwater[3]. Therefore, the tree ring emerging from the outer living layer of sapwood should record the average temperature of the atmosphere at that time, except for possible isotope exchange between the heartwood and water. The matter of isotope exchange between intact heartwood and water does not seem to be a serious threat since it has been shown, at least in species having tight rings, that the sap does not interact with the heartwood. Huber has shown, using biological dyes in many tree species, that water conduction remains limited to the outermost annual ring[4]. In addition, radiocarbon injected into or ingested by a living tree does not exchange with neighbouring rings[5,6]. Furthermore, we have observed that when *Sequoia gigantea* wood was soaked for 37 d in an air atmosphere saturated at 100% humidity, and previously labelled to $\delta D_{(\text{SMOW})} = 1{,}170‰$, no deuterium exchange was detected even though water saturation was optically evident. This is reasonable because wood is a most remarkable polymer, containing very large molecules, largely cross linked internally and to each other with hydrogen bonds. Furthermore, the bonds of cellulose and lignin are very strong, by comparison with almost any other molecular bonds, so that isotope exchange at room temperature with water or dissolved CO_2 becomes very improbable.

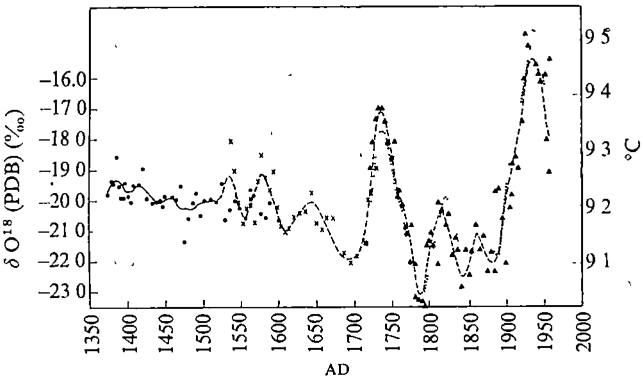

Fig. 1 ^{18}O ratio in German Oak, *Quercus petraea* (Spessart Mountains), compared with the annual average temperature of England (. . .). Thirty-year running averages of each isotope ratio are plotted against tree ring years. Five-sample (or ~ 30 yr) running average for oak from Marburg, Germany; ●, 4.7-yr sample; ▲, Seven-sample (~ 30 yr) running average for Spessart oak No. 1; × five-sample (~ 30 yr) running average for Spessart oak No. 2. The temperature record of England is shown here for comparison because it extends much further back than do the next most lengthy records, namely those for Basel and Geneva. The agreement with these latter temperature records is equally good, however. PDB, Pee Dee Belemnite, a fossil shell used as a standard; ———, smoothed by eye.

Temperature records

The trees most useful for testing this method of determining temperature histories and making calibrations are European trees since only Europe has temperature records extending back three centuries[7] (for England) and more than two centuries (for Basel and Geneva).

To demonstrate the effect experimentally, we needed to measure modern trees whose rings have been correctly counted and to obtain lengthy mercury temperature records from places near where they grew, preferably from the same altitude. The oldest temperature records in the World Weather Records are for Basel and Geneva, at about 300 m. We therefore obtained from the laboratory of B. Huber in Munich (the only tree ring laboratory in Europe when we started this work) a German oak, grown in middle Germany at an altitude of about 300 m, which had been correlated with the fiducial tree ring sequential pattern developed by Huber and his colleagues[8]. Later we obtained samples of similarly calibrated trees from his students, B.B. and D. Eckstein.

So far, we have measured isotope ratios in three modern trees of three different species and have compared them with local temperature records from mercury thermometers; we have also studied two old trees of two different species and compared the isotope ratios with temperature records deduced from surrogate evidence such as lateness of cherry tree bloomings, number of snow days per year, and number of days per year when lakes were frozen. We found significant correlations.

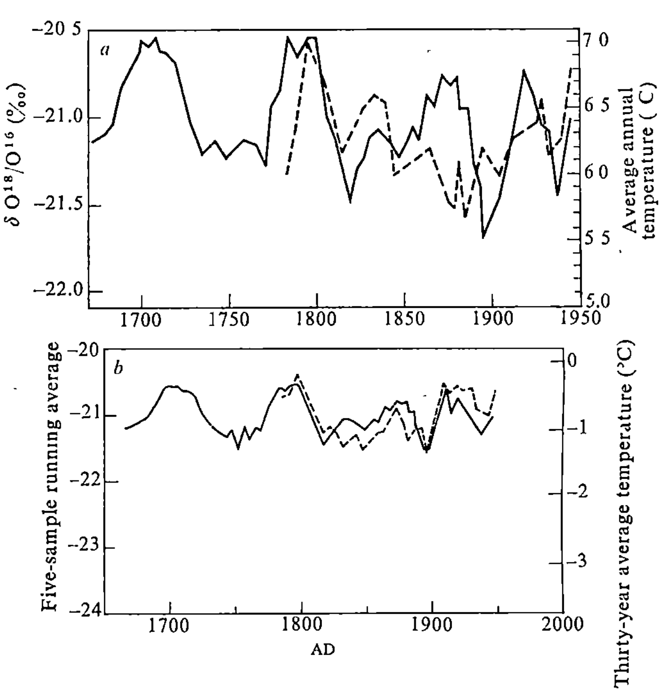

Fig. 2 ^{18}O ratio (—) for Bavarian fir, *Abies alba*, compared with: *a*, annual average temperature; *b*, average of January, February and March temperature for Höhen Peissenberg, Bavaria, at the same altitude of about 1,000 m above sea level, but about 150 miles south-west of the Bavarian Forest where the fir grew. This is mountainous country so that local differences in temperature may be expected. Temperatures for January, February and March seem to fit as well or better in all three modern trees analysed so far. This might perhaps be explained by the fact that the trees we have analysed up to now have grown where winter snow collects and melt water freezes into the ground. When the ground thaws, sap begins to flow (for example, the voluminous flow of maple sap and turpentine sap in early spring) and growth begins (for example, the fast rate at which pines shoot their candles in early spring). In the past three centuries, judging from mercury thermometer records, the major climatic change has been in temperatures during winter months. Temperatures in summer months have remained relatively constant since thermometer records began.

In Fig. 1 we compare ^{18}O measurements for a German oak, *Quercus petraea*, the rings of which were counted by Huber and Siebenlist[8], with English temperature records[9-11] back to the time of the invention of the thermometer in the late seventeenth century. The temperature coefficients have been evaluated by least squares analysis[12,13]. Figure 2 shows the ^{18}O data for a Bavarian fir, *Abies alba*, the rings of which were counted by Becker and Siebenlist[14]; they are compared with temperature records made near where the tree grew[7]. Similar results have been obtained with deuterium measurements (Fig. 3) for the oak.

General applicability

Since the method seems to have worked for European oak and fir, we felt that it would probably work elsewhere. Direct measurements of the isotopic composition of atmospheric moisture (as rain and snow) and indirectly of carbon dioxide, the ^{18}O of which is probably in isotopic equilibrium with atmospheric moisture[15], have been made and are available in the publications of the International Atomic Energy Agency (IAEA)[2]. Figure 4 shows the ^{18}O and D correlation with temperature for Austrian stations for the past 15 yr or so. The isotope composition of precipitation varies similarly with

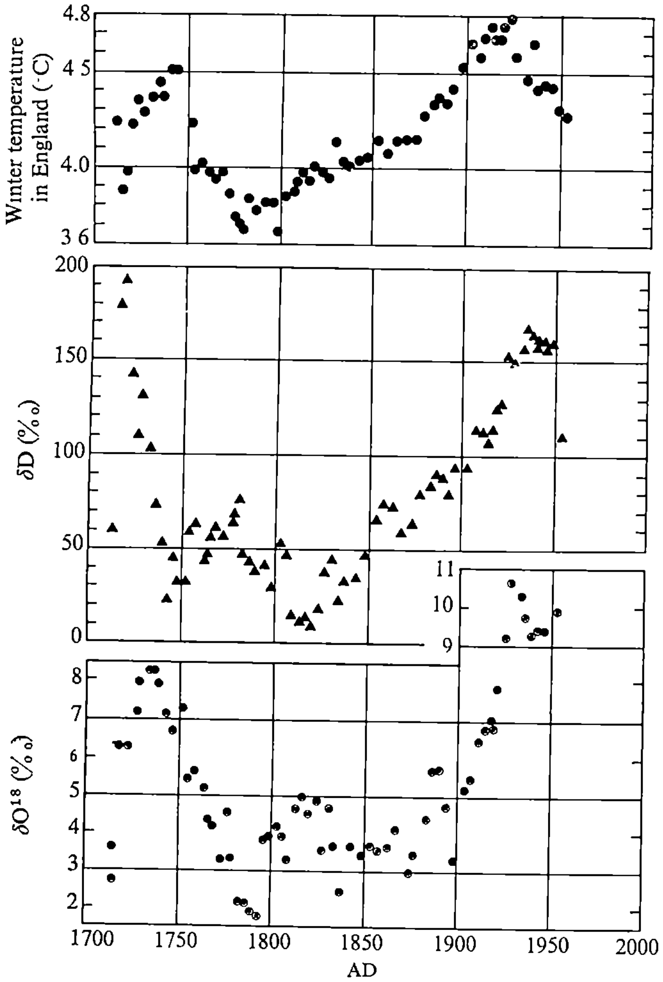

Fig. 3 Deuterium and oxygen ratios in German oak compared with English winter temperatures (30-yr running averages, see ref. 11). The procedure we used was to sample with a milling tool a number of tree rings, obtaining about 5 mg per sample; heat with $HgCl_2$ to produce CO_2 and HCl (ref. 22); remove the HCl with quinoline; and measure the ^{18}O abundance in a mass spectrometer. For measurement of the deuterium, we burnt the wood, reacted the water with metallic uranium to produce hydrogen gas and measured its D abundance in a hydrogen mass spectrometer (negative ratios).

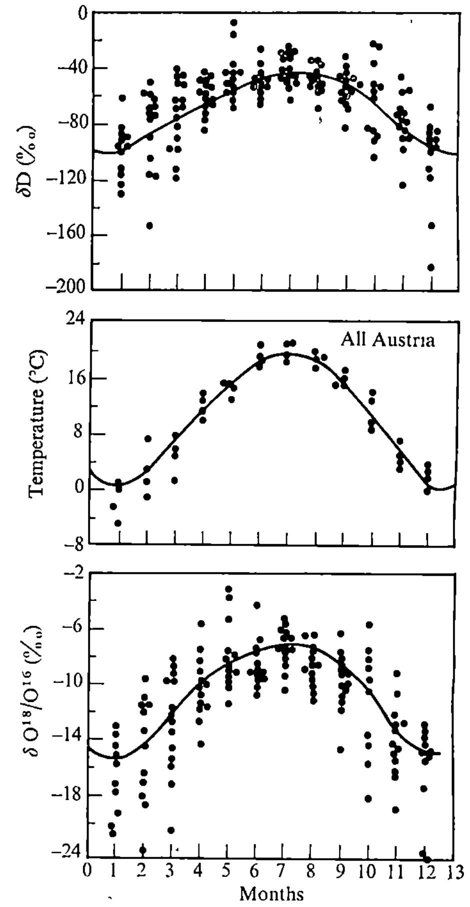

Fig. 4 Deuterium and ^{18}O isotope measurements in Austrian precipitation (Vienna 1961–71, Petzenkirchen 1966–71, Apetlon 1966–69, Podersdorf 1966–68) compared with average monthly temperature (Vienna 1961–64) taken from ref. 2. We have also plotted the IAEA data from these years for Stuttgart and many other places and find similar temperature dependences. When the climate deteriorates or improves, presumably the curve of annual dependence moves down or up on the isotope axis; the IAEA data have been measured for only about 20 yr, so long term changes have not yet been demonstrated.

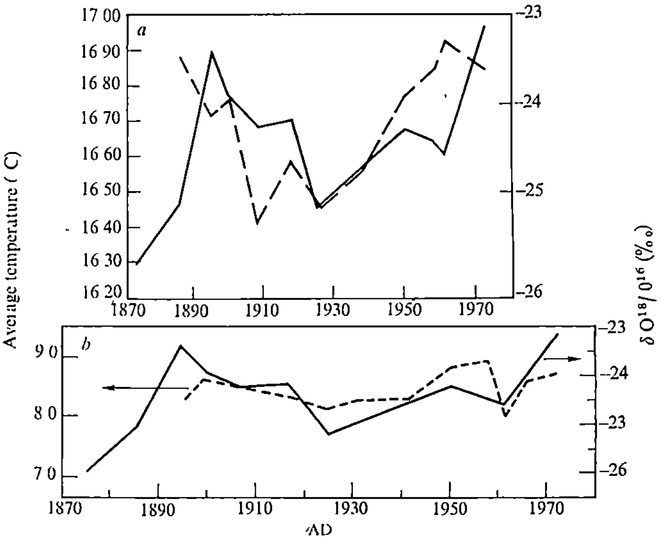
Fig. 5 ^{18}O (—) in modern *Cryptomeria japonica* compared with: *a*, average annual; *b*, January, February and March air temperatures measured at Miyazaki, Japan[19]. The *Cryptomeria* grew at an altitude of 1,350 m, whereas Miyazaki is at sea level, about 150 miles north-east of Yaku Island. Averages over about 8 yr are shown.



temperature in many other places, as may be seen by plotting the IAEA isotope data against air temperature[2].

Old Europe and Japan

Thus we have had the temerity to measure German oak rings which grew before thermometers were available[8]. In Fig. 1 we show warm intervals at AD 1530, 1580 and 1650 and cold periods at about AD 1700 and 1800, in agreement with Bergthorsson's deductions of climate variations in Iceland[16], and in agreement with the historical evidence of severe climate deterioration in the First and Second Little Ice Ages in Europe.

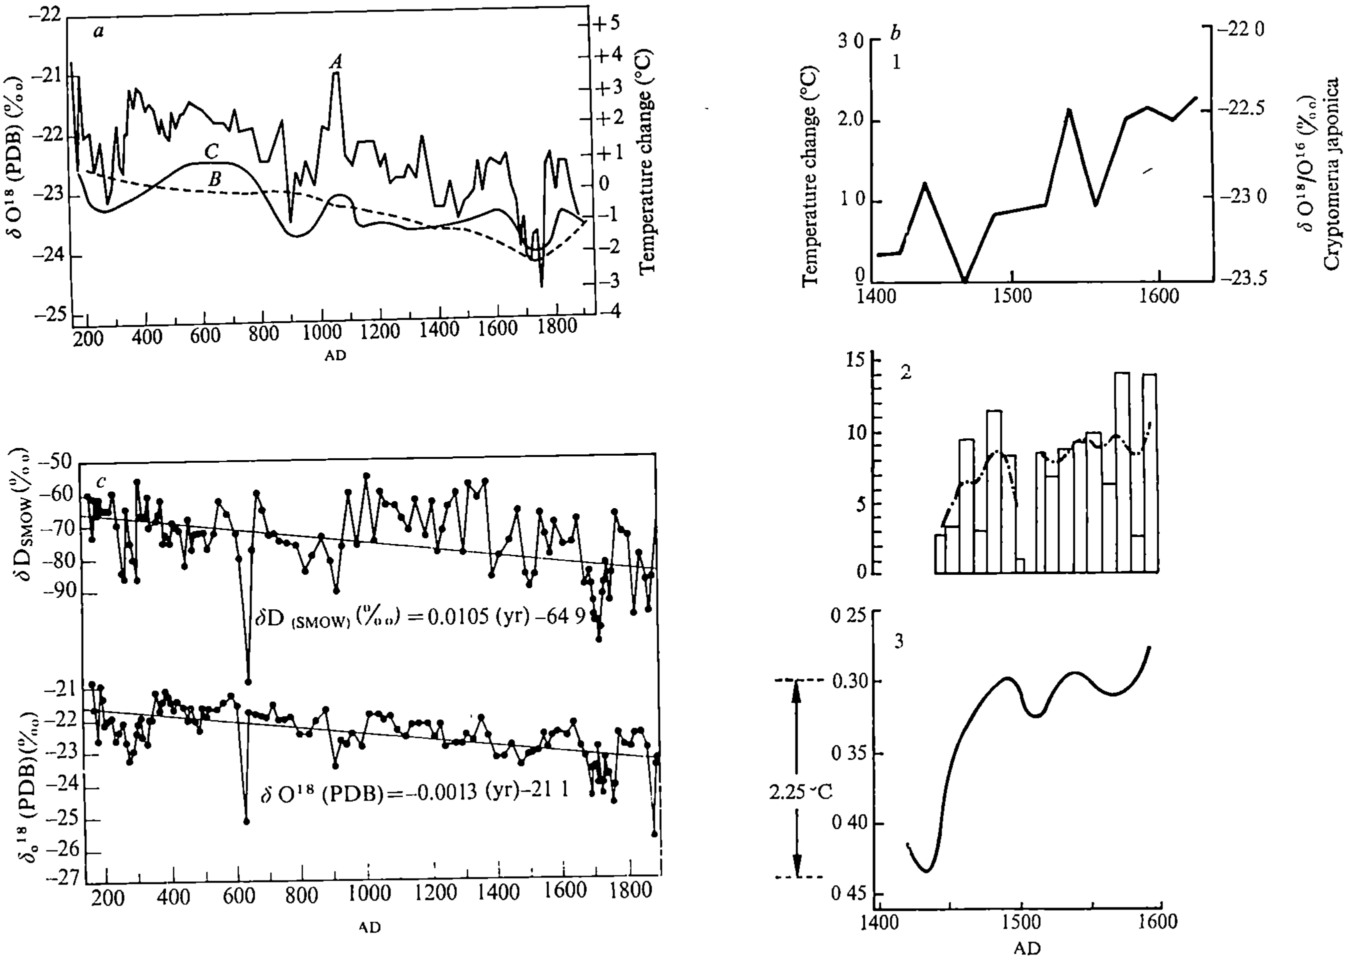


Fig. 6 ^{18}O ratio (*a*) in historic *Cryptomeria japonica*: *a*, compared with Chinese air temperatures (*b*) and Norwegian snow line (*c*)[19]; *b*, compared with Japanese air temperatures[18]. Averages over about 8 yr are shown. *b*: 1, oxygen data against temperatures obtained from cherry tree blooms; 2, change of the first freezing date of Lake Suwa; 3, change of number of snow days a year, calibrated by comparison with modern changes and modern temperatures. *c*, D/H ratio and ^{18}O/^{16}O ratio against time, the least squares fits against time, and the least squares fit to the dependence of δD on δ^{18}O with a slope of 8.2.

Further, we have measured an old Japanese cedar, *Cryptomeria japonica* or Yaku-Sugi (the ^{14}C in the rings of which were measured by Kigoshi[17]), for both hydrogen and oxygen isotope ratios. Kigoshi counted the rings of this tree and verified the count by making 50 radiocarbon datings on them. Ten dates were made on the oldest part of the tree, each to an accuracy of ±100 yr, for the years counted as AD 137–537. The accuracy of his count in the oldest part is thus substantiated to an accuracy of $\pm100/\sqrt{10}$ or ±30 yr, by the radiocarbon evidence. In Fig. 5 we have compared the modern part of the cedar with temperatures[18] measured at Miyazaki, a nearby weather station. Although Miyazaki is at sea level, our *Cryptomeria* grew at a higher altitude, about 5,000 feet. In spite of climatic differences which might be expected to arise from difference in altitude, there seems to be significant agreement, allowing us to calibrate the isotope changes in terms of temperature differences.

Measurements of the isotopic composition of atmospheric moisture are compared, in Fig. 6 *a* and *b*, with temperatures deduced from surrogate evidence obtained from old diaries for Japan[19] and for China[20]. Figure 6*a* raises several questions. Are the tree ring ages correct in this tree? Is the surrogate evidence giving rise to the Yamamoto and Chu comparison temperatures and to the Norwegian snow line data either pertinent or correct? It may be possible to find other evidence for the temperature changes indicated by the isotope variations in the cedar and thus indirectly check the method further.

The fact that

$$\delta D = 8.2\delta^{18}O + \text{constant}$$

for the cedar, showing a slope consistent with that for worldwide rainwater within experimental error[12,21], indicates that the tree is storing old rainwater. Furthermore, it supports the hypothesis that the CO$_2$ and H$_2$O are in isotopic equilibrium in the atmosphere.

The absolute values of the deuterium ratios, about −70 SMOW, are about the same as in rainwater. The absolute values of the oxygen ratios, around +20 SMOW, are halfway between that for rain (about −7 SMOW), and that for atmospheric CO$_2$ (about +40 SMOW). This is to be expected for water vapour in equilibrium with atmospheric carbon dioxide and keeping in mind that carbon dioxide absorbed by the leaves exchanges its oxygen with sap.

We have made Fourier transforms of the data in Fig. 5*c* to deduce the power spectrum of periodicities. The results are shown in Fig. 7 *a* and *b*, and in Table 1. The same periods are found in both D/H and in $^{18}O/^{16}O$ data, within experimental error, as obtained from the widths of the peaks in the power spectra.

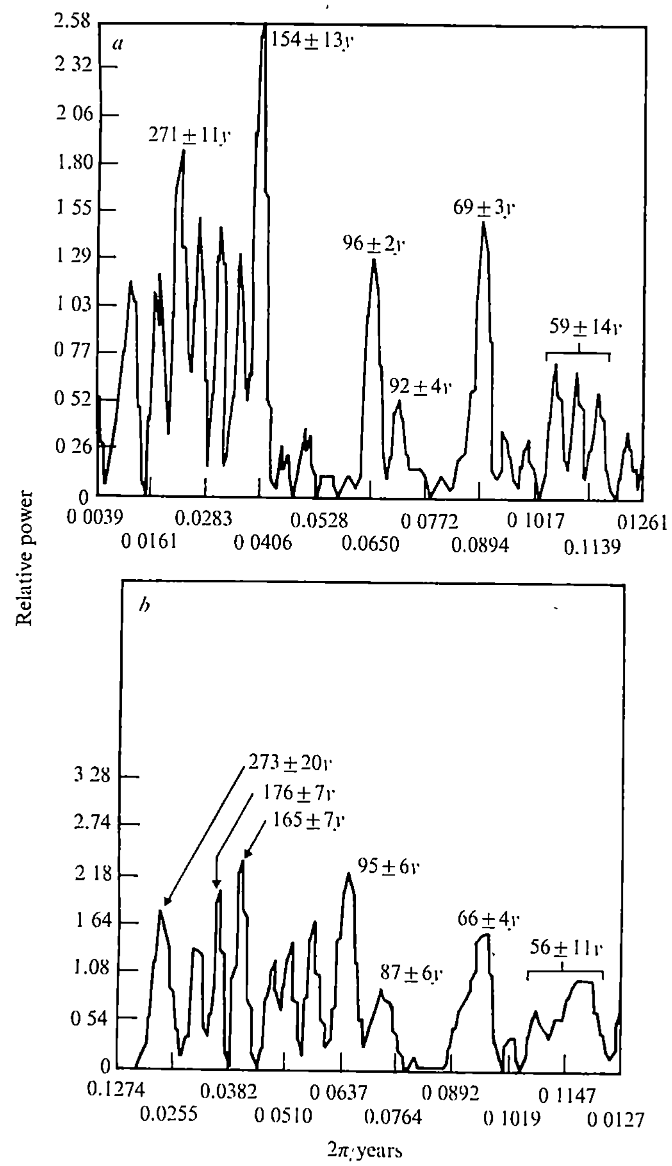

Fig. 7 Power spectra obtained from Fourier transforms of the data in Fig. 6*c*. The indicated periods are not sensitive to various ways of cutting off the ends of the data. *a*, Fourier transform of $\delta^{18}O$, average slope subtracted; *b*, Fourier transform of δD, average slope subtracted.

Table 1 Periods and their respective powers found in Fourier transforms of oxygen and hydrogen stable isotope data in Japanese Cedar AD 140–1950

$\delta^{18}O$ Period (yr)	$\delta^{18}O$ Relative power	δD Period (yr)	δD Relative power
59±14	0.67	56±11	1.00
69±3	1.50	66±4	1.64
92±2	0.52	87±3	1 00
96±2	1.29	95±2	2.18
154±6	2.58	153±7	2.18
174±7	1.29	174±8	2.00
202±7	1.45	205±9	1.70
271±11	1.80	273±20	1.64

Our samples represented approximately 5 yr each, so we cannot expect to find evidence for periods of less than about 40 yr in these data. As the sets of data span only about 1,800 yr, we cannot expect to find evidence for periods of more than about 250 yr. Both data sets show a long term decline of about 1.6 °C in average temperature over the past 1,800 yr. This is significant, especially considering that there was a decline of about 10 °C in the last ice age. In making the Fourier transforms we have used the deviations of the isotope ratios from the long term slopes—that is, we have corrected for the slope. One may ask whether the periods of about 58 yr and about 68 yr are really different from each other, and likewise for the periods of about 90 yr and 95 yr. The peaks in Fig. 7 suggest that they are. We need to measure more trees to find out. We varied the methods of cutting off the data at the end points to confirm that the period of 272 yr is real. Also we fed artificial periodicities of 50 and 55 yr and of 90 and 95 yr into the Fourier transform and found them separable.

Future research

It seems wise to measure more modern ring sequences and compare them with local mercury thermometer records in order to establish the tree thermometer phenomenon beyond question. And, of course, there are experiments to be done growing woody material in conditions of controlled temperature and isotopic ratios in atmosphere and water. We plan also to study old tree ring sequences. We have such sequences in our laboratory, including sequoias, firs, cedars, and pines provided by B. Becker, Dieter Eckstein and other experts on tree ring counting.

When we have measured isotope ratios in each ring of a lengthy sequence (as opposed to making measurements of five rings at a time) we shall explore the Fourier transforms of the data for evidence of the sunspot cycle of about 21 yr and other periodicities of less than 50 yr and for sum and difference frequencies. When we have determined whether there are shorter periodicities, and substantiated the longer periodicities listed in Table 1, we plan to put them in the phase relationships indicated by the trees and predict the trends of climate to be expected for the next twenty years or so.

The exciting possibility of studying trees felled by the advancing ice sheet at the Two Creeks site in Wisconsin 12,000 yr ago is an obvious application of this technology. It seems likely that if the method is sound we can establish the history of climate back many millennia, as far back, in fact, as there are tree remnants to be found.

This research was initially supported by ARPA, and more recently by the NSF.

Stratospheric ozone as viewed from the Chappuis band

Ronald J. Angione & Edward J. Medeiros
Astronomy Department, San Diego State University, San Diego, California 92182

Robert G. Roosen*
Laboratory for Solar Physics and Astrophysics, NASA/GSFC New Mexico Station, Albuquerque, New Mexico 87131

Stratospheric total ozone values have been obtained for the period 1912–50 from analysis of Smithsonian data. Naturally caused variations of 25% or more are common over time scales ranging from months to decades. We suggest that the ozone layer acts as a shutter on the incoming solar energy, providing one of the long sought trigger mechanisms between solar activity and climatic change. The present state of knowledge of ozone climatology is not sufficient to support popular speculations about man's effects on the ozone layer.

MUCH speculation has been published about the naturally occurring ozone in the Earth's stratosphere. The controversy has centred around theoretical attempts to demonstrate that certain of man's activities such as the flight of SSTs or the production and release of fluorocarbons will reduce the mean amount of naturally occurring ozone and lead to unwanted biological effects[1]. These theoretical speculations generally predict a total depletion of nearly 7%. Because of its absorption bands in the ultraviolet, visible and infrared parts of the spectrum, ozone is also an important climatological parameter. Thus it is particularly interesting to examine the history of natural variations in ozone amounts over a time span of several decades.

We are trying to determine historical baselines for atmospheric constituents using data obtained by the Smithsonian Institution's Astrophysical Observatory (APO) in their solar constant observing programme from 1902 to 1961. As a normal part of their observing procedure, they obtained spectrobolometric tracings of the direct solar radiation reaching the ground over the spectral range 0.35–2.2 μm. We have previously analysed the published portion of these data for changes in atmospheric transmission caused by suspended aerosols[2]. We have now extended our analysis of these data to determine values for total stratospheric ozone above high altitude stations in southern California from 1912–1950 and northern Chile from 1918–1948.

In the past, virtually all long term monitoring programmes for total ozone have used Dobson spectrophotometers or other instruments such as filter photometers. These instruments operate in the ultraviolet part of the spectrum to observe the strong ozone absorption in the Huggins bands (0.30–0.35 μm). The APO transmission measurements included the Chappuis band (0.5–0.7 μm) and therefore offer both an extension of the baseline in time and place, and a valuable check on the Dobson ozone amounts determined with this different band. The measured transmission in the Chappuis band has been reduced by ozone, Rayleigh scattering, and aerosol scattering. We used the transmission data outside the ozone band to calculate the Rayleigh and aerosol components. Absorption coefficients from Vigroux[3] were then used to calculate the total ozone.

The Chappuis band has generally not been used for ozone because it is a very weak feature. The APO data are, however, of sufficient quality that we were able to model the Rayleigh and aerosol contributions so that the resulting daily probable error in ozone amounts was only 7%. An advantage of the Chappuis band is that its absorption coefficient is unaffected by temperature[3]—a property not shared by the ultraviolet bands.

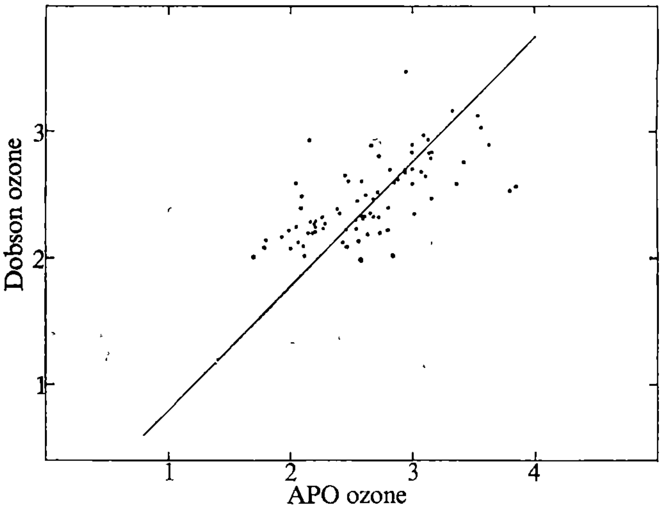

Fig. 1 Correlation between ozone amounts determined from 78 d of observation at Table Mountain, California with both a Dobson spectrometer and an APO spectrobolometer. Ozone concentrations here and in subsequent Figs are measured in mmHg (NTP).

A comparison between Dobson values and our values is possible from 78 d of nearly simultaneous APO and Dobson observations made at Table Mountain, California from August, 1928 to May, 1929 (Fig. 1). A simple linear regression analysis yields a correlation coefficient of 0.7 and a slope of 0.98 between the two data sets. The lack of perfect agreement is attributed to several causes. First, the APO observations were carried out a few hours earlier on each day than the Dobson work. Second, the ozone absorption coefficients are not precisely known; inaccuracies of up to 10% may still exist[4]. Third, the calculated error for values derived from the daily APO measurements is 0.23 mm s.d. in the APO–Dobson comparison. It is for this last reason that we present here monthly mean values of ozone, where the calculated error is reduced typically to ~0.10 mm.

---

*Present address: Sandia Laboratories, Albuquerque, New Mexico, 87115.

Figures 2 and 3 show monthly mean and 12-month running mean total ozone amounts for southern California and northern Chile, expressed in terms of the equivalent height of a vertical column of pure ozone at NTP. Each point before 1930 represents the mean of $\sim$6 d. Observations were made at Mt Wilson only during the summer months. Only $\sim$50 values per site were published for the period 1940–1950; thus each point in that period represents typically 1 or 2 d compared to typically 6 d for the earlier period.

It is apparent from Figs 2 and 3 that at both sites total ozone amounts commonly show variations of as much as 20–30% on time scales ranging from months to decades. Comparison with other work[5] shows that such variations are not at all unusual in Dobson spectrophotometry. We also present 12-month running means (dashed line) for comparison with the highly smoothed data usually found in the literature. Even here large variations are found that are comparable to those recently reported by other workers. For instance, Angell and Korshover[6] found changes of up to 8% over 3 yr, and Komhyr *et al.*[7] found changes from 2–10% per decade for the period 1960–70. We find that such changes occurred throughout the forty-year APO record analysed here.

Because the large natural variations in the ozone layer are not uncommon, consideration of the amount of incident solar energy absorbed by the Chappuis band suggests a new perspective on the long sought link or 'trigger mechanism' between solar activity and the Earth's weather and climate[8]. Stratospheric ozone is created photochemically by solar radiation in the wavelength region from $\sim$1,800 to 2,100 Å (ref. 9). Although the solar energy output shows substantial variations in this region and at shorter wavelengths[10], this total energy change is such a small fraction of the average solar output that it is generally considered to fall far short of meteorological significance. Also, photons in this wavelength region are absorbed in the stratosphere, requiring that any tropospheric effects should be indirect[8]. Since the ultraviolet Hartley and Huggins bands are saturated and Rayleigh and aerosol scattering are very large in the ultraviolet, the net atmospheric transmission of radiation in the near ultraviolet is not strongly affected by variations in stratospheric ozone.

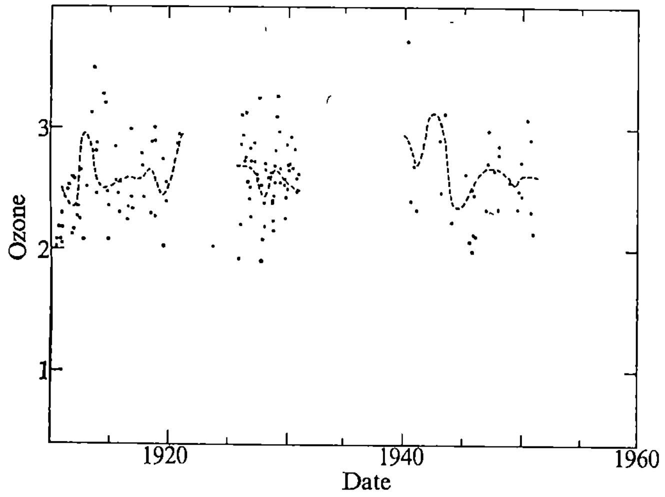

Fig. 2 Monthly mean values of total ozone for the southern California sites Mt Wilson (1912–20) and Table Mountain (1925–30 and 1940–50). The dashed line represents twelve month running means. Typical probable error is 0.10 mm.

On the other hand, because of its location near the peak of the solar energy spectrum, the Chappuis band absorbs on average $\sim$2% of the total solar flux at midlatitudes[11]. Thus, for example, if solar variations and stratospheric transport combine to produce an increase in stratospheric ozone of 25% over a given mid-latitude station, the total solar energy reaching the troposphere above that station would be decreased by $\sim$0.5%, an amount of importance to both weather and climate. Thus ozone can serve as a stratospheric shutter operated by ultraviolet rays but modulating the energy flux in the visible region. Because of the longer slant path lengths and larger amounts of ozone, the effect is much larger in the polar regions. Ozone climatology is further complicated by the absorption band at $9.6\ \mu m$ which makes an important contribution to the greenhouse effect[12,13].

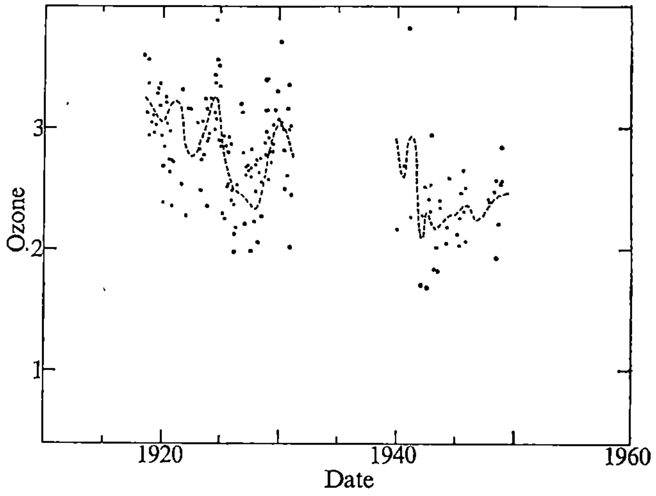

Fig. 3 Monthly mean total ozone for northern Chile sites Calama (1918–20) and adjacent Mt Montezuma (1920–30 and 1940–48). The dashed line represents twelve month running means. Typical probable error is 0.10 mm.

The possibility that man might inadvertently modify the ozone level is a matter of much concern. The presence of large variations in ozone amounts makes it clear that we must really think in terms of a natural range in ozone amounts, rather than a single level. Considering the magnitude of the spatial and temporal variations involved, there exists only a relative handful of measurements of past ozone levels, and it is not now possible to say what might constitute an optimum ozone level at a particular time and place, or if such a level can even be defined. Finally, we note that because of the presence of natural biological processes, it is questionable whether man can permanently modify the ozone layer[14,15].

7-methylguanosine 5′-monophosphate inhibits protein synthesis in a fractionated, messenger-dependent, reticulocyte cell-free system. This compound also inhibits binding of histone mRNA to reticulocyte ribosomes as well as interaction of VSV mRNA and histone mRNA but not EMC virus RNA with purified initiation factor IF-M$_3$. These studies provide evidence that the role of 7-methylguanosine in the mechanism for initiation of eukaryotic mRNA translation may be related to specific recognition of mRNA by initiation factor IF-M$_3$.

WITHIN the past two years a number of investigators have identified a unique 5′-triphosphate linkage of 7-methylguanosine (m^{7}G) to the 5′-terminal nucleotide of various eukaryotic mRNAs[1-12]. It has also been reported[7] that chemical removal of m^{7}G from rabbit globin mRNA and the absence of either the 7-methyl group or m^{7}G in reovirus mRNA[13] results in reduced ability of these RNAs to serve as templates for protein synthesis. Hickey *et al.*[14] have found in a wheat germ cell-free system that 7-methylguanosine-5′-monophosphate (m^{7}G$^{5'}$p) inhibits translation of several eukaryotic mRNAs containing the 5′terminal m^{7}Gppp... group. Translation of satellite tobacco necrosis virus RNA, a plant virus RNA with a free 5′-terminal phosphate (see ref. 14), was not, however, inhibited by m^{7}G$^{5'}$p. From these and other studies it was concluded that m^{7}G$^{5'}$p acted as an inhibitor of mRNA addition to the initiation complex[14].

In the present study we have tested the effects of m^{7}G$^{5'}$p on protein synthesis in the rabbit reticulocyte cell-free system. In preliminary experiments m^{7}G$^{5'}$p was added to unfractionated reticulocyte lysate. In these conditions, there was only a slight inhibition of protein synthesis at high concentrations of this nucleotide (1.25 mM m^{7}G$^{5'}$p produced only a 15% inhibition). This is in contrast to our previous results with unfractionated wheat germ extract in which 0.125 mM m^{7}G$^{5'}$p inhibited mRNA translation by more than 90% (ref. 14). A major difference between these systems is that wheat germ extract is dependent on exogenous mRNA for protein synthesis, whereas reticulocyte lysate contains large quantities of endogenous mRNA already associated with polysomes. We have, therefore, used a fractionated, reticulocyte mRNA and initiation factor dependent, cell-free system to study the mechanism of inhibition of protein synthesis by m^{7}G$^{5'}$p. With this system under the direction of homologous reticulocyte mRNA, m^{7}G$^{5'}$p produces a marked inhibition of protein synthesis. In addition, m^{7}G$^{5'}$p specifically inhibits mRNA from entering into a stable 40S or 80S "initiation complex" with reticulocyte ribsomal subunits. Finally, we show that m^{7}G$^{5'}$p inhibits the interaction of certain mRNAs with purified reticulocyte initiation factor IF-M$_3$.

Inhibition of protein synthesis

A cell-free protein synthesising system, dependent on exogenous mRNA and initiation factors, was prepared from rabbit reticulocytes by treating polysomes with low concentrations of pancreatic RNase, followed by washing the ribosomes with 0.5 M KCl and sedimenting them through a 1.0 M sucrose cushion[15]. Other reticulocyte components were prepared as reported previously[16]. This system has been characterised previously[15] and demonstrates all the steps necessary for synthesis of authentic polypeptides with relatively high efficiency and linear incorporation of amino acids into protein for up to 1 h (ref. 16). With saturating levels of exogenous reticulotype poly(A)$^+$ mRNA and initiation factors, m^{7}G$^{5'}$p produced a marked reduction in ^{14}C-leucine incorporation (Fig. 1). Inhibition of protein synthesis by m^{7}G$^{5'}$p was not reversed by threefold excess initiation factors added separately or as a crude mixed factor preparation. Little inhibition was observed with either 7-methylguanosine or 7-methylguanosine-2(3)′-monophosphate (Fig. 1). Since globin mRNA has been found to contain 5′-terminal m^{7}Gppp... (refs 7 and 13), these results suggest that inhibition of exogenous mRNA translation by m^{7}G$^{5'}$p is related to a structural homology between m^{7}G$^{5'}$p and the 5′-terminus of this eukaryotic mRNA.

Inhibition of initiation complex formation

To study the mechanism of inhibition of protein synthesis by m^{7}G$^{5'}$p, purified initiation factors and radioactive mRNAs have been used. In this way the interaction of mRNA with ribosomal subunits and initiation factors could be followed directly. For this purpose we have used a radioactive cellular mRNA, histone mRNA, which was shown previously to be translated faithfully by the reticulocyte cell-free system[18-19]. ^{3}H-histone mRNA was incubated with unfractionated rabbit reticulocyte lysate in protein synthesis conditions but in the presence of 0.2 mM sparsomycin to inhibit movement of labelled mRNA into large polyribosome structures (L.A.W., M. C. Williams, and C. B., unpublished). After a brief incubation at 30 °C, ribosomes and ribosomal subunits were separated by sucrose gradient centrifugation. Association of mRNA with ribosomes was determined by the appearance of label in sucrose gradient fractions compared with the ribosome A_{260} profile. Binding of ^{3}H-histone mRNA to reticulocyte ribosomes occurred rapidly in these conditions (Fig. 2*a*) and 68% of the added label sedimented in the 80S region after 2 min of incubation. Little ^{3}H-material appeared in the 40S subunit region,

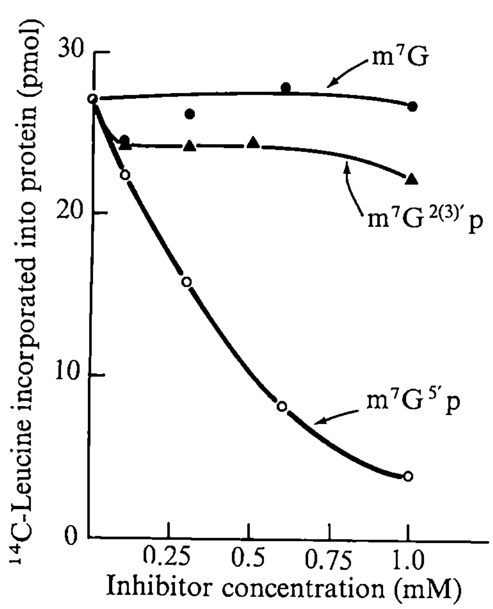

Fig. 1 Inhibition of protein synthesis in reticulocyte messenger-dependent cell-free system by 7-methylguanosine 5′-monophosphate. The preparation of rabbit reticulocyte lysate, 0.5 M KCl-washed ribosomes, 105,000*g* supernatant protein and crude initiation factors was as previously reported[16]. Ribosomes were rendered dependent on exogenous mRNA by incubation with very low levels of pancreatic RNase as previously described[15]. Messenger RNA (RNA which contains a 3′-terminal poly(A) sequence) was prepared from reticulocyte polysomes by standard procedures, including multiple extractions with phenol–chloroform–isoamyl alcohol and adsorption of poly(A)$^+$ material to oligo(dT)–cellulose according to the method of Aviv and Leder[17]. For the complete system, incubations in a total volume of 50 µl were performed at 30 °C for 30 min and contained 15 mM Tris-HCl, *p*H 7.4 ,80 mM KCl, 3 mM $MgCl_2$, 1 mM ATP, 0.2 mM GTP, 3 mM phosphoenolpyruvate, 0.2 IU of pyruvate kinase (rabbit muscle), 1 mM dithiothreitol, 80 µM L-amino acids minus leucine, L-^{14}C-leucine (specific activity 80 mCi mmol^{-1}), 0.1 A_{260} unit of 0.5 M KCl-RNase treated reticulocyte ribosomes, 0.06 A_{260} units deacylated rabbit liver tRNA, 300 µg of 105,000*g* supernatant protein, 150 µg of crude reticulocyte initiation factors, and 0.2 A_{260} units of partially purified reticulocyte mRNA. Where indicated, 7-methylguanosine (m^7G) (●), 7-methylguanosine 2(3)′-monophosphate ($m^7G^{2(3)'}p$) (○), or 7-methylguanosine 5′-monophosphate ($m^7G^{9'}p$) (▲) were added to the complete system. Reactions were stopped by the addition of ice-cold 10% trichloroacetic acid and protein synthesis determined by incorporation of ^{14}C-leucine into hot trichloroacetic acid-insoluble material[16].

and unbound ^{3}H-histone mRNA remained near the top of the gradient. In a control experiment ^{3}H-histone mRNA was added to an incubation mixture kept at 0 °C. This did not result in binding of mRNA to ribosomes or ribosomal subunits (data not shown). Addition of 0.25 mM $m^7G^{5'}p$ to the incubation mixture (Fig. 2*b*) resulted in a 36% reduction of ^{3}H-histone mRNA binding to ribosomes and 1 mM $m^7G^{5'}p$ produced a 75% reduction in ^{3}H-histone mRNA binding (Fig. 2*c*). $m^7G^{5'}p$ did not cause a shift in ^{3}H-histone mRNA binding from the 80S to the 40S region (Fig. 2*b*, *c*).

Various investigators have reported that Met-tRNA$_f$ forms a ternary complex with GTP and a specific initiation factor IF-MP[20] (also referred to as IF-I[21,22], IF-E2[23], and IF-L3[24]). Formation of this complex is thought to lead to Met-tRNA$_f$ association with the 40S subunit independent of mRNA, and it has been reported that Met-tRNA$_f$–40S subunit interaction is required for incorporation of mRNA into the "initiation complex"[23-25]. To measure formation of the Met-tRNA$_f$–40S complex, purified rabbit reticulocyte Met-tRNA$_f$ charged with ^{3}H-methionine (3 Ci mmol^{-1}) and the sucrose gradient assay described by Darnborough *et al.*[25] were used. As shown in Fig. 3, binding of ^{3}H-Met-tRNA$_f$ to the 40S ribosomal subunit is not inhibited by $m^7G^{5'}p$. From these studies (Fig. 2 and Fig. 3) we conclude that $m^7G^{5'}p$ inhibits protein synthesis by preventing mRNA from forming a stable complex with ribosomes or ribosomal subunits, but this does not occur by inhibition of Met-tRNA$_f$–40S subunit complex formation.

Effect of $m^7G^{5'}p$ on IF-M3-mRNA interaction

To determine whether $m^7G^{5'}p$ might inhibit protein synthesis by competing with mRNA for a common binding site on one of the initiation factors, a direct assay of mRNA-protein interaction was used. Hellerman and Shafritz[26] reported that reticulocyte initiation factor IF-MP forms a complex with ^{3}H-labelled rabbit globin mRNA. This complex was demonstrated by its retention on a nitrocellulose filter, in conditions in which free mRNA passed through the filter. A similar complex between IF-MP and bacteriophage R17-RNA has been reported by Kaempfer[27]. More recently, using labelled vesicular stomatitis virus (VSV)-mRNA or duck globin mRNA of much higher specific activity, we have found that reticulocyte initiation factors IF-M$_3$ and IF-M$_{2A}$ also form complexes with mRNA. Other purified reticulocyte initiation factors form such complexes to a much lesser extent (to be reported in detail elsewhere).

For experiments of this type, as well as these reported below, highly purified initiation factors are required. Details for the purification of these factors have been published[20,28-30] and materials used in the present study were prepared as follows: IF-MP was purified up to and including step 5 in ref. 20, IF-M$_{2A}$ up to and including step 6 in ref. 28, IF-M$_{2B}$ up to and including step 5 in ref. 29, and IF-M$_3$ up to and including step 5 in ref. 30, plus an additional purification by ion exchange chromatography with phosphocellulose in HEPES buffer at *p*H 6.8. This IF-M$_3$ preparation contains predominantly one polypeptide component (~80–90%) of molecular weight ~80,000 on sodium dodecyl sulphate (SDS)–polyacrylamide gel electrophoresis and seems to correspond to factor IF-E6 of Staehelin *et al.*[23].

In the present study, we have examined mRNA–protein complex formation with ^{3}H-histone mRNA, ^{3}H-VSV mRNA

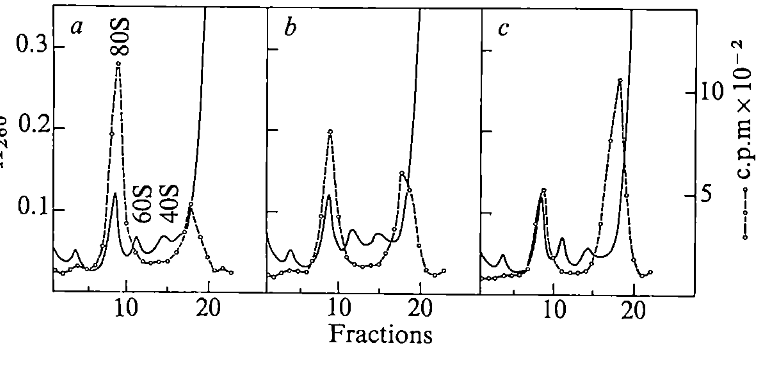

Fig. 2 Inhibition of histone mRNA binding to reticulocyte initiation complexes by 7-methylguanosine-5′-monophosphate. For each 25 µl incubation of unfractionated reticulocyte lysate, 5,000 c.p.m. of ^{3}H-histone mRNA (specific activity > 200,000 c.p.m. µg) were added together with 0.1 mM sparsomycin and $m^7G^{9'}p$, where indicated. Sparsomycin was added specifically to bind mRNA to 80S initiation complexes, since this drug prevents elongation, but does not inhibit initiation[25]. At the end of the incubation 0.4 ml of ice-cold 10 mM NaCl, 10 mM Tris *p*H 7.4 and 1.5 mM $MgCl_2$ were added and the samples fractionated by 16 h centrifugation at 22,000 r.p.m. on 15–30% sucrose gradients prepared in the same buffer. Fractions of 0.8 ml were collected and counted directly by addition of 15 ml of scintillation fluid containing 1 volume Triton X-100, 2 volumes of 0.8% butyl-PED (CIBA) and 0.3 volume water. *a*, Control, no $m^7G^{9'}p$ added. *b*, 0 25 mM $m^7G^{9'}p$ added. *c*, 1.0 mM $m^7G^{5'}p$ added.

and ^{3}H-encephalomyocarditis (EMC) virus RNA. Histone mRNA and VSV mRNA contain "blocked", methylated 5′-termini (ref. 31 and B. Moss, personal communication), whereas EMC virus RNA contains an unblocked 5′-terminal structure[32]. In addition, histone mRNA does not contain 3′-terminal poly(A)[33]. As shown in Table 1, complexes can be demonstrated between all three ^{3}H-mRNAs and initiation factors IF-MP, IF-M$_3$ and IF-M$_{2A}$ but not with IF-M$_{2B}$. Inhibition of mRNA-protein complex formation by m^{7}G$^{5'}$p is found exclusively with IF-M$_3$. Assuming a molecular weight of 2.7×10^6 daltons for EMC virus RNA and an average molecular weight of 0.5×10^6 for 12–18S VSV mRNA and roughly equivalent percentages of uridine in these molecules, complex formation between IF-M$_3$ and EMC virus RNA on a molar basis is approximarely one-fourth that obtained with VSV mRNA. In addition, complex formation between ^{3}H-EMC virus RNA and IF-M$_3$ is not inhibited by m^{7}G$^{5'}$p (Table 1). Since all three mRNAs form complexes with initiation factors IF-MP, IF-M$_3$ and IF-M$_{2A}$, a 3′-poly(A) sequence does not seem to be required for the observed phenomena.

It is important to note that highly purified IF-M$_3$ is required to obtain the observed degree of inhibition with m^{7}G$^{5'}$p; only 30–40% inhibition is found with less purified material. Inhibition of IF-M$_3$–mRNA complex formation also seems to be specific for m^{7}G$^{5'}$p, as other guanosine nucleotides tested do not produce this effect (Table 2). Together with the experiments reported in Figs 2 and 3, these results indicate that inhibition of protein synthesis by m^{7}G$^{5'}$p correlates with the ability of this compound to prevent interaction of mRNA with IF-M$_3$. Presumably, IF-M$_3$–mRNA interaction is required for mRNA association with the 40S ribosomal subunit, but as yet we have not developed an assay system to test this directly.

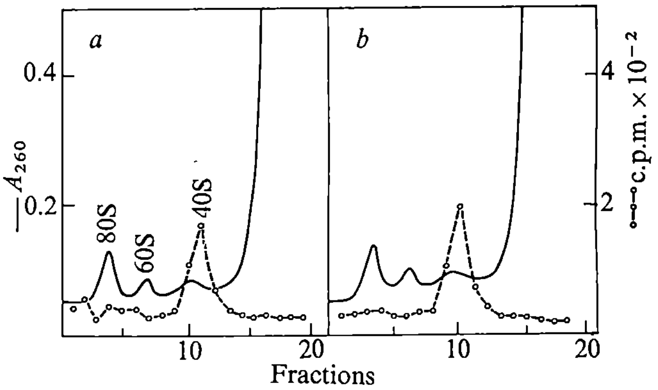

Fig. 3 Binding of ^{3}H-Met-tRNA$_f$ to the small ribosomal subunit in unfractionated rabbit reticulocyte extract in the absence (*a*) or presence (*b*) of m^{7}G$^{5'}$p. The binding reactions were carried out according to Darnbrough *et al.*[25] in 0.1 ml of the complete reticulocyte lysate system. To each incubation was added 0.1 mM sparsomycin and 1 mM m^{7}G$^{5'}$p was added to *b*. After 2 min at 30 °C, 3 pmol of ^{3}H-Met-tRNA$_f$ (1,500 c.p.m. pmole^{-1}) from rabbit reticulocytes were added for 2 min. The incubations were terminated by the addition of 0.4 ml of ice-cold 10 mM NaCl, 10 mM Tris *p*H 7.4 and 1.5 mM MgCl$_2$. The samples were fractionated by centrifugation on 15–30% sucrose gradients in the same buffer for 16 h at 22,000 r.p.m. in the Beckman SW27 rotor. 0.8-ml fractions were collected and counted after addition of 0.25 mg carrier yeast tRNA and precipitation with 1.5 ml of 2% acetyltrimethylammonium bromide. The precipitates were collected on Millipore filters and counted as in Fig. 2.

Relationship of m^{7}Gppp . . . to the eukaryotic initiation process

In spite of many recent advances in our understanding of the mechanism of initiation of eukaryotic protein synthesis, little progress has been made in elucidating how mRNA is recognised by the ribosome or how specific factors might participate in selecting specific mRNAs or particular nucleotide sequences of mRNAs. To approach this problem, we have begun to study the properties of proteins associated with mRNA and the relationship of these proteins to reticulocyte initiation factors. We reported that IF-MP activity is present on messenger

Table 1 Inhibition by m^{7}G$^{5'}$p of binding of ^{3}H-uridine-labelled mRNAs to reticulocyte initiation factors

Factor	^{3}H-VSV mRNA bound (c.p.m.)		^{3}H-histone mRNA bound (c.p.m.)		^{3}H-EMC virus RNA bound (c.p.m.)	
	Control	+ m^{7}G$^{5'}$p	Control	+ m^{7}G$^{5'}$p	Control	+ m^{7}G$^{5'}$p
IF-MP	2,710	2,580	872	919	16,588	13,917
IF-M$_3$	1,930	643	796	69	18,261	22,059
IF-M$_{2A}$	2,618	2,411	452	360	40,429	36,614
IF-M$_{2B}$	126	—	23	—	197	284

Binding of ^{3}H-VSV mRNA, ^{3}H-histone mRNA and ^{3}H-EMC virus RNA to purified reticulocyte initiation factors was determined by the nitrocellulose filter assay reported previously[26]. ^{3}H-VSV mRNA was prepared from virus-infected HeLa cells incubated with ^{3}H-uridine by the method of Grubman *et al.*[35]. This RNA contains poly(A), sediments between 12S and 18S, and has been shown to have m^{7}G$^{5'}$ppp at the 5′-terminus[31]. ^{3}H-histone mRNA was prepared from HeLa cells synchronised in S phase and incubated with ^{3}H-uridine. The histone mRNA was isolated by phenol extraction and repeated sucrose gradient centrifugation (L. A. W , M. C. Williams, and C.B., unpublished). Histone mRNA, labelled with ^{3}H-methylmethionine and isolated as described above, has been shown to have a blocked 5′-terminus (B. Moss, personal communication). The ^{3}H-methylhistone mRNA was enzymatically digested and analysed by chromatography on DEAE–cellulose in 7 M urea at *p*H 7.6. About 80% of the c.p.m. applied were eluted with a charge of −5 or −6, which is the position expected for blocked 5′-termini[36]. Encephalomycarditis (EMC) virus RNA was prepared from HeLa cells. The cells were concentrated to 4×10^7 ml^{-1} in serum-free MEM medium containing 14 mM HEPES buffer *p*H 7.4 and 2 mM glutamine. EMC virus was added at a multiplicity of 10 PFUs cell^{-1} for 15 min at 23 °C. The culture was diluted tenfold with warm medium containing 7% foetal calf serum and 5.5 μg ml^{-1} actinomycin D. After 30 min at 37 °C ^{3}H-uridine (26.2 Ci mmol^{-1}) was added to a final concentration of 50 μCi ml^{-1}. After 14 h, the culture was frozen and thawed three times and centrifuged 10 min at 10,000*g*. The supernatant was neutralised with 1 M Tris and made 6% in polyethylene glycol The precipitate which formed after stirring for 16 h at 4 °C was collected by 15 min centrifugation at 15,000*g* and resuspended in 2 ml of 0.1 M NaCl, 10 mM Tris *p*H 7.5 and 10 mM mercaptoethanol. This suspension was incubated for 20 min at 37 °C with 50 μg ml^{-1} of trypsin and SDS added afterwards to 0 5%. Virus was purified by 2-h centrifugation at 150,000*g* through a 2-ml layer of 15% sucrose in SDS–buffer[37]. The pellet was resuspended in SDS–buffer and the RNA extracted with phenol–chloroform[37]. RNA was recovered by ethanol precipitation and was purified by 15-h centrifugation at 25,000 r.p.m. on a 15–30% sucrose gradient. The 35S viral RNA was precipitated with ethanol and reprecipitated twice. The EMC virus RNA has a specific activity of 380,000 c.p.m. μg^{-1}. Incubations in a total volume of 50 μl were performed at 23 °C for 5 min and contained 20 mM Tris-HCl, *p*H 7.4, 100 mM KCl, 1 mM dithiothreitol and 0.53 μg IF-MP, 3.5 μg IF-M$_3$, 1.1 μg IF-M$_{2A}$ or 0.99 μg IF-M$_{2B}$. In each case, 4,000–5,000 c.p.m. ^{3}H-VSV mRNA (specific activity 450,000 c.p.m. per A_{260} unit), 3,000 c.p m. of ^{3}H-histone mRNA (specific activity > 200,000 c.p.m. μg^{-1}) or 60,000 c p.m. ^{3}H-RMC virus RNA (specific activity 380,000 c.p.m. μg^{-1}) was included as substrate and reactions were performed either in the absence (control) or presence of 1.0 mM m^{7}G$^{5'}$p. Reactions were stopped by the addition of 3 ml of ice-cold buffer solution (20 mM Tris-HCl, *p*H 7.4, 100 mM KCl). RNA–protein complexes were collected on HAWP 0.45 μm pore size, 25 mm diameter, nitrocellulose filters (Millipore) and rinsed three times with 3 ml of the same buffer. The filters were dissolved in 10 ml Bray's solution[38] and counted by liquid scintillation spectroscopy at 23% efficiency for ^{3}H. Blanks of 175 c.p.m., 84 c.p.m. or 671 c.p.m., representing isotope retension on the nitrocellulose filter in the absence of added protein factors, were subtracted from the appropriate values.

* For experiments with ^{3}H-EMC virus RNA, the amount of the protein factors was reduced to one-third that used for the other mRNAs.

ribonucleoprotein particles (mRPNs) obtained from reticulocyte polysomes and that purified IF-MP can interact with globin mRNA to form an mRNA–protein complex[26]. In the present studies, we have found that in addition to IF-MP, purified initiation factors IF-M$_3$ and IF-M$_{2A}$ can also form complexes with mRNA. Of the various factors tested, however, only the interaction of IF-M$_3$ with mRNA is inhibited by m^{7}G$^{5'}$p. This inhibition requires both the 7-methyl and the 5′-phosphates moieties, and the requirements for inhibition of IF-M$_3$–mRNA complex formation are the same as those for inhibition of overall protein synthesis.

The amount of m^{7}G$^{5'}$p required for inhibition of either protein synthesis or IF-M$_3$–mRNA interaction is far in excess of the amount of mRNA present in the system (greater than 1,000/1). Therefore, the interaction of m^{7}G$^{5'}$p with IF-M$_3$ seems to represent a low affinity binding and the 5′-terminal region of natural mRNAs recognised by IF-M$_3$ may contain additional nucleotides. Since we are limited in the amount of specific initiation factors we can add to the cell-free system, the high ratio of m^{7}G$^{5'}$p to IF-M$_3$ may explain our inability to obtain reversal by excess IF-M$_3$. It should also be noted that endogenous protein synthesis with unfractionated reticulocyte lysate is only slightly inhibited by m^{7}G$^{5'}$p. In the reticulocyte lysate system, however, m^{7}G$^{5'}$p does inhibit association of exogenous histone mRNAs with ribosomes (Fig. 2), as well as translation of exogenous histone mRNA (our unpublished observations). At the moment, we have no explanation for the low inhibition of endogenous protein synthesis by m^{7}G$^{5'}$p in reticulocyte lysate. One possible interpretation of these findings is that endogenous mRNA in reticylocyte lysate is already associated with specific proteins (such as IF-M$_3$) and that translation of performed mRNA protein complexes cannot be inhibited by m^{7}G$^{5'}$p, whereas translation of added deproteinised mRNA can be. We hope to test this hypothesis in future experiments by comparing the effect of m^{7}G$^{5'}$p on translation of exogenous reticulocyte mRNA compared with reticulocyte mRNP in the fractionated messenger dependent cell-free system.

Table 2 Specificity for inhibition of ^{3}H-VSV mRNA-IF-M$_3$ complex formation by guanosine nucleotides

Inhibitor added	c.p.m. ^{3}H-VSV mRNA bound	% Inhibition
None	2,260	—
m^{7}G	1,900	16
m^{7}G$^{2(3)'}$p	1,965	13
m^{7}G$^{5'}$p	800	65
G$^{5'}$p	2,021	10

For incubation conditions and assay procedure see Table 1. Where indicated, incubations were performed in the presence of 1.0 mM m^{7}G, m^{7}G$^{2(3)'}$p, or m^{7}G$^{5'}$p, G$^{5'}$p added before 3H-VSV mRNA.

From the present studies, it seems that association of mRNAs containing m^{7}Gppp . . . with initiation factor IF-M$_3$ may be essential for binding of certain mRNAs to the ribosome. In addition, inhibition of IF-M$_3$–mRNA interaction by m^{7}G$^{5'}$p may be the result of competition between this nucleotide and mRNA for a specific recognition site on IF-M$_3$. Since m^{7}G$^{5'}$ppp . . . has been identified as the 5′-terminal group in various eukaryotic mRNAs, a normal function of IF-M$_3$ might be to form a complex with certain mRNAs through their 5′-terminal m^{7}Gppp . . . sequence. This would agree with previous findings of Both *et al.*[13,34] that absence of 7-methylguanosine from the 5′-terminus of certain eukaryotic mRNAs markedly reduces messenger–ribosome complex formation and translation of these messengers and would support the hypothesis of these investigators[34] that the m^{7}Gppp . . . region of mRNA may serve as a specific recognition signal for initiation of eukaryotic protein synthesis.

As indicated above, the affinity of natural mRNA for IF-M$_3$ is probably much greater than that observed with m^{7}G$^{5'}$p. Therefore, the present studies should not be taken to imply that m^{7}G$^{5'}$p represents the complete sequence of mRNA recognised by IF-M$_3$ or that IF-M$_3$ binds solely to this region of mRNA. The reduced but yet significant binding of EMC virus RNA to IF-M$_3$ and the lack of inhibition of this complex by m^{7}G$^{5'}$p would support such a conclusion. These results are also consistent with the observation of Staehelin *et al.*[23], that threefold greater quantities of factor IF-E6 (IF-M$_3$) are required for translation of EMC virus RNA compared with rabbit globin mRNA. In future studies, we hope to better define the process by which IF-M$_3$ interacts with mRNA by comparing the affinity of various ^{3}H-labelled nucleotides for this protein (m^{7}G$^{5'}$p, m^{7}G$^{5'}$pp, m^{7}G$^{5'}$ppp, m^{7}G$^{5'}$pppNp, for example), and to determine the relationship of this event to other mRNA factor interactions which may be involved in the eukaryotic initiation mechanism. Since it has been shown recently that *in vitro* translation of "unblocked" mRNAs, such as satellite tobacco necrosis virus (STNV) RNA[14] and encephalomyocarditis (EMC) RNA L. A. W., E. R. Feman, E. D. Hickey, M. C. Williams, and C. B., unpublished,) is not inhibited by m^{7}G$^{5'}$p, it will also be important to determine whether translation of mRNAs not containing 5′-terminal 7-methylguanosine, proceeds through the same or a different mechanism.

letters to nature

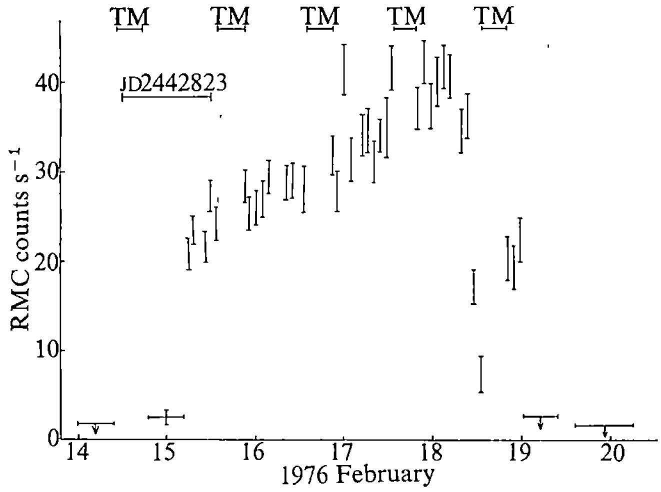
X-ray outburst from Circinus X-1

During observations of the Circinus–Norma region by the rotation modulation collimator (RMC) experiment on board Ariel V, a sudden strong X-ray outburst was detected from Cir X-1. The source appeared on 1976 February 15 at 0500(UT) at an intensity of 20 counts s^{-1}. It gradually brightened to over 40 counts s^{-1} on February 17 at 2200(UT) and then rapidly declined on February 18. Our best position, RA = 229. 19°, Dec = −57.00°, with Error Circle, 0.02° radius (90% confidence), is in excellent agreement with the known position[1] of Cir X-1.

The light curve is shown in Fig. 1. The data have been corrected for instrumental response and source visibility. Data gaps occur whenever the experiment is switched to its 'time' mode of operation, when positional resolution is sacrificed for better time resolution. The data points have a nominal time resolution of ~100 min (1 orbit) except where indicated. The onset of the outburst is extremely rapid. The initial detection in a single orbit gives an intensity of ~20 counts s^{-1}; analysis of the data from the previous orbit gives an upper limit (3σ) of 5 counts s^{-1}. For compatibility with data preceding and succeeding the outburst and the known times when the source was in the field of view, the transition to the high stage must have occurred between 0400 and 0512 (UT) on 1976 February 15. When the data for the preceding 10 h is summed, we obtain a marginal detection at 2.5 ± 0.8 (1σ) counts s^{-1}. Earlier observations give a 3σ upper limit of 1.2 counts s^{-1} for 1976 February 6.5 to February 14.0.

The source showed a rapid decline in intensity following peak brightness, falling to just above the detector threshold in a few hours. After the data gap, however, the source had recovered to half its maximum intensity, remaining at this level for five hours. It subsequently faded to below the detector threshold. Because about six bright sources are in the field of view of the experiment, it is not possible to recover accurately the absolute intensity of Cir X-1 from the time-mode data. The general recovery of the source is, however, qualitatively evident in that data. In the half day period after the source went below the threshold the summed data give an upper limit of 2.5 counts s^{-1} for the time averaged intensity; in any single orbit during this period the upper limit is 7 counts s^{-1}.

Fig. 1 The light curve of Cir X-1 in 2.9–7.6 keV X rays measured by the RMC experiment on Ariel V. The data are corrected for detector response and source visibility. Error bars are ± 1σ and upper limits are 3σ. Time resolution, if not indicated, is ~100 min (1 orbit). For comparison, 1 count s^{-1} is approximately equivalent to 12 Uhuru counts s^{-1}. TM, time mode.



The photon flux is measured by the RMC experiment in three pulse height channels corresponding to energy ranges 2.9–4.3, 4.3–5.9 and 5.9–7.6 keV respectively. This enables us to compute the photon number spectrum for the source, which is plotted in Fig. 2 for maximum X-ray intensity. Throughout the outburst reported here the spectral data can be fitted by a thermal exponential spectrum with kT = 1.7–2.4 keV at a column density of 10^{22} atoms cm^{-2}. But, the data are too insensitive for good evaluation of the absorption term. Unfortunately

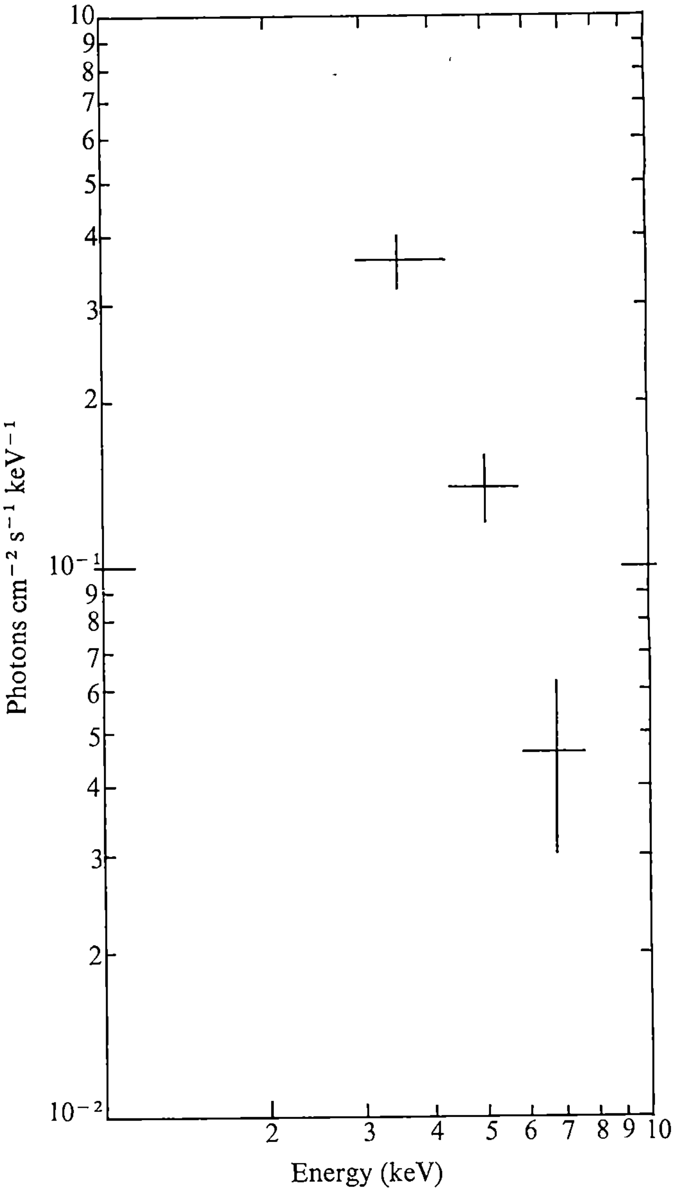


Fig. 2 The X-ray spectrum of Cir X-1 at maximum intensity. Data used are taken from 1976 February 17, 1900(UT) to 1976 February 18 0500(UT). Error bars are ± 1σ.

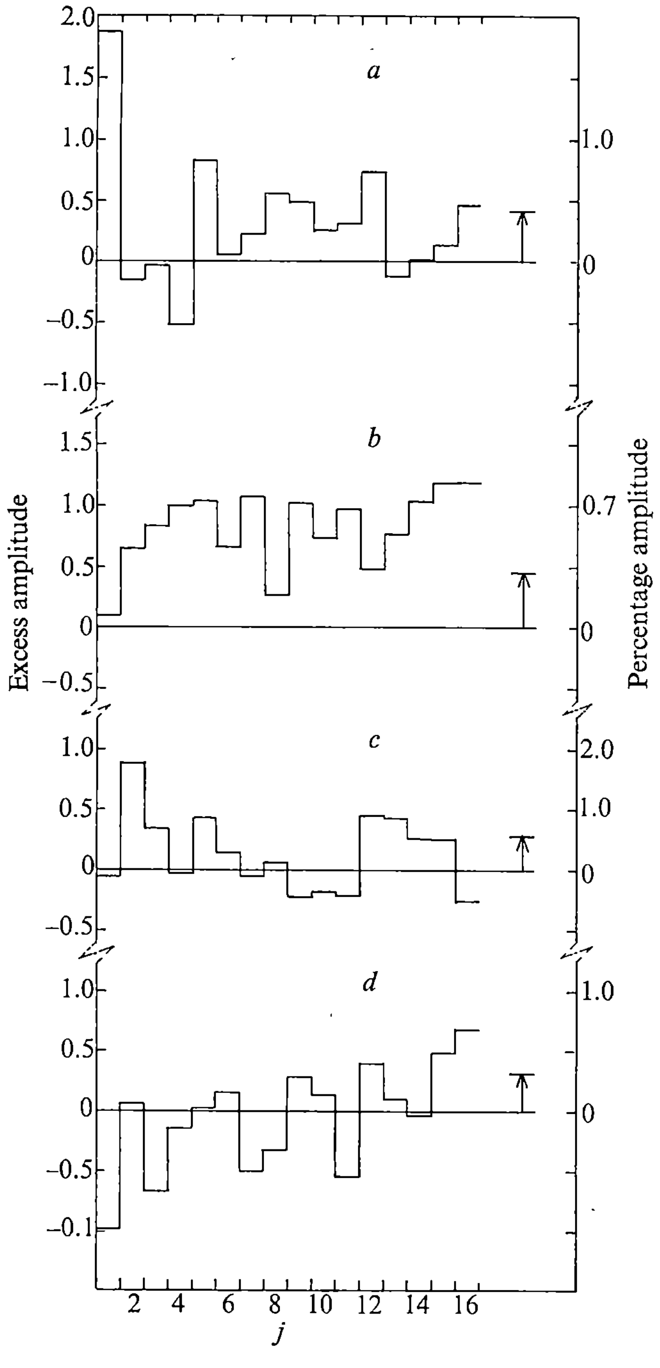
photon statistics are too poor to allow us to follow spectral changes during the decay phase of the outburst, or to measure a spectrum in the period immediately before the high intensity onset.

In the time mode operations indicated in Fig. 1, counts are simply accumulated in consecutive time bins of 32 s. Sequences of 32 bins were selected which were free of passages through regions of high particle background, and free of occultation of the Sun or the source by the Earth. Any trends in the data were determined by a least squares analysis fitting a polynomial, degree 3, and subtracted out, except for the pre-outburst data. Power spectra were then obtained for each sequence and summed. The results are summarised in Fig. 3. The abscissa is: $(P_j - \langle P\rangle)/\langle P\rangle$ where P_j is the amplitude in the jth frequency bin and $\langle P\rangle$ is that expected from counting statistics from a constant source; $\langle\sigma_p\rangle$ is the expected s.d. from counting statistics.

Fig. 3 Mean power spectra measured by the RMC experiment on Ariel V. The abscissa is the excess amplitude measured in units of the expected amplitude; the corresponding percentage amplitude is indicated. The ordinate, j, is frequency bin number, bin 1 corresponds to 0.00098 Hz, bin 16 corresponds to 0.0156 Hz. *a*, Six sequences of 32 time bins measured on 1976 February 13–14; *b*, nine sequences of 32 time bins measured on 1976 February 15–17; *c*, three sequences of 32 time bins measured on 1976 February 18; *d*, ten sequences of 32 time bins measured on 1976 February 20–21. Arrow on abscissa gives the s.d. $\langle\sigma_p\rangle$.



The pre-outburst mean power spectrum shows a non-random power distribution which we attribute to other sources in our field of view. During the outburst from Cir X-1, excess power density is measured at all frequencies with no single frequency-bin outstanding. The power density in the decay phase of the outburst is much less and approaches that measured in data since the outburst.

The first definite observation[2] of Cir X-1 was made in 1969. Previous observations give a conflicting view of the sky in that region and source confusion must be assumed. Since then many observations[1,3–7] of the source show it predominantly at a low intensity, with occasional outbursts to a higher level, with rapid, erratic changes in its behaviour, variable on time scales down to ⩽ 1 s. The model of Cir X-1 as a young runaway binary in a highly elliptical, long period orbit[9], would predict high X-ray emission from Cir X-1 near periastron. The data of Baity *et al.*[4], and Davison and Tuohy[7] suggest an interval of ~220 d between times of high X-ray emission. Since the Copernicus observation[7], SAS-3 has observed Cir X-1 (ref. 8) and our report further extends the base line. Our data give a well determined time at which an outburst occurred, and record a complete cycle of increased emission. The behaviour is consistent with an outburst of high intensity every 220–250 d, but consideration of the reported times of previous outbursts suggests that the phenomenon is not strictly periodic but irregular. Our data are not good enough to confirm any softening of the spectrum with enhanced emission[1,4], or to give any new information on changes in absorption during the event[2]. The softness of the spectrum does not conflict with the suggestion that the long term intensity variations of Cir X-1 are due to low energy X rays[4].

We are grateful for the advice and encouragement of A. P. Willmore and the other members of the Ariel V team at Birmingham. A.M.W. is in receipt of a SRC studentship, and G.F.C. a SRC research fellowship.

The infrared spectrum of Nova Cygni 1975

Grasdalen and Joyce[1] have observed emission lines from Nova Cygni 1975 in the 2 and 3 μm spectral regions. In mid-September 1975, the dominant spectral features were recombination lines of hydrogen. Grasdalen and Joyce noted the presence of a number of additional lines in a later spectrum and identified these with forbidden transitions in highly ionised forms of Mg, Ca, Al, and Si. The prerequisite for formation of such coronal lines is an

Table 1 Infrared line identifications

λ_{obs} (μm)	Peak flux (Jy) September 12, 1975	Peak flux (Jy) October 27, 1975	λ_{pred} (μm)

emitting region of low density and extremely high temperature, $T \sim 10^6$ K, which, moreover, must span a considerable range of temperature in order for species such as Al V, VI, VIII and IX to exist simultaneously. This would seem to preclude an isothermal shock as the mechanism responsible for a high temperature region in Nova Cygni. We propose a more conservative identification of these new lines, namely that they are all lines of He I with one possible exception. Furthermore, their sudden appearance and increase in relative intensity are in accord with somewhat more temperate conditions ranging from $T \sim 10^4$ K in September 1975 to $T \sim 10^5$ K in October. This identification is also more consistent with the known behaviour of very fast novae, which rarely exhibit optical coronal emission lines[2].

Table 1 lists the wavelengths of the features observed by Grasdalen and Joyce and our suggested identifications. The observed wavelengths are from the table of Grasdalen and Joyce or are estimated from their figures. The peak fluxes have been estimated from the published spectra and from the scaling procedure used in the original analysis. These fluxes are presented to illustrate the change in relative fluxes between September 12 and October 27; they should not be taken literally. The predicted wavelengths have been taken from standard references[3,4].

The strongest lines in the September spectrum were correctly identified by Grasdalen and Joyce as Brackett and Pfund series lines of hydrogen. As many as five lines of He I also appear, although two are blended with stronger H lines. We suggest that these are not recombination lines, but rather the result of pumping of metastable He I (2^1S) by the very broad, very strong hydrogen Balmer continuum short of 3,646 Å. This pumping occurs through the transition 2^1S–5^1P^0 at 3,614 Å, and the 5^1P^0 state decays through a cascade which includes all the singlet transitions listed in Table 1. Table 2 lists additional lines in the visible and near infrared which would also appear as part of this fluorescence process, and which should share the intensity variation exhibited by the infrared lines. The absence of detectable triplet transitions in He I (which should dominate the recombination spectrum if He were ionised to the same degree as H) is consistent with a collision-excited plasma with $T \sim 10^4$ K in September.

Table 2 He I lines excited by Balmer continuum

Transition	Wavelength (Å)
4^1S–2^1P^0	5,047
4^1D–2^1P^0	4,921
5^1P^0–3^1S	11,013
5^1P^0–3^1D	12,756
3^1P^0–2^1S	5,015
3^1S–2^1P^0	7,281
3^1D–2^1P^0	6,678

According to our interpretation, the October spectrum shows strong He I recombination lines. The agreement between observed and predicted wavelengths is at least as good as that found by Grasdalen and Joyce for the coronal ions, and all the more striking since only one species is involved. The relative intensities of the suggested He I lines are in harmony with transition probabilities[4] and qualitative expectations from recombination theory. Note that the He I lines are as strong as the H lines in the October spectrum. This can occur in a plasma at $T \sim 10^5$ K in which H and He are present in normal cosmic abundance (10–15% He by number) and are both singly ionised. At such temperatures, He recombines nearly ten times faster than H because of dielectronic recombination and should thus exhibit an appropriately stronger recombination cascade. A temperature of $T \sim 10^5$ K is further supported by the appearance of strong emission from the N III 4,640 Å blend in October because at $T = 10^{4.9}$ N III becomes the dominant stage of nitrogen[5]. This interpretation of the infrared spectrum of Nova Cygni is clearly subject to further observational tests through examination of He I lines in visible spectra obtained during the same time period. Not only the physical evolution of the emitting region, but also the helium abundance may be determined from such studies A more detailed analysis of the recombination spectra in Nova Cygni 1975 will be published elsewhere.

The existence of regions in Nova Cygni with $T \sim 10^5$ K seems physically reasonable. Although the optical decline was probably paralleled by a true decrease in luminosity, some energy source must have remained to provide for the substantial optical and infrared flux. From the observations reported by Gallagher and Ney[6], the luminosity can be estimated at $\sim 10^4 L_\odot$ in late October. Both theoretical and empirical arguments suggest that, by this stage, the nova remnant would have a small radius and correspondingly high effective temperature (G. T. Bath and G. Shaviv, and J. S. Gallagher and S. G. Starrfield, unpublished). The He I emission might then originate in a dense, hot medium near the underlying star.

Finally, we call attention to the unidentified line at 3.50 μm and to the line at 3.18 μm, which appear not to be He I lines. The latter may indeed be [Ca IV] as suggested by Grasdalen and Joyce since Ca exists predominantly in this stage of ionisation at our inferred temperature.

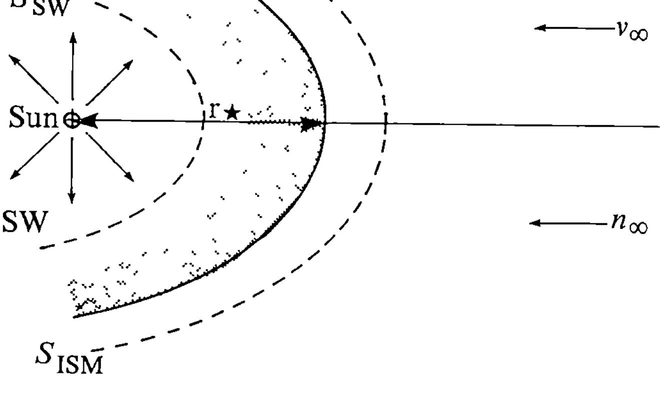
Can cosmic clouds cause climatic catastrophes?

SEVERAL authors[1–3] have discussed whether past immersion of the Solar System in dense interstellar matter (ISM) might have left observable imprints on the Earth. Accretion cannot affect the solar constant significantly unless the surrounding ISM attains densities of 10^5–10^7 cm^{-3} (refs 2 and 3). We demonstrate here, however, that a much more modest ISM density of 10^2–10^3 cm^{-3} (a value typical of dense interstellar clouds in spiral arms) would prevent the solar wind from reaching the Earth, and propose that such a change in the Earth's space environment may trigger drastic climatic changes.

Suppose that the Sun moves with velocity v_∞ through ISM of density n_∞ and temperature T_∞. The solar wind can be envisaged as a supersonic radial flux of fully ionised particles with density n_E and velocity v_E at the Earth ($r = 1$ AU). If there were no mixing or interpenetration between solar wind and ISM, there would be a contact discontinuity with the rough shape shown in Fig. 1, located at a distance r_* from the Sun in the 'upstream' direction. (In practice, the SW may be shocked before reaching r_*; and the ISM, if its properties were sufficiently 'fluid-like', might pass through a shock outside r_*.)

Fig. 1 Schematic depiction of the termination of the solar wind (SW) by the interstellar medium (ISM). With respect to the Sun, the ISM has streaming speed v_∞, density n_∞, at $r \to \infty$. The termination radius r_* is found by balancing ram pressure on either side of an imaginary contact discontinuity C. If the ISM is largely neutral, r_* is the outer boundary of a region of interpenetration (shaded). In the text, we show that the value of n_∞ necessary to make r_* smaller than 1 AU never exceeds $n_\infty \simeq 100\,(v_\infty \simeq 10$ km s^{-1}) cm^{-3} by more than a factor of 2 or 3, regardless of the ionisation level of the ISM. Allowance for possible shock discontinuities S_{SW} and S_{ISM} would reduce the required n_∞. Clouds populating the spiral arms of the Galaxy may have sufficient densities to prevent the solar wind from reaching the Earth.



In the idealised case shown in Fig. 1, r_* has the value at which the 'ram pressure' $\propto n_E v_E^2/r_*^2$ of the solar wind balances the pressure of the infalling ISM. We can estimate this as follows. The speed of a typical ISM particle at distance r is

$$v(r) \simeq \left(v_\infty^2 + v_{th}^2 + \frac{v_{esc}^2}{r_{AU}}\right)^{\frac{1}{2}}$$

where $v_{esc} \simeq 42$ km s^{-1} is the escape speed from the Sun at 1 AU. In most cases of interest, v_∞ will be greater than the thermal velocity $v_{th} \simeq (T_\infty/100)^{\frac{1}{2}}$ km s^{-1}; and we therefore neglect v_{th} to keep our discussion short. If the mean free path in the ISM is so large that, until reaching r_*, each particle follows an independent hyperbolic orbit under the influence of the Sun's gravity, then the density at a distance r ahead of the Sun is $n(r) \simeq n_\infty \; v(r)/v_\infty$ due to 'gravitational focusing'. Defining r_* by the equality $n(r_*)\,[v(r_*)]^2 = n_E v_E^2/r_*^2$, we obtain

$$r_* \propto \begin{cases} n_\infty^{-1/2} v_\infty^{-1} & \left[r_* \gtrsim \left(\dfrac{v_{esc}}{v_\infty}\right)^2\right] \quad (1a) \\[2ex] n_\infty^{-2} v_\infty^{2} & \left[r_* \lesssim \left(\dfrac{v_{esc}}{v_\infty}\right)^2\right] \quad (1b) \end{cases}$$

Once n_∞ becomes large enough to bring r_* below $(v_{esc}/v_\infty)^2$ AU, the gravitational focusing causes r_* to depend much more sensitively on n_∞. When the inflow of the ISM is fluid-like and standard accretion theory can be used, the density enhancement goes as $(v/v_\infty)^3$ rather than just as (v/v_∞), so the dependence is more sensitive still. Taking $v_E = 450$ km s^{-1} and $n_E \simeq 5$ cm^{-3}, equation. (1*b*) implies that r_* would lie within 1 AU when $n_\infty \gtrsim 100\,(v_{esc}/10$ km s^{-1}) cm^{-3}. Allowance for fluid-like behaviour of the ISM would lower the required n_∞ further, but we note that it is in any case comparable with 'typical' interstellar cloud densities. (If the ISM outside r_* behaved as a fluid, we would obtain an even more drastic result than equation (1*b*): r_* would be forced down to zero (the solar wind would be entirely 'snuffed out') whenever r_* were forced within a value $\sim (v_{esc}/v_\infty)^2$ AU, because within that radius the ram pressure provided by radial accretion is $\propto r^{-5/2}$, which is steeper than the r-dependence of the solar wind pressure.

When the ISM is mainly neutral, hydrogen is acted on by radiation pressure from the solar Lyman α (refs 4 and 5). This yields a repulsive force comparable to the Sun's gravitational attraction, thereby reducing the gravitational focusing. Significant photoionisation of neutral interstellar hydrogen (H I) would occur within a few AU; and any penetration of ionised ISM into the solar wind would be prevented by plasma instabilities and the transverse solar wind magnetic field. If some ISM encounters the solar wind while still neutral, the contact discontinuity will be replaced by a region of interpenetration whose thickness is governed by the length scale for ionising the remaining neutral particles. Once ionised, such particles rapidly join the bulk solar wind flow. This flow will be slowed down by charge exchange reactions in the interpenetration region[4].

The character of the transition region at $r \lesssim r_*$ is rather complicated; and effects such as radiation pressure and charge exchange would modify the simple formulae we have given for r_*. We find, however, that the ISM density required to reduce r_* below 1 AU exceeds that inferred from equation (1) by a factor of no more than 2 or 3 (M. Begelman, in preparation); moreover, the corrections for fluid-like behaviour outside r_* (which become more important for high n_∞) tend to reduce the required density. Of course r_* is measured along the line of stagnation. The termination distance in the plane containing the Sun and perpendicular to the line of stagnation is, however, unlikely to be much more than $\sim 2r_*$. Therefore, if $r_* \lesssim 0.5$ AU the Earth will spend part of each year out of reach of the solar wind. If the solar velocity relative to the ISM makes a large angle with the plane of the ecliptic, the Earth may be entirely cut off from the solar wind.

The ISM attains densities $\gtrsim 10^2$ cm^{-3} in H I clouds, in regions of star formation (for example the Orion Nebula)[6,7], and in thin sheets swept up by supernova remnants or by the winds of O or B stars[8,9]. These dense regions would be concentrated in spiral arms. The Solar System traverses an arm every $(1-3)\times10^8$ yr (this figure being uncertain because we know neither the speed of the spiral wave, nor how regular or long-lived the spiral pattern is); and during each traversal its orbit may encounter several such dense regions. McCrea[2,3] has suggested that there may be a causal connection between spiral arm traversals and the quasi-periodic epochs of glaciation inferred from the geological record. He tentatively relates the Quaternary glaciation to the Sun's passage into the Orion Arm. But the specific mechanism that he proposed—an alteration of the solar constant caused by accretion—requires an interstellar cloud of density 10^5–10^7 cm^{-3}, and such clouds are so compact and unusual that the Sun would have little chance of encountering even one.

There is now an impressive array of evidence suggesting that solar activity influences the Earth's climate through the effects of the solar wind. Immersion in the less extreme and more widespread ISM regions with density 10^2–10^3 cm^{-3} can prevent the solar wind from reaching the Earth. This circumstance therefore suggests a possible physical basis for McCrea's conjectured link between spiral arms and terrestrial climate which obviates the need for the extreme ISM densities required by his specific accretion mechanism.

Exclusion of the Earth from the 'heliosphere' might have four major effects: (1) If the ISM were largely neutral at 1 AU, the Earth would be bathed in an enhanced background of cool neutral material: this material could penetrate the magnetosphere and join the upper ionosphere, perhaps significantly changing its composition over periods of $\gtrsim 10^6$ yr. If charge exchange reactions were important in the interpenetration zone, neutral hydrogen would flow past the Earth at solar wind speeds. These particles would also penetrate the magnetosphere, and probably cause ionisation by collisions in the ionosphere. (2) Ions in the vicinity of the Earth would typically have speeds much lower than those of typical solar wind particles. This would affect the rate at which they could be trapped by the magnetosphere, as well as the rate at which trapped particles could be funnelled into the atmosphere over the polar regions. (3) In the absence of solar wind modulation, an enhanced flux of low energy interstellar cosmic rays would reach the Earth. (4) The Earth's magnetosphere would be isolated from the solar magnetosphere. This would seriously inhibit bursts of energetic particles, emitted in such events as solar flares, from reaching the Earth, and is perhaps the most crucial effect.
